Although the cellular inflammatory response to BDV following neonatal infection is restricted, a phenomenon ascribed to the immaturity of rat postnatal immune function, a brief surge in mononuclear cell infiltrates occurs (Hornig et al. 1999), along with elevations in the expression of proinflammatory cytokine (Hornig et al. 1999; Sauder and de la Torre 1999), chemokine (Sauder et al. 2000), and chemokine receptor (Rauer et al. 2002) transcripts. However, this transient immune response does not colocalize with sites of neuropathologic damage (Weissenböck et al. 2000). Neuropathology instead parallels regions and the time course of microglial proliferation and expression of MHC class I and class II, ICAM, CD4, and CD8 molecules (Weissenböck et al. 2000). Humoral immune response to BDV in neonatally infected animals is also curtailed, with anti-BDV antibody titers remaining below 1:10 through 133 days post infection (Carbone et al. 1991b).

Reduced levels of neurotrophic factor mRNAs occur in the neonatal model (Hornig et al. 1999; Zocher et al. 2000). However, these changes are restricted to the hippocampus; thus, a different mechanism must be invoked to account for losses of Purkinje cells in cerebellum. It is conceivable that abnormal regulation of apoptosis – either failure of normal apoptotic sequences to be curtailed with age, or excess activation of apoptotic cell programs – may contribute to abnormal CNS architecture in neonatal infections with BDV or other neurotropic viruses. Excitotoxic stimulation, including activation of glutamatergic circuitry, is one factor that might trigger neuronal apoptosis. Complex alterations in mRNAs for apoptosis mediators, including increased levels of mRNAs for FAS and ICE (caspase-1), two promotors of apoptosis, and decreased mRNA for bcl-x, a factor that inhibits apoptosis, have been identified in hippocampus, amygdala, prefrontal cortex, nucleus accumbens, and cerebellum, and are consistent with the promotion of apoptosis throughout the brains of rats neonatally infected with BDV (Hornig et al. 1999).

Recent studies in tissue culture systems are providing insights into mechanisms for viral damage that may illuminate pathogenesis in neonatal infection. Inhibition of cell-to-cell spread of BDV by a MAPK/ERK kinase (MEK) inhibitor in cell culture (Planz et al. 2001b) and analyses of neuronal differentiation of PC12 cells (Hans et al. 2001) indicate an interaction of BDV with cellular MAP kinase signaling pathways. Infected PC12 cells demonstrate constitutive phosphorylation of MEK, ERK, and the transcriptional activator Elk-1; however, nuclear translocation of ERK is impaired, and cells fail to differentiate with NGF treatment (Hans et al. 2001). Inhibition of neurite outgrowth is also reported in other infected cell lines, and has been ascribed to interference by BDV P with the normal interaction between the neurite outgrowth factor, amphoterin, and its receptor, RAGE (*R*eceptor for *A*dvanced *G*lycation *E*nd-products). Complex formation between amphoterin and P leads to altered intracellular distribution of amphoterin in infected cells, with reduced levels of amphoterin and of RAGE activation at growth cones of extending cells (Kamitani et al. 2001).

MOUSE MODEL

Mice are readily infected and have high titers of virus in the brain (Kao et al. 1984). Until recently mice were considered to be relatively resistant to disease; however, two reports indicate that disease can be induced by adaptation of virus through multiple passages in mice (Rubin et al. 1993) or infection of specific host strains during the neonatal period (Hallensleben et al. 1998). As in rats, severe clinical disease is mediated by MHC class I-restricted cytotoxic T cells (Hallensleben et al. 1998; Hausmann et al. 1999). The immunopathological process mediated by $CD8^+$ T cells in a $CD4^+$ T cell-dependent fashion is most obvious in mouse strains carrying the $H\text{-}2^k$ allele of the MHC. In $H\text{-}2^k$ mice the BDV N peptide T_{129}ELEISSI$_{136}$ has been identified as the dominant cytotoxic T-cell epitope that sensitizes cells for lysis (Schamel et al. 2001).

TREE SHREWS

Little is known about BDV pathogenesis in phylogenetically higher species such as nonhuman primates and the prosimian tree shrew (*Tupaia glis*). Intracerebral inoculation of tree shrews leads to persistent infection and a disorder characterized primarily by hyperactivity and alterations in sociosexual behavior, rather than motor dysfunction (Sprankel et al. 1978). Disturbances in breeding and social behavior were most profound in animals caged in mating pairs. Females, rather than males, initiated mating, and infected animals failed to reproduce despite increased sexual activity. Although detailed neuroanatomic studies were not performed, the syndrome was interpreted to be due to neuropathological changes in the limbic system.

NONHUMAN PRIMATES

The only reported studies of experimentally infected primates employed adult Rhesus macaques (*Macaca mulatta*). These animals were initially hyperactive and subsequently became apathetic and hypokinetic. Pathology was remarkable for meningoencephalitis and retinopathy (Stitz et al. 1981).

Immune response and BDV persistence in the CNS

Neurotropism affords BDV an opportunity to persist in an environment characterized by a restricted immune response. However, this does not reflect a failure to induce an immune response. Indeed, humoral immunity appears to play a role of confinement of infection to the CNS (Stitz et al. 1998a), and cellular immunity is essential to the expression of classic disease. Early studies of BD reported a correlation between the severity of meningoencephalitis and the clinical manifestations of disease (Zwick 1939). The first direct evidence for the role of the immune response in the pathogenesis of BD emerged from studies in which splenectomized Rhesus monkeys became persistently infected but had prolonged incubation periods and less severe disease than immune competent animals (Cervos-Navarro et al. 1981; Stitz et al. 1981). Experiments with infected athymic rats or adult rats immunosuppressed by treatment with cyclophosphamide and cyclosporin A (Stitz 1991; Narayan et al. 1983a; Herzog et al. 1985; Stitz et al. 1989) provided further evidence that BD is immune mediated.

In acute BD, CNS infiltrates are comprised of macrophages, $CD4^+$ T lymphocytes, $CD8^+$ T lymphocytes, NK cells and, to a lesser extent, plasma cells (Deschl et al. 1990; Bilzer et al. 1995). Antibodies to CD4 and CD8 markers were initially used to deplete these cells and investigate their individual contributions to immunopathogenesis. Although depletion of either $CD4^+$ or $CD8^+$ T lymphocytes resulted in amelioration of the inflammatory response in brain and the severity of acute clinical disease (Stitz et al. 1992; Planz et al. 1995), only depletion of $CD8^+$ cells was found to reduce brain atrophy (Bilzer and Stitz 1994). Although these data may suggest that $CD4^+$ T lymphocytes are not important in BD pathogenesis, others demonstrated that the recruitment of $CD8^+$ cells is dependent on $CD4^+$ T lymphocytes (Nöske et al. 1998). It has been argued that neuronal cells express little or no MHC class I surface markers and should not be susceptible to $CD8^+$ CTL lysis (Joly et al. 1991); however, both neurons and astrocytes in BDV-infected rats have been shown to express MHC class I protein (Bilzer and Stitz 1994; Planz et al. 1993). Furthermore, lymphocytes isolated from BD rat brain were found to lyse infected target cells in an MHC class I-restricted manner (Planz et al. 1993). Adoptive transfer experiments have been pursued with N protein-specific $CD4^+$ T lymphocytes. Immunosuppressed, persistently infected rats so treated had a neurological disease that was similar but not identical to BD (Richt et al. 1989). The cellular immune response to BDV in the rat seems to be restricted to N, and the N peptide A_{230}SYAQMTTY$_{238}$ has been identified as the relevant T-cell epitope naturally recognized in the context of MHC class I in Lewis rats (Planz et al. 2001a; Planz and Stitz 1999).

In animals that progress to chronic BD there is a pronounced decrease in CNS infiltration. The numbers of macrophages, $CD4^+$ T lymphocytes, and $CD8^+$ T lymphocytes in brain are markedly reduced; however, numbers of plasma cells are increased. In contrast to the immunopathogenesis of acute BD, which has been extensively studied by several investigators, little is known about the basis for the decline in CNS infiltration in chronic infection. Potential mechanisms include altered viral gene expression or modulation of the immune response. The first possibility is unlikely because viral titers do not change substantially over the course of disease (Narayan et al. 1983a). In addition, brain levels of N and P, the only BDV proteins that can be readily quantified, and of RNAs coding for M, G, and L (Hatalski 1996), are similar in early and late disease. There is, however, evidence for modulation of the immune response over the course of BD, manifest as induction of BDV-specific type 1 T lymphocyte (Th1) tolerance. Whereas lymphocytes isolated from the brains of acutely infected rats have potent cytolytic activity, lymphocytes from brains of chronically infected rats do not lyse BDV-infected target cells (Sobbe et al. 1997). Induction of BDV-specific tolerance in chronic infection may reflect the time course for presentation of viral antigens in the thymus (Rubin et al. 1995). Alternatively, Th1 cells may become anergic or undergo apoptosis owing to the presentation of BDV antigens in brain without essential co-stimulatory signals (Schwartz 1992; Karpus et al. 1994; Khoury et al. 1995). Support for this hypothesis is found in the observation that apoptosis of perivascular inflammatory cells is most apparent at 5–6 weeks post infection, coincident with the onset of decline in encephalitis (Hatalski et al. 1998a).

Variability in cytokine expression in brain over the course of BD may also be important for modulation of the immune response. Cytokine mRNA levels have been measured in rat brain at different times post infection by RT-PCR (Shankar et al. 1992), RNase protection assay, or Northern hybridization (Hatalski et al. 1998a). Interferon-γ (IFN-γ), tumor necrosis factor-α (TNF-α), interleukin (IL)-1α, and IL-6 mRNAs are transiently expressed in the acute phase of disease (Shankar et al. 1992; Hatalski et al. 1998a). Message for another proinflammatory cytokine, IL-2, was detected by RT-PCR experiments throughout infection (Shankar et al. 1992); however, RNase protection assays revealed that IL-2 mRNA peaks in the acute phase of infection and declines thereafter (Hatalski et al. 1998a). IL-2 and IFN-γ are produced by Th1 cells for the recruitment and activation of CTL and the stimulation of antigen-presenting cells (Mosmann and Coffman 1989). The peak in CNS levels of these proinflammatory cytokine mRNAs in acute BD is temporally correlated with the peak of

immune cell infiltration. Cytokines produced by type 2 T lymphocytes (Th2), such as IL-4, have the potential to down-regulate the cellular immune response. IL-4 mRNA levels are elevated throughout the course of BD, but increased in the chronic phase of infection (Hatalski et al. 1998a). IL-10 mRNA peaks in the acute phase of BD and declines thereafter (Hatalski 1996). As in experimental allergic encephalomyelitis (Kennedy et al. 1992), the peak in IL-10 mRNA expression is correlated with a shift away from CNS recruitment of immune cells. The high levels of IL-4, IL-6, and IL-10 mRNAs observed in acute BD are likely to contribute to B-cell activation. Indeed, in rats, progression toward the chronic phase of disease is accompanied by an increase in brain levels of BDV-specific antibodies (Hatalski et al. 1998b).

The cytokine profile in chronic BD is consistent with modulation of the CNS immune response to reduce Th1 T-cell activation and increase the Th2 humoral response. TGF-β mRNA expression is elevated in BD rat brain from the onset of acute disease forward (Hatalski et al. 1998a), and its presence in chronic BD is compatible with a Th2 response. TGF-β has the potential to mediate inhibition of the proinflammatory effects of TNF-α, suppression of T- and B-cell growth, reduction of free radical formation, and inhibition of antibody production and CTL activity (Barnard et al. 1990; Fontana et al. 1992). Experimental administration of TGF-β to BD rats reduced the severity of encephalitis but did not prevent the onset of acute disease; thus, the role of TGF-β in BD pathogenesis remains unclear (Stitz et al. 1991).

The basis for the Th1 to Th2 switch in BD is a matter only for speculation. There are no data to indicate whether presentation of antigen on MHC class I is insufficient or activation of the Th1 cells is inefficient owing to inadequate costimulation. However, the result of this switch is consistent with the induction of Th1 down-regulation, an event that would allow survival of the host and foster viral persistence.

BDV and human disease

Recognition of BDV's broad experimental host range and the observation that disturbances in behavior in experimentally infected animals are reminiscent of some aspects of human neuropsychiatric diseases, including major depressive disorder, bipolar disorder, schizophrenia, and autism, led to the proposal that BDV might be implicated in their pathogenesis. Although there is consensus that humans are likely to be susceptible to BDV infection, the epidemiology and clinical consequences of human infection remain controversial. There have been no large controlled prevalence studies. Furthermore, methods for the diagnosis of human infection are not standardized; thus, it is difficult to pursue meta-analysis. Most reports suggesting an association between BDV and human disease have focused on neuropsychiatric disorders, including unipolar depression, bipolar disorder, or schizophrenia; however, BDV has also been linked to chronic fatigue syndrome, AIDS encephalopathy, multiple sclerosis, motor neuron disease, and brain tumors (glioblastoma multiforme) (Tables 2 and 3). The improbably broad spectrum of candidate disorders has led some investigators to propose that infection is ubiquitous, and that in some disorders elevation of serum antibody titers or the presence of viral transcripts in peripheral blood mononuclear cells or neural tissues reflects generalized (AIDS) or localized (glioblastoma multiforme) immunosuppression.

There are only infrequent reports where infectious virus has been isolated from humans (Bode et al. 1996; Nakamura 1998; Planz et al. 1999; Nakamura et al. 2000), and only two reports in which BDV gene products were found in human brain by in situ hybridization and immunohistochemistry (de la Torre et al. 1996; Nakamura et al. 2000). Methods most commonly used for serologic diagnosis of infection include indirect immunofluorescence with infected cells and Western immunoblot or enzyme-linked immunosorbent assays (ELISA) with extracts of infected cells or recombinant proteins. One study found that the majority of human serum antibodies binding BDV proteins in these assays did so with low avidity; the authors suggested, therefore, that cross-reactivity accounts for much of the seroprevalence data in BDV epidemiology (Allmang et al. 2001). However, more detailed analyses of the same sera using peptide arrays representing BDV N and P sequence, indicated that some low-avidity sera also contain low levels of high-avidity antibodies (Billich et al. 2002). Another explanation for the erratic performance of serologic assays in the Borna system may be that antibodies are bound in circulating immune complexes (CIC). In the one study based on the use of this serologic method, CICs were detected in more than 90 percent of subjects with major depressive disorder or bipolar disorder, versus 30 percent of healthy controls (Bode et al. 2001).

Infection has also been diagnosed through the demonstration of BDV transcripts and proteins in tissues or peripheral blood mononuclear cells (reviewed in Hatalski et al. 1997). Most frequently, detection of viral RNA has been achieved through nested reverse transcription-polymerase chain reaction (nRT-PCR). Although sensitive, this method is prone to artifacts because of the inadvertent introduction of template from laboratory isolates or cross-contamination of samples (Schwemmle et al. 1999a). Amplification products representing bona fide isolates are difficult to distinguish from artifacts by sequence analysis. As noted earlier, BDV is characterized by extraordinary sequence conservation. Studies of N and P sequence from widely

a) Divergence of P-gene nucleotide sequence from common BDV isolates (strain V and He/80); [Protein], [virus, protein] indicates antigen analysis, or virus and antigen analysis.

disparate BDV isolates revealed variability of up to 4.1 percent at the nucleotide level and 1.5–3 percent at the predicted amino acid level (Schneider et al. 1994a); only a single sequence has been identified that shows greater divergence (Nowotny et al. 2000). Thus, similarities in sequence between putative new isolates and confirmed isolates cannot be used to exclude the former as artifacts.

VACCINES AND ANTIVIRALS

Lapinized BDV 'Dessau' was used as a vaccine for horses in regions of endemic infection in Germany for decades. Concerns about the efficacy and safety of this vaccine led to its abandonment in the western states of Germany in 1980, and in the eastern states of Germany in 1992 (Dürrwald and Liebermann 1991; Richt and Rott 2001). There are two published reports of efforts to develop vaccines in rodent models using strain He/80. In one study rats were inoculated with either high or low doses of virus attenuated by multiple passages in MDCK cells. Low-dose recipients had classic T-cell-mediated disease and succumbed to encephalitis (although with a longer course); high-dose recipients had high antibody titers to BDV and only mild disease (Oldach et al. 1995). In another study, rats were infected with a recombinant vaccinia virus expressing BDV nucleoprotein and subsequently challenged with BDV. Although vaccination resulted in enhanced viral clearance, disease was aggravated (Lewis et al. 1999). No studies are described for vaccines based on BDV G; however, results of passive immunotherapy experiments wherein a monoclonal antibody directed against G was protective suggest that this approach might be effective (Furrer et al. 2001).

Three compounds are described as having antiviral efficacy against BDV: amantadine, ribavirin, and 1-β-D-arabinofuranosylcytosine (ARA-C). Findings with amantadine are controversial. The drug was found to inhibit replication of some human BDV isolates in cell culture and improve the clinical course in some subjects with affective disorders (Bode et al. 1997; Dietrich et al. 2000). The antidepressant response to amantadine has been variously attributed to drug effects on viral replication (Bode et al. 1997; Bode and Ludwig 2001) or on brain levels of neurotransmitters implicated in depression (Lieb et al. 1997b). Interestingly, tests of animal isolates indicated no antiviral effect in vitro or in vivo (Cubitt and de la Torre 1997; Hallensleben et al. 1997; Stitz et al. 1998b). The sensitivities of the other human isolates, RW98 (Planz et al. 1999) and HuP2br (Nakamura et al. 2000), are unknown. Ribavirin inhibits transcription and replication of both He/80 and strain V BDV in a variety of cell lines (Mizutani et al. 1998; Jordan et al. 1999). In addition to its antiviral effects through the depletion of cellular GTP pools, interference with mRNA capping, and direct interaction with viral polymerases, ribavirin can promote a Th1-type immune response (Hultgren et al. 1998; Tam et al. 1999). This led to concerns that enhancement of cellular immunity might aggravate the immunopathology of BD (Sobbe et al. 1997; Hatalski et al. 1998a; Lewis et al. 1999). The efficacy of ribavirin was assessed in the rat model, wherein the drug was administered directly to the brain by intraventricular injection. Although ribavirin had no effect on viral load, treated animals had less inflammation and milder disease, presumably owing to antimitotic effects on microglia (Solbrig et al. 2002b). Ara-C, a nucleoside analog that inhibits DNA polymerase enzymes, also inhibits BDV replication. The mechanism of action remains unclear, but is postulated to be direct inhibition of the viral polymerase rather than an indirect effect mediated by host cell factors (Bajramovic et al. 2002).

The establishment of two functional BDV minireplicon assays (Perez et al. 2003; Schneider et al. 2003) was recently reported. The importance of N:P protein stoichiometry was demonstrated in both.

Hepatitis A and E

BETTY ROBERTSON

Introduction	1	Hepatitis E virus	16
Hepatitis A virus	2	References	21

INTRODUCTION

Enterically transmitted viral hepatitis

Although descriptions of epidemic jaundice go back to earliest recorded human history, the infectious nature of hepatitis was not widely appreciated until this century. Investigations during the Second World War led to the first clear recognition that there were distinct forms of transmissible hepatitis: one that was acquired through ingestion of contaminated food or water ('infectious jaundice') and another that was associated with the administration of blood or blood products ('homologous serum jaundice') (Havens 1944; Barker et al. 1945). MacCallum and Bradley (1944) classified these as type A and type B hepatitis, setting in place a classification scheme that still exists. The distinguishing epidemiological features of these infectious diseases and the lack of cross-protection engendered by their respective agents were confirmed by Krugman and his associates in a classic series of studies carried out among institutionalized children (Krugman and Ward 1958; Ward et al. 1958; Krugman et al. 1960). However, the modern era of hepatitis A virology began with the identification of virus particles in human fecal samples (Feinstone et al. 1973).

The subsequent development of an immune electron microscopy assay for virus-aggregating antibodies resulted in a variety of increasingly sophisticated diagnostic tests for hepatitis A virus (HAV) infection. Widespread application of these new serologies, coupled with recently developed assays for hepatitis B virus (HBV) and its related antibody responses, led to the recognition that there were at least two additional human viruses responsible for reported cases of non-A, non-B (NANB) hepatitis. One type of NANB hepatitis, now recognized to be due to infection with Hepatitis C virus (HCV), resembled hepatitis B in that it was frequently associated with chronic liver disease and often transmitted by transfusion or other parenteral blood exposures (Choo et al. 1989). However, a distinctive agent responsible for waterborne or enterically transmitted NANB hepatitis was recognized to be the cause of large outbreaks of acute hepatitis in the Indian subcontinent and subsequently elsewhere (Khuroo 1980). These outbreaks included an epidemic in Delhi in 1955 that involved over 30 000 people and was associated with a breach in the city's sanitary water supply system. Although for many years this epidemic was considered to be due to type A 'infectious' hepatitis, serological tests carried out in the late 1970s indicated otherwise (Wong et al. 1980). The responsible agent, Hepatitis E virus (HEV), was identified by Balayan et al. (1983) in human fecal samples.

Similar and contrasting properties of HAV and HEV

HAV and HEV share a number of physical and biological characteristics (Table 1). Both are non-enveloped, RNA viruses with single-stranded genomes of positive polarity. Both display strong tropism for the liver (hepatocytes) and typically cause self-limited infections associated with acute hepatic inflammation. Above all, however, it is the fecal–oral transmission of HAV and HEV that distinguishes these viruses from other human hepatitis viruses, including HBV, hepatitis delta virus (HDV) and HCV. Both HAV and HEV are shed

Table 1 *Similar and contrasting properties of HAV and HEV*

Common properties		
Particle shape	Icosahedral	
Particle size	27–32 nm

at high titers in the feces of infected individuals. In each case, the virus present in feces is replicated primarily in the liver and reaches the intestinal tract following secretion from the hepatocytes into biliary canaliculi and passage through the bile ducts. The absence of a lipid envelope is an important factor in this process, as it renders both HAV and HEV stable when suspended in bile. In contrast, the other human hepatitis viruses possess an outer lipid envelope and are likely to be rapidly inactivated in bile. Therefore, newly replicated HAV and HEV particles have a direct route to the outside environment that is denied the other hepatitis viruses. This allows HAV and HEV to cause explosive outbreaks of disease that are not seen with other types of hepatitis. However, neither HAV nor HEV causes persistent infections in humans and thus, unlike HBV and HCV, they have no association with chronic viral hepatitis or hepatocellular carcinoma.

Despite these similarities, HAV and HEV are very different viruses with a number of distinguishing features that result in their classification within different virus families (Table 1). These differences include fundamental aspects of virion structure and genome organization, as well as molecular mechanisms of translation and RNA replication.

HEPATITIS A VIRUS

Classification

On the basis of several features that distinguish HAV from other picornaviruses (Table 2), it is classified as the only member of the *Hepatovirus* genus of the *Picornaviridae* family (Minor 1991). Unique attributes of HAV include its tropism for the liver, its unusually slow and usually noncytolytic replication cycle, and its lack of close genetic relatedness to any other picornavirus.

Morphology of the HAV particle

The HAV virion appears as a relatively smooth, 27–30 nm rounded particle when viewed by electron microscopy in negatively stained preparations (Figure 1). Icosahedral symmetry is evident in many particles, but information concerning finer aspects of the capsid structure is limited. Infectious virions have a sedimentation constant of ca. 157S and band in CsCl at ca. 1.325 g/cm^3 (Lemon et al. 1985). Most virus preparations contain a large proportion of empty 70S capsids that are antigenically identical to virions.

Genome organization

The genomic RNA is single-stranded, ca. 7.5 kb in length and of positive polarity. The extreme 5′ end of the virion RNA is covalently coupled to a small viral protein, 3B (VPg), which is presumed to be removed from the RNA after its release from the capsid. The organization of the genome is similar to that of all picornaviruses (Figure 2, p. 4) (Najarian et al. 1985; Cohen et al. 1987c), but there are several unique features. There are at least three functionally separate domains: the 5′ and 3′ nontranslated RNA (NTR) and a single, intervening, long open reading frame (ORF) which encodes the viral polyprotein.

5′ NONTRANSLATED RNA

The 5′ NTR is approximately 735 nt long and contains an extensive secondary and tertiary RNA structure (Figure 3, p. 4). The segment from nucleotides 1–94 contains a 5′ terminal hairpin followed by 2 RNA pseudoknots (Brown et al. 1991; Shaffer et al. 1994) that, on the basis of studies of the corresponding cloverleaf-like RNA structure in poliovirus, probably play a controlling role in the initiation of positive-strand RNA

synthesis (Andino et al. 1993). At nucleotides 95–154 there is a unique pyrimidine-rich tract (pY1) that contains a series of repetitive (U)UUCC(C) sequence motifs assuming a poorly defined higher ordered structure, followed by a short, single-stranded domain (Shaffer et al. 1994). Both in location and in base composition, the pY1 domain resembles the much longer, nearly pure poly(C) tracts of the cardioviruses and aphthoviruses, other genera within the *Picornaviridae*. It seems that the pY1 tract is dispensable for viral

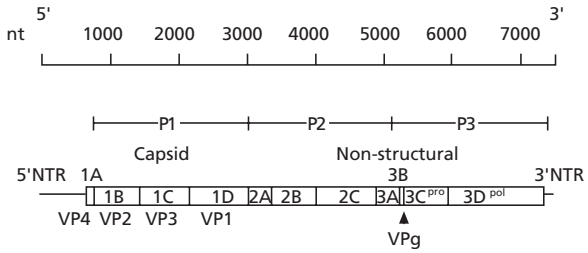

Figure 2 *Organization of the single-stranded positive-sense RNA genome of HAV.*

replication, both in primates in vivo and in cultured cells (Shaffer et al. 1994, 1995). The single-stranded domain located at nucleotides 135–155 seems to play a functional role in viral RNA replication, as deletion mutations in this region confer a temperature-sensitive viral replication phenotype due to a defect in RNA synthesis (Shaffer and Lemon 1995). Further downstream, the segment of 155–735 nt contains several complex stem–loops that comprise an internal ribosomal entry site (IRES) and direct the cap-independent translation of the long ORF (pp 696 and 699) (Brown et al. 1991, 1994; Glass and Summers 1992).

LONG ORF

The long ORF encodes a large polyprotein of c. 2200 amino acid residues that is proteolytically cleaved cotranslationally and post-translationally to generate mature viral proteins. As illustrated in Figure 2, the polyprotein can be functionally divided into three segments, P1, P2, and P3, as defined for other picornaviruses (Rueckert and Wimmer 1984). The P1 segment contains the structural proteins that form the viral capsid: 1A (also known as VP4), which is very small and not yet demonstrated to be a component of the HAV virion; 1B (VP2); 1B (VP3); and 1D (VP1). The P2 segment contains three nonstructural polypeptides, 2A, 2B, and 2C. The 2A protein appears to play a role in viral assembly and is present in immature virions as uncleaved VP1/2A (Borovec and Anderson 1993), while 2B and 2C have functions related to RNA replication (see section on Replication of HAV). The P3 segment contains four additional nonstructural proteins, including 3A (which probably helps anchor replication complexes to cellular membranes), 3B (VPg, the genome-linked protein), $3C^{pro}$ (a cysteine protease), and $3D^{pol}$ (an RNA-dependent RNA polymerase). As in poliovirus infections, some intermediate precursor proteins (e.g. 3AB, 3ABC, or 3CD) appear to have functions distinct from their processed end products (see section on Replication of HAV).

3′ NONTRANSLATED RNA

The 3′ NTR is ca. 60 nt in length and is polyadenylated at its 3′ terminus. Little is known about the functions of

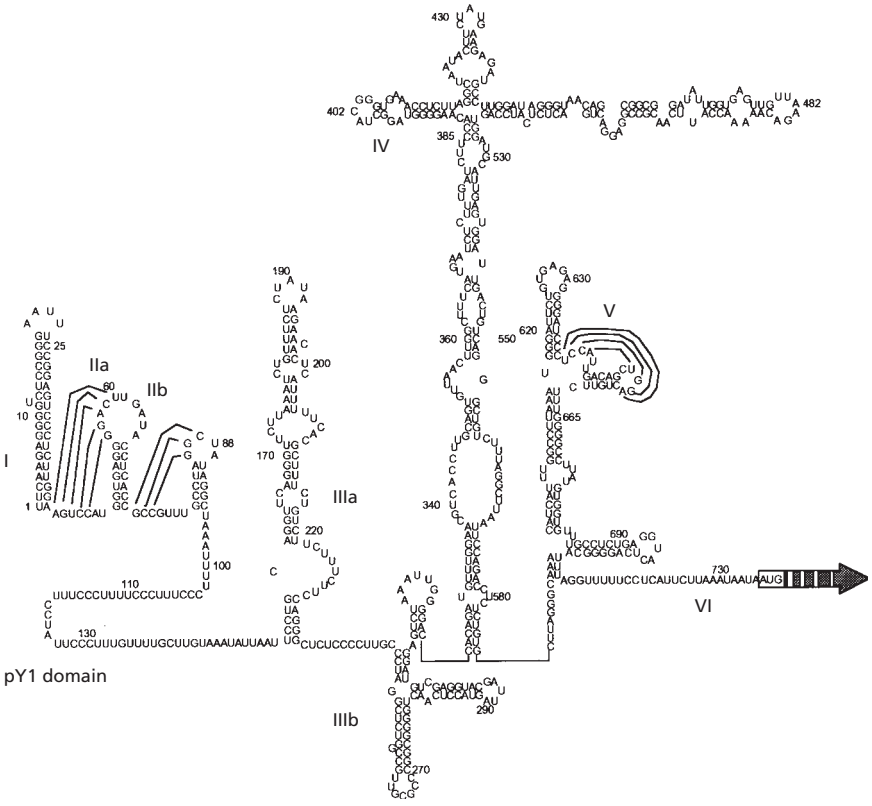

Figure 3 *Secondary and tertiary structure within the 5′ nontranslated RNA of HAV (Brown et al. 1991).*

the 3′ NTR sequence in virus replication. As with the 5′ NTR, the 3′ NTR is suspected to have substantial secondary structure and to interact with specific viral or host-cell proteins (Nuesch et al. 1993).

GENETIC VARIATION AMONG HAV STRAINS

Although the nucleotide sequences of different HAV strains have a relatively high degree of conservation, there is sufficient sequence heterogeneity to distinguish distinct phylogenetic lineages (Jansen et al. 1990; Robertson et al. 1991, 1992). A comparison of the sequences of a 168-nt segment near the VP1/2A junction of 152 different strains of HAV revealed seven distinct 'genotypes' that differed from each other at >15 percent of base positions (Figure 4) (Robertson et al. 1992). Representatives of three of these genotypes (I, II, VII) have been recovered only from human sources, whereas another genotype (III) contains viruses isolated both from humans and from captive Panamanian owl monkeys. The remaining three genotypes (IV, V, VI) are represented by single strains of simian HAV recovered from nonhuman primates (African green and cynomologus monkeys). Genotypes I and III include the vast majority of identified human strains and each contains two subgroups that differ at >7.5 percent of base positions. These have been designated subgenotypes IA and IB, IIIA and IIIB. Recently, the full genome sequences for representatives of human genotypes II (CF53/Berne, Lu et al. 2004), and VII (SLF88, Ching et al. 2002) have been determined, and the data indicate these two strains represent two subtypes of the same genotype and have been proposed to be subgenotypes IIA and IIB within genotype II (BH Robertson, unpublished observations). Similar conclusions were derived by Costa-Mattioli and coworkers (2002) based upon their evaluation of the complete VP1 region of 81 strains from France, Kosovo, Chile, Argentina, and Uruguay.

The molecular epidemiology of HAV using sequence comparison has characterized patterns of virus spread within different regions of the world and transmission patterns in outbreaks (Jansen et al. 1990; Robertson et al. 1991, 1992, 2000; Hutin et al. 1999; Diaz et al. 2001; Bruisten et al. 2001; Taylor 1997; de Paula et al. 2002; Costa-Mattioli et al. 2001a, b; Arauz-Ruiz et al. 2001; Mbayed et al. 2002). For example, multiple genotype IA virus strains recovered in China, North and Central America, and Cuba comprise separate, phylogenetically and geographically-related clusters within genotype IA while in South America no consistent pattern of virus derivation is apparent. In contrast, most HAV strains recovered in Europe show extensive genetic divergence, suggesting the absence of a dominant circulating virus and consistent with a large proportion of European cases being caused by virus strains imported from other regions (Jansen et al. 1990; Robertson et al. 1992; Costa-Mattioli et al. 2001b; Bruisten et al. 2001). Sequence analysis has identified identical sequences within common source and community wide outbreaks (Niu et al. 1992; Hutin et al. 1999; Robertson et al. 2000) and provided the ability to

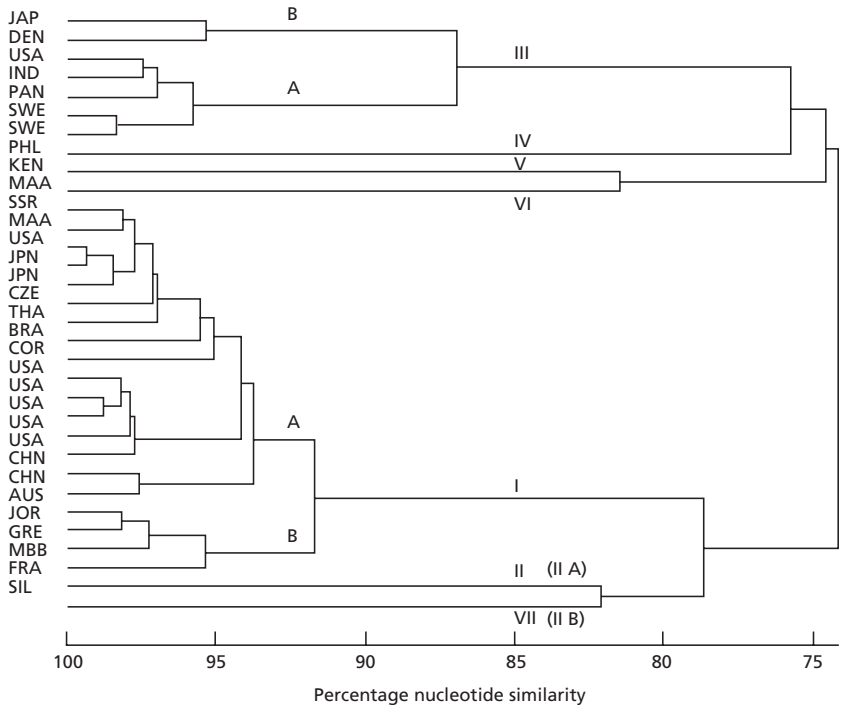

Figure 4 *Phylogenetic analysis of RNA sequences near the VP1/2A junctions of hepatovirus strains recovered from human sources in different geographic regions (genotypes I, II, III, and VII) or simian sources (genotypes IV, V, and VI) (Robertson et al. 1992).*

discriminate between outbreaks in the same city with different sources of transmission (Dentinger et al. 2001).

Structure of HAV

STRUCTURAL POLYPEPTIDES

The structural (capsid) proteins of HAV are encoded by the most 5′ (P1) region of the long ORF. The primary proteolytic cleavage of the nascent viral polyprotein seems to occur between the 2A and 2B polypeptides (Almela et al. 1991; Cho and Ehrenfeld 1991; Winokur et al. 1991; Borovec and Anderson 1993). The site of this cleavage, which is mediated by the viral protease $3C^{pro}$, was recently shown to occur at residue 867 of the polyprotein, making 2B considerably larger than in other picornaviruses (Martin et al. 1995). Subsequent cleavage of the P1-2A precursor at the VP2/VP3 and VP3/VP1 junctions by $3C^{pro}$ results in 1A1B (also known as VP0), VP3 and VP1-2A (otherwise known as PX). VP1-2A seems to be an intermediate in virus assembly, as it can be detected within infected cells in pentameric subunits and possibly in some early virions (Borovec and Anderson 1993).

The VP4 sequence, located at the extreme amino terminus of the polyprotein, includes two potential methionine initiation codons (codons 1 and 3) which precede a consensus myristylation signal (GxxxT/S) (Chow et al. 1987). This has led to speculation that 'VP4' might be cleaved during replication to place the myristylation signal at the N terminus of the polyprotein, as such a signal is present at the amino terminus of the VP4 proteins of enteroviruses and rhinoviruses. Moreover, in the genera *Aphthovirus* and *Cardiovirus* of the *Picornaviridae*, a 'leader' (L) protein, located at the amino terminus of the polyprotein, is proteolytically removed to yield the free amino end of VP4, which is then myristylated (Chow et al. 1987). Thus, the VP4 proteins of all other picornaviruses are N terminally myristylated. However, despite numerous attempts, no one has yet been able to demonstrate the presence of VP4 within the HAV particle, or to determine by labeling experiments whether any of the viral capsid proteins are myristylated. In addition, site-directed mutagenesis of the two potential initiator methionines resulted in a change in the size of VP0, proving that there is no early cleavage within the sequence of VP4 and strongly suggesting that HAV VP4 is not myristylated (Tesar et al. 1992, 1993). Thus, although myristylation of VP4 seems to be important for the assembly of other picornaviruses, it does not seem to be necessary for HAV morphogenesis.

As in other picornaviruses, cleavage of VP0 to VP4 and VP2 occurs after the encapsidation of viral RNA (Bishop and Anderson 1993), resulting in a difference in the protein profile of empty capsids and complete virions. However, this cleavage occurs slowly with HAV, a feature that might be important to pathogenesis as it may prevent the infection of intestinal epithelial cells by virus secreted in the bile into the upper intestinal tract. The precise arrangement of the polypeptides within the assembled capsid is not known, as the hepatoviruses represent the only genus of the *Picornaviridae* for which the capsid structure has not been solved by X-ray crystallography. A hypothetical structure has been proposed, modeled after the structures of mengo virus and rhinovirus (Luo et al. 1988). However, this model does not correlate particularly well with experimental data obtained from biochemical and enzymatic studies, or with analysis of neutralization-resistant escape mutants (see below). Extended incubation of virus (up to 24 h) in the presence of large amounts of protease (1–10 mg/ml) results in the cleavage of VP2 by chymotrypsin and of VP1 and VP2 by trypsin. However, protease digestion has no effect on infectivity or antigenicity of the virus (Lemon et al. 1991a). Chemical iodination of exposed tyrosine residues occurs at two surface sites, one involving VP1 and the other, VP2. The VP1 residue is located between amino acids 233 and 273, whereas the VP2 site was at Tyr^{100} (Robertson et al. 1989).

ANTIGENIC STRUCTURE

Available evidence indicates that HAV strains comprise a single serotype, and that infection or immunization with any one strain confers protection against all others (LeDuc et al. 1983; Lemon and Binn 1983a; Lemon et al. 1992a). Although antigenic differences between human and simian viruses can be detected with a selected monoclonal antibody (mAb) (Nainan et al. 1991; Tsarev et al. 1991), the simian viruses react with other mAbs as well as polyclonal antibodies raised to human strains. The dominant antigenic determinants of HAV are highly conformational, as mAbs to the virus fail to recognize any capsid polypeptide in immunoblot assays. In addition, the antigenicity of the virus is curiously monotonic. Many mAbs are able to inhibit competitively by >50 percent the binding of polyclonal antibodies to the virus, and mAbs can be classified into several different groups on the basis of their ability to block the binding of two reference monoclonals (Stapleton and Lemon 1987; Ping and Lemon 1992; Schofield et al. 2002). Some mAbs recognize antigenic determinants common to 70S empty particles and 14S pentamer subunits (which are formed by five copies of the VP2–VP3–VP1 protomer subunit), whereas others recognize an antigenic determinant that is present only on 70S particles and is thus likely to span pentamer–pentamer interfaces (Stapleton et al. 1993). With few exceptions, mAbs to the virus are able to neutralize infectivity (Ping and Lemon 1992). No monoclonal antibodies have been identified that are directed toward the binding site for the putative HAV receptor, HAVcr-1 (see section on Replication of HAV).

Neutralization-resistant HAV mutants have been produced by successive rounds of neutralization and passage of virus in the presence of mAb (Stapleton and Lemon 1987). These mutants have only a limited number of amino substitutions, all in VP3 or VP1 (Ping et al. 1988; Ping and Lemon 1992; Nainan et al. 1992). Most, if not all, of these amino acid substitutions are likely to be at residues that interact directly with the complementarity-determining regions of the cognate mAb. They thus serve to map the neutralizing epitopes of the virus. The most frequently identified mutations are at Asp^{70} of VP3, but escape mutations have also been found at Pro^{65}, Ser^{71}, and Glu^{74} of this protein. Mutation at Asp^{70} profoundly alters the antigenicity of the virus, significantly reducing the reactivity of the virus with most polyclonal antibodies (Lemon et al. 1991b; Ping and Lemon 1992). Several different amino acid substitutions have been identified at this residue. Other neutralization escape mutants have substitutions within the VP1 sequence, at Ser^{102}, Asp^{104}, Lys^{105}, Val^{171}, Ala^{176}, or Lys^{221}. Except for several mutants with different amino acid substitutions at Lys^{221} of VP1 (all of which determine resistance to a single mAb), most escape mutants demonstrate extensive cross-resistance to multiple mAbs (Ping and Lemon 1992). The simian strains of HAV all contain an Asp^{70} mutation that results in lack of recognition of these viruses by monoclonal antibodies against human HAV (Nainan et al. 1992). These data suggest that residues 65–74 of VP3 (centering on Asp^{70}) and 102–105 and 171–176 of VP1 contribute to a single immunodominant antigenic site that contains a limited number of closely related and overlapping epitopes. This interpretation is consistent with the monotonicity of the polyclonal antibody response to the virus noted above.

There is also limited evidence for a neutralization epitope located near the amino terminus of VP1. Antibodies raised against a synthetic peptide representing residues 13–24 of VP1 generated neutralizing antibodies (Emini et al. 1985), and low levels of neutralizing antibodies were found in some animals immunized with a chimeric poliovirus containing this segment of the HAV VP1 molecule placed within an antigenic surface loop of poliovirus VP1 (Lemon et al. 1992b). Because the amino terminal domain of VP1 is located internally within the crystallographically determined structures of other picornaviruses, it is likely that this epitope becomes exposed only after interaction of the virus with its putative cellular receptor.

Consistent with the conformational nature of HAV epitopes, individual recombinant HAV capsid proteins generally fail to elicit antibody responses that are reactive with the viral capsid. However, such proteins may prime for B cell responses in small animals (Johnston et al. 1988). Epitope(s) responsible for such priming reside within the carboxy terminal 156 residues of VP1 (Harmon et al. 1993). Also consistent with the conformational nature of HAV epitopes, a large number of synthetic peptides representing different segments of the HAV capsid proteins have been shown not to express any relevant HAV antigenic activity (Lemon et al. 1991c). There is data suggesting that a synthetic peptide 'mimotope' selected using a combinatorial approach may be able to stimulate production of antibodies that are reactive with the virus capsid (Mattioli et al. 1995).

Five antigenic domains over the entire HAV polyprotein using 237 overlapping 20mer peptides were identified using convalescent antisera (Khudyakov et al. 1999). These domains, probably composed of linear epitopes, include amino acids 57–90 (within VP2); amino acids 767–842 at the VP1–2A junction; amino acids 1403–1456 encompassing the P2C–P3A junction; amino acids 1500–1519 comprising the entire P3B protein; and amino acids 1719–1764 which encodes the P3C–P3D junction. In general, the nonstructural proteins have not proved to be adequate targets for antibody detection. Studies using expressed 3C protease for antibody detection demonstrated the presence of these antibodies after the acute phase of the illness, but they declined more rapidly than antibodies directed toward the capsid (Robertson et al. 1993; Stewart et al. 1997).

Replication of HAV

PROPAGATION OF VIRUS IN CULTURED CELLS

Replication of wild-type HAV is very slow and inefficient in cell culture, typically taking days to weeks to reach maximum virus yields (Provost and Hilleman 1979; Daemer et al. 1981; Binn et al. 1984). However, with patience and continued passage, virus yields are increased and the otherwise lengthy replication period is shortened. HAV variants that have been adapted to cell culture will replicate in many primate cell lines, but certain cell lines derived from African green monkey (BS-C-1 or CV-1) or fetal rhesus monkey kidney (FRhK-4) seem to be most permissive for virus growth (Provost and Hilleman 1979; Daemer et al. 1981; Binn et al. 1984). Other mammalian cell types are also permissive for limited replication of the virus (Dotzauer et al. 1994). Thus there does not seem to be a strict host species requirement in cell culture. Viruses that are well adapted to growth in monkey kidney cell cultures are often highly attenuated when inoculated into susceptible primates or humans (Provost et al. 1982; Karron et al. 1986) (see below).

The specific cell culture infectivity (cell culture infectious units per genome copy) of one virus variant (HM175/P16) that had been adapted to growth in cultured cells during 16 sequential passages in African green monkey kidney cells was >3 000 times that of the related wild-type virus (Jansen et al. 1988). However, even virus isolates that are well adapted to growth in

cultured cells replicate much more slowly than picornaviruses such as encephalomyocarditis virus (EMCV) or poliovirus (Lemon et al. 1991b). Most HAV strains fail to induce a cytopathic effect in cultured cells, although cytopathic variants have been selected from strains that are highly adapted to growth in cultured cells (Anderson 1987; Cromeans et al. 1987; Robertson et al. 1988; Lemon et al. 1991b). Such cytopathic variants may reach maximum yields in <24 h under one-step growth conditions (Lemon et al. 1991b). However, even these strains of HAV do not induce a specific shutdown in host cell macromolecular synthesis. To a considerable extent, the poor growth of HAV in cultured cells has limited investigations of the replication cycle.

In most cases, the replication of HAV in cell cultures can be detected only by immunological techniques or demonstration of the viral RNA by nucleic acid hybridization. The quantal, radioimmunofocus assay allows accurate titration of viral infectivity by immunostaining of viral replication foci developing beneath an agarose overlay over a period of 6–14 days (Lemon et al. 1983).

HAV CELL RECEPTOR

Recently, a putative receptor for HAV has been identified as a mucinlike class I integral membrane glycoprotein. This molecule (HAVcr-1) was identified by two independent groups using AGMK cells (Kaplan et al. 1996) and a marmoset–Vero cell hybrid (Ashida and Hamada 1997). It consists of an N-terminal Cys-rich region with homology to the immunoglobulin superfamily followed by a threonine, serine, proline-rich region which is similar to mucinlike proteins. The human homologue (huHAVcr-1) was cloned from human kidney and liver cDNA and determined to be 79 percent identical to the AGMK derived receptor, excluding three insertions/deletions within the mucinlike domain (Feigelstock et al. 1998). The huHAVcr-1 molecule does not appear to be liver specific, as it has been identified in all organs evaluated, with highest levels within kidney and testis. Evaluation of deletion mutants of the HAVcr-1 revealed that the Cys-rich region and the N-terminal N-glycosylation site is required for binding of HAV (Thompson et al. 1998); evaluation using immunoadhesins also revealed that it neutralizes bound HAV (Silberstein et al. 2001). Interestingly, a related protein from mice (Tim-1) and rats (Kim-1), expressed on T cells, is associated with airway hyperreactivity within inbred mice (McIntire et al. 2001).

In contrast to these findings, Dotzauer et al. (2000), have presented evidence that an alternative mechanism can be used by the virus to target it to liver cells. They propose that in addition to other host-derived materials found associated with HAV virions, IgA molecules bound to virus can serve to target virions to the liver using the asialoglycoprotein receptor. Initial infection would be from ingested IgA–virus complexes or the result of local IgA stimulated within the small intestine.

CAP-INDEPENDENT TRANSLATION OF THE VIRAL POLYPROTEIN

The first step in replication following the uncoating of the viral RNA is the cap-independent translation of the viral polyprotein. The initiation of translation is carried out under direction of the IRES located between nucleotides 155 and 735 of the 5′ NTR (Brown et al. 1991, 1994). Although the IRES shares several structural features with that of EMCV, it is ca. 50–100-fold less active in directing translation than the EMCV IRES, even in HAV permissive cells (Brown et al. 1994; Whetter et al. 1994; Schultz et al. 1996b). It is likely that weak IRES activity contributes to the slow and noncytopathic growth of HAV, because studies indicate that translation is rate limiting in infection of cultured African green monkey kidney cells with wild-type virus (Schultz et al. 1996b).

The IRES of HAV binds specifically to several cellular proteins, including polypyrimidine tract-binding protein (PTB) and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) (p39) (Chang et al. 1993; Schultz et al. 1996a). Experimental data indicate that the binding of GAPDH destabilizes RNA secondary structure and is thus likely to be detrimental to IRES-directed translation (Schultz et al. 1996a). PTB and GAPDH compete with each other for binding to certain stem–loop structures within the 5′ NTR, and the relative levels of these cellular proteins may be important in determining the translational activity of the HAV IRES (Yi et al. 2000). Specific hepatocyte factors may enhance translation directed by the HAV IRES (Glass and Summers 1993).

REPLICATION FUNCTIONS ASSOCIATED WITH NONSTRUCTURAL PROTEINS

The nonstructural proteins of HAV are responsible for proteolytic processing of the polyprotein and replication of the viral RNA. There are at least seven distinct nonstructural proteins: 2A, 2B, 2C, 3A, 3B (the genome-linked protein, VPg, which is covalently attached to the 5′ end of virion RNA), $3C^{pro}$ (the viral protease) and $3D^{pol}$ (the RNA-dependent RNA polymerase). Many of the specific functions of these proteins are not well understood.

Although the 2A proteins of other picornaviruses have protease activities and are responsible for the primary *cis*-active cleavage of the polyprotein (at either VP1/2A or 2A/2B), this is not the case for HAV. The HAV 2A protein shares no sequence identity with these other picornaviral 2A proteins and does not have proteolytic activity. Unlike other picornaviruses, primary cleavage of the HAV polyprotein precursor occurs between 2A and 2B, resulting in a P1–2A intermediate. While the 2A/2B cleavage site has been identified as

Gln^{836}/Ala^{837} and is mediated by $3C^{pro}$ (Martin et al. 1995), the cleavage of VP1–2A has been more difficult to determine. Early data suggested that this junction was cleaved by the $3C^{pro}$ (Schultheiss et al. 1994; Schultheiss et al. 1995); Probst et al. (1997) also concluded that $3C^{pro}$ is responsible for the maturation cleavage of VP1/2A between amino acids Val^{272}-Glu^{273} and Ser^{274}. In contrast, two studies provide evidence that $3C^{pro}$ is not involved in this cleavage – mutation of the only sites possible for $3C^{pro}$ cleavage did not abolish infectivity or virus maturation (Martin et al. 1999). This conclusion was supported by identification of the C-terminal amino acids of VP1 (Graff et al. 1999); the C terminus was found to be heterogeneous and composed of Leu^{270}-Pro^{271}-$Thr^{272}/Glu^{273}/Ser^{274}$. The predominant terminal amino acid was Ser^{274}, but with detectable amounts of Glu^{273} and Thr^{272}. This process had been proposed to be mediated by an unknown cellular protease. Cohen et al. (2002) created deletion mutants within the 2A region, and found that deletion of the amino terminal 40 percent abolished infectivity, while deletions in the carboxy terminal 60 percent resulted in small plaque phenotype. However, earlier studies of large (15 amino acid) deletions within 2A were found not to impair virus growth in cultured cells (Harmon et al. 1995). The N-terminal deletions would alter the VP1–2A cleavage that occurs after pentamer assembly, thereby affecting virus maturation. These studies have lead to the conclusion that there are two domains within 2A; an amino terminal molecular chaperon-like domain that directs the folding of the capsid precursor for proper 3C processing, while the C terminal domain is needed for non-$3C^{pro}$-mediated processing of the VP1–2A precursor to generate mature VP1.

The 2B and 2C proteins of HAV have functions related to replication of the viral RNA and, on the basis of studies with poliovirus, presumably play essential roles in directing the assembly of a membrane-based replicase complex (Bienz et al. 1992; Cho et al. 1994). Since mutations in 2B and 2C are important for adaptation of wild-type HAV to replication in cultured cells (Emerson et al. 1992a; Emerson et al. 1993), it is very likely that these proteins interact in an as yet undefined but highly specific fashion with cellular proteins or other components of the intracellular membrane. 2C contains a 'DEAD' motif, suggesting that it may have RNA helicase activity, and has been shown to be an NTPase. The HAV 2B and 2C proteins most probably function as a complex, as mutations in these proteins which play an important role in defining the replication properties of rapidly replicating, cytopathic viruses act in a highly cooperative fashion (Zhang et al. 1995). The 2C proteins of HAV and poliovirus are clearly related phylogenetically, and mutations that confer resistance of poliovirus to guanidine (an inhibitor of poliovirus RNA replication) map to the 2C protein. HAV replication has been suggested to be sensitive to guanidine (Cho and Ehrenfeld 1991), but this has not been found to be the case by other investigators (Siegl and Eggers 1982).

The function of the 3A protein in viral replication is also poorly defined, but it is likely to serve as an anchor for 3AB or 3ABCD within the membranous replication complexes. Mutations in 3A may play a role in determining the cytopathic phenotype, as multiple cytopathic strains that have been sequenced in this region contain deletions of one or more amino acids near the amino terminus of 3A (Lemon et al. 1991b; Beneduce et al. 1995). However, any role that mutations in 3A may play in determining this phenotype is of secondary importance to the role played by mutations in 2BC (Zhang et al. 1995). The 3B (VPg) protein is covalently attached to the 5′ nucleotide of the virion RNA (Weitz et al. 1986). Studies with other picornaviruses suggest that it is removed shortly after uncoating of the viral RNA, and that it is also likely to be present at the 5′ end of newly synthesized minus-strand RNAs. Its precise functions may include a role in priming for RNA synthesis, or possibly in cleavage of the RNA if negative-strand synthesis originates from a snap-back, self-priming mechanism.

$3C^{pro}$ is clearly the best studied of the nonstructural proteins of HAV because its three-dimensional structure has been determined by X-ray crystallography (Allaire et al. 1994). It is a cysteine protease with both structural and functional relatedness to chymotrypsin and the serine proteases. $3C^{pro}$ seems to be responsible for each of the proteolytic cleavages of the viral polyprotein (Harmon et al. 1992; Kusov et al. 1992; Schultheiss et al. 1994; Tesar et al. 1994), with the exception of the VP4/VP2 cleavage (Bishop and Anderson 1993) and the VP1/2A as indicated above. The substrate specificity of the $3C^{pro}$ enzyme has been studied extensively using synthetic peptide substrates (Jewell et al. 1992; Malcolm et al. 1992). The dipeptide sequences present at the various HAV cleavage sites are considerably more variable than in other picornaviruses. Studies with poliovirus suggest that $3C^{pro}$ has specific RNA-binding activity and interacts with the 5′ NTR during initiation of plus-strand RNA synthesis; structural studies indicate that the RNA-binding site is located on the opposite side of the molecule from the protease active site. Poliovirus $3C^{pro}$ has also been considered to contribute to host cell shutdown at the transcriptional level by directing cleavage of the human TATA-binding protein (Clark et al. 1993; Das and Dasgupta 1993). However, either the HAV $3C^{pro}$ protein lacks this activity or it is expressed at much lower levels during viral replication, because HAV infection has never been shown specifically to impair host cell metabolic processes. The putative RNA-dependent RNA polymerase activity of $3D^{pol}$ is suggested by the presence of a conserved 'GDD' amino acid motif. Thus far, however, attempts to express an active polymerase have resulted in an insoluble product with no detectable activity.

GENETIC CHANGES ASSOCIATED WITH ADAPTATION TO GROWTH IN CULTURED CELLS

The genetic changes associated with adaptation of the HM175 and GBM strains of HAV to growth in cell culture have been identified by comparisons of the nucleotide sequences of wild-type and cell culture-adapted variants (Cohen et al. 1987a; Jansen et al. 1988; Ross et al. 1989; Graff et al. 1994). These studies are important because cell culture-adapted viruses are often highly attenuated and have been used as candidate vaccines in humans. The HM175 strain has been studied intensively, with complete genomic sequences determined for three independently isolated, cell culture-adapted viruses (Cohen et al. 1987a; Jansen et al. 1988; Ross et al. 1989). The mutations associated with cell culture adaptation are scattered throughout the genome, but tend to concentrate in the 5′ NTR and P2 domains.

Several individual mutations are present in multiple, independent cell culture-adapted isolates, signifying their importance to efficient replication in cell culture. The construction of an infectious cDNA clone of the HM175 virus (Cohen et al. 1987b) has allowed a detailed molecular genetics analysis of mutations that are associated with the adaptation of HAV to growth in cultured cells. Emerson and colleagues (1991, 1992a, b) found that mutations within the P2 region (2B and 2C proteins) are necessary for efficient growth in cultured cells. A relatively conservative Val^{216} to Ala^{216} substitution in 2B (nucleotide 3889) seems to be the most important single mutation with respect to growth in cultured cells. These P2 mutations probably facilitate interactions between these viral proteins and a host cell-specific factor(s) required for replication, but further details are lacking.

Mutations within the 5′ NTR, strongly associated with host-cell restricted growth, have been demonstrated in virus grown in CV-1, BS-C-1, MRC-5, HEK, and HFS cells lines. Analogous host restricted mutations are not necessary for growth in FRhK4 cells (Emerson et al. 1991, 1992a; Funkhouser et al. 1994; Graff et al. 1994; Graff et al. 1997). The mutations responsible for this effect (Day et al. 1992) are located in or near the viral IRES, and enhance cap-independent translation (Schultz et al. 1996b). These results indicate that there are cell type-specific factors that influence the efficiency of translation directed by the HAV IRES in certain cell lines. Differing cytoplasmic levels of GAPDH and PTB may play an important role in determining the activity of these 5′ NTR mutations, as these two cellular proteins compete for binding to the 5′ NTR with opposing effects on viral translation (Chang et al. 1993; Schultz et al. 1996a).

In contrast, BS-C-1-adapted HAV was grown in guinea-pig embryo cells for five passages, and selected regions (5′ NTR, 2ABC3AB, and the 3′ NTR) were amplified and sequenced. Only two nucleotides within these regions were changed; 2B nucleotide 3679, and 2C nucleotide 4419 (Frings and Dotzauer 2001). Under these circumstances, host-cell growth restriction is not regulated by interaction of cellular factors with 5′ NTR sequences. Likewise, replication of a subgenomic replicon containing luciferase in the place of the capsid proteins within Huh-7 cells was enhanced by mutations within the P2 and P3 regions, especially mutations at 2B nucleotide 3889, while the 5′ NTR region had no effect within this system (Yi and Lemon 2002).

The nearly complete nucleotide sequences have been determined for three rapidly replicating, cytopathic variants (*rr/cpe+*) recovered from cells that were persistently infected with the HM175 virus (Lemon et al. 1991b). These clonally isolated variants contained identical mutations within the 5′ and 3′ NTRs as well as within the RNA encoding the P2 and P3 proteins (2B, 2C, 3A, and 3D), while the intervening genomic sequences contained unique silent and nonsilent mutations. This suggested that the mutations that were common to the three cytopathic variants were likely to be responsible for the *rr/cpe*$^+$ phenotype. To determine which mutations are responsible for the *rr/cpe*$^+$ phenotype, infectious cDNA chimeras were constructed that contained various segments of one of these cytopathic variants (HM175/18f) in the genetic background of a noncytopathic virus (Zhang et al. 1995). Analysis of the chimeric viruses demonstrated that complete expression of the *rr/cpe*$^+$ phenotype required the cooperative effects of multiple mutations in 2B, 2C, the 5′ NTR and the P3 regions of the genome. Thus, the *rr/cpe*$^+$ phenotype represents a super-adaptation of HAV to growth in cell culture, and reflects changes in multiple virus functions.

Clinical and pathological aspects of HAV infection

PATHOGENESIS OF HEPATITIS A

To a considerable extent, present understanding of the pathogenesis of hepatitis a derives from studies of HAV infections in several species of susceptible nonhuman primates: chimpanzees, certain species of tamarins, and New World owl monkeys (Dienstag et al. 1975; Dienstag et al. 1976; Bradley et al. 1977; Cohen et al. 1989). Although these primate species can be infected either by oral or by intravenous challenge with virus, HAV infection typically follows oral exposure to the virus in humans, due either to close personal contact with an infected individual or to the ingestion of fecally contaminated water or food. Viral replication occurs primarily within hepatocytes, and the secretion of virus into bile results in large quantities of virus being shed in the feces. The titer of virus excreted in stools may be at least as high as 10^8 particles or 10^6 infectious virions/g (Purcell et al. 1984; Lemon et al. 1990). A sustained viremia throughout the incubation period and the early

stages of acute liver disease parallels the fecal shedding of virus, but at titers that are 100–1000-fold lower (Cohen et al. 1989; Lemon et al. 1990) (Figure 5).
Early studies demonstrated viral antigen within the liver, in hepatocytes and Kupffer cells, as well as in splenic macrophages and along the glomerular basement membrane in the kidney (Dienstag et al. 1976; Mathiesen et al. 1978a, 1980; Shimizu et al. 1982). However, it is not clear whether the presence of viral antigen in phagocytic cells reflects nonspecific trapping of viral antigen or replication of virus.

The genetic basis of pathogenesis has been evaluated by Emerson and coworkers (2002) by generating 14 chimeric viruses from clonal wild-type and attenuated sequences of HM-175 which contained 19 individual nucleotide changes over the whole genome. The resulting chimeras were evaluated in tamarins for their ability to cause disease. Nucleotides 3025 and 3196 within the VP1–2A junction and nucleotides 4043, 4087, 4222, and 4563 within the 2C genome region were necessary for expression of virulence within tamarins and were associated with severity of acute hepatitis. The mutations within the 2C protein, combined with a mutation at nucleotide 3889 within 2B controlled efficient replication in cultured cells.

The relationship between pathogenesis and the infected host species was approached by inoculating simian HAV (AGM27 from African green monkeys) into five different primate species (Emerson et al. 1996). The results revealed that different clinical patterns are seen depending upon the host. The most severe disease pattern was seen in African green monkeys and marmosets while infection of rhesus monkeys and cynomologus monkeys resulted in less severe symptoms; infection of chimpanzees did not result in detectable biochemical changes or histopathology, and seroconversion was delayed until 5–6 weeks after inoculation. Cross-challenge with a standard challenge dose of wild-type human HAV HM-175 in animals who had been exposed to AGM-27 revealed that all the animals were protected from acute infection, consistent with protection due to the presence of antibodies generated by the AGM-27 infection.

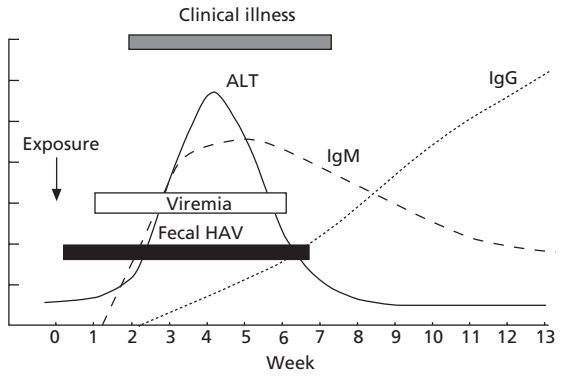

Figure 5 *Virological and pathological events during a typical infection with HAV.*

Although most if not all of the virus found in feces and blood is likely to be replicated within hepatocytes, there are limited data that indicate that HAV also infects intestinal epithelial cells in vivo. The early events in hepatitis A infection and the mechanism by which the virus reaches the liver remained poorly defined. HAV antigen has been identified within intestinal epithelial cells of experimentally infected tamarins (Karayiannis et al. 1986) as well as orally inoculated owl monkeys (Asher et al. 1995). In owl monkeys, viral antigen was observed in epithelial cells lining crypts in the small intestine within 3 days of inoculation. These findings in vivo are supported by studies demonstrating the growth of cell culture-adapted HAV in polarized cultures of colonic carcinoma cells (CaCo-2) grown on semi-permeable membranes (Blank et al. 2000). Such cells could be infected only from their apical surface, and released progeny virus in a vectorial fashion only from the apical surface. Infectious virus has also been detected at low levels within pharyngeal secretions, but later in infection when viremia was also present (Cohen et al. 1989; Asher et al. 1995). It is difficult to be certain whether this reflects virus produced locally or simply secretion of virus into saliva from the blood.

The light microscopic findings in acute hepatitis A include features common to all forms of acute viral hepatitis, including inflammatory cell infiltration, hepatocellular necrosis, and liver cell regeneration. Studies in chimpanzees demonstrated that the early histological lesions of hepatitis A infection involve periportal liver cell necrosis with relative sparing of the perivenular area of the lobule (Dienstag et al. 1976). These histological observations have been confirmed in humans undergoing biopsies at different stages of the acute disease. Portal infiltration by lymphocytes, plasma cells and periodic acid–Schiff (PAS)-positive macrophages are prominent features in early biopsies. These features are more pronounced in later biopsies (Abe et al. 1982; Teixera et al. 1982). Some biopsies taken during acute hepatitis A infection demonstrate extension of the inflammatory infiltrate from the periportal region into the hepatic parenchyma, with significant erosion of the limiting plate. Although this histological picture is more suggestive of chronic hepatitis, the histopathological features of hepatitis A are reversible and generally resolve completely given sufficient time.

CELLULAR IMMUNE RESPONSE TO HAV INFECTION

Because infection of cultured cells with wildtype HAV does not result in the cytopathic effects observed with many other well characterized picornaviruses, it is generally assumed that HAV infection is also noncytopathic in vivo and that hepatitis A is an immunopathologically mediated disease. This is probably correct, as virus repli-

cation and fecal virus shedding are maximal in the late incubation period, before the onset of symptoms or biochemical evidence of liver injury. Thus, liver injury and viral clearance are closely related. $CD8^+$, MHC class I-dependent, cytotoxic T cells that are capable of lysing autologous HAV infected cells, but not of controlling uninfected cells, are present both in the circulation and in the liver at the site of disease (Vallbracht et al. 1986; Vallbracht et al. 1989; Fleischer et al. 1990). These virus-specific T cells also produce interferon-γ (Maier et al. 1988). It is likely that interferon-γ and other cytokines secreted by virus-specific $CD8^+$ cells serve to recruit additional, less specific, inflammatory cells to the site of the infection that may be responsible for much of the liver injury. The exact mechanism by which the infection is cleared is inadequately defined, but this process probably involves a combination of antibody-mediated neutralization of infection, interferon-mediated inhibition of viral replication, and cytotoxic T cell-induction of cellular apoptosis. A prominent feature of this response may be the upregulation of the normally low levels of MHC class I markers displayed by hepatocytes in response to interferon-γ and other cytokines. Specific T-cell epitopes of HAV have not been identified.

HUMORAL IMMUNE RESPONSE TO HAV

In addition to the cellular immune responses described above, there is a vigorous antibody response to the virus during the later stages of infection. These antibodies are directed against conformational epitopes that are displayed by intact virions as well as empty viral capsids. Serum-neutralizing antibodies provide protection against reinfection with HAV, whereas cell-mediated immunity seems to be involved in viral clearance once infection has been established. Serum antibody responses are first noted at the onset of symptoms and include virus-specific IgM as well as IgG and IgA. IgM anti-HAV is detected concurrently with the onset of clinical symptoms, but IgG is also present during the acute symptomatic phase of the infection (Locarnini et al. 1979; Lemon et al. 1980). Both IgM and IgG antibodies have virus-neutralizing activities (Lemon and Binn 1983b; Lemon 1985b). The IgG response is durable and provides longstanding protection against reinfection. However, there are suggestions that it may decline to low and potentially nondetectable levels after many decades, particularly in people infected early in life. Upon re-exposure, such individuals may experience asymptomatic reinfections associated with anamnestic IgG antibody responses in the absence of detectable IgM (Villarejos et al. 1982). Although coproantibodies have been detected by immunoassay, saliva and stool do not contain virus-specific neutralizing antibodies (Locarnini et al. 1980; Stapleton et al. 1991). These data suggest that secretory antibody plays little if any role in protection against hepatitis A.

Sensitive and specific immunoassays are widely available for the detection of total and IgM-specific antibodies to HAV. However, measurements of virus-neutralizing antibody are tedious and labor intensive. The radioimmunofocus reduction assay (Lemon and Binn 1983b) or HAV antigen reduction assay (Krah et al. 1991) are the most accurate methods available for determination of virus-neutralizing antibody. In addition to antibodies directed against the virus capsid, antibodies reactive with nonstructural proteins (especially $3C^{pro}$) have also been detected. The presence of such antibodies may differentiate immunity due to natural infection from that gained by immunization with inactivated HAV vaccine (Robertson et al. 1993; Stewart et al. 1997).

CLINICAL MANIFESTATIONS

HAV causes an acute, self-limiting infection that does not progress to a chronic phase. Manifestations of the disease are generally restricted to the liver. However, although extrahepatic manifestations suggesting involvement of the central nervous system or kidneys are rare, their occurrence is well documented (Bromberg et al. 1982; Hammond et al. 1982; Malbrain et al. 1994; Ogawa et al. 1994; Zikos et al. 1995). The typical clinical course of type A hepatitis is shown in Figure 5. Following exposure, an incubation period of 15–45 days precedes the development of clinical symptoms. However, virus is present in the blood and shed in the stools within a few days of exposure (Asher et al. 1995; Ward et al. 1958; Krugman et al. 1962; Bower et al. 2000). The magnitude of the viremia and the amount of virus shed in the feces continues to increase until just before the onset of symptoms. Symptoms typically occur abruptly, with liver injury heralded by fever, myalgia, malaise, nausea, anorexia, and vomiting, accompanied occasionally by abdominal pain in the right upper quadrant. More distinctive signs of hepatitis and the disruption of normal hepatobiliary metabolism appear rapidly thereafter, including the passage of dark, 'Coca-Cola'-like urine, light, clay-colored stools, and frank icterus. These clinical findings coincide with the appearance of characteristic biochemical abnormalities, including abnormal elevations of serum levels of the liver-derived enzymes alanine aminotransferase (ALT), alkaline phosphatase (AST), and γ-glutamyl transpeptidase (GGTP), as well as increased levels of serum bilirubin. All these events signal the host immune response to the infection, including the appearance of virus-specific neutralizing antibodies (Lemon and Binn 1983b). Resolution is marked by slow recovery and often a prolonged period of convalescence. Nevertheless, serum enzyme levels are almost always normal by 6–12 months after onset of the disease, often much sooner. Rarely, however, HAV infection may trigger the onset of a chronic, autoimmune hepatitis (Vento et al. 1991).

The severity of symptoms associated with HAV infection is closely correlated with age. Acute, symptomatic,

icteric infections seem to be the rule in older adolescents and adults (Lednar et al. 1985). On the other hand, infection in children under 2 years of age is almost never recognized clinically as hepatitis (Hadler et al. 1980). Most people with antibodies to HAV have no history of acute hepatitis, probably reflecting infection at an early age many years previously. Individuals over 50 years of age at the time of infection are at substantially increased risk of developing fulminant hepatitis, and clinical evidence of hepatic failure such as ascites, bleeding diathesis or hepatic coma (Forbes and Williams 1990; Hadler 1991; Lemon and Shapiro 1994). A systematic study has not been done, but patients with pre-existing chronic liver disease due to any cause may be at increased risk of fulminant disease when infected with HAV. Fortunately, fulminant hepatitis A is relatively rare, and accounts for fewer than 100 deaths annually in the USA (Lemon and Shapiro 1994).

Cholestatic hepatitis A and relapsing hepatitis A represent two less severe complications of type A hepatitis. Cholestatic hepatitis is characterized by persistent jaundice associated with pruritus, anorexia, and weight loss. Patients eventually recover after several weeks to months, but may recover more rapidly following a brief course of corticosteroids (Gordon et al. 1984). Such therapy should be attempted with caution, and only when there is no doubt about the diagnosis. There are many reports of clinical relapses 1–3 months after apparent recovery from acute hepatitis A. Relapsing hepatitis A is characterized by secondary rises in levels of serum enzyme, persistence of IgM anti-HAV, and possibly recurrent viremia and fecal virus shedding (Sjogren et al. 1987; Glikson et al. 1992). The pathogenesis of relapsing hepatitis A is unknown, but may involve viral escape from immune surveillance.

DIAGNOSIS

The diagnosis of acute viral hepatitis is usually suggested by the presence of the typical constellation of signs and symptoms associated with elevation of serum ALT activities. However, in the absence of a specific epidemiological setting suggestive of hepatitis A, the clinical manifestations of HAV infection are not sufficiently different from those of other types of acute viral hepatitis to allow a virus-specific diagnosis to be made without serological testing. Generally, the diagnosis is confirmed by the demonstration of IgM antibodies to the virus, which are almost always present at the onset of symptoms and which persist for up to 6 months following infection. These antibodies are usually measured by solid phase, IgM-capture immunoassays (Lemon et al. 1980; Decker et al. 1981). Competitive-inhibition immunoassays allow non-isotype-specific detection of viral antibodies (Mathiesen et al. 1978b; Decker et al. 1979). When such tests are positive in the absence of IgM antibodies, they are considered indicative of the presence of IgG antibodies to the virus. This result is consistent with immunity due to prior infection or immunization against HAV.

Epidemiology of hepatitis A

TRANSMISSION OF HEPATITIS A

Almost all transmission occurs by the fecal–oral route. Within the USA, the most common risk factor for infection is close contact with a person with hepatitis A (Centers for Disease Control 1994). Person-to-person transmission accounts for most infections among household contacts as well as institutionalized individuals and children and staff in preschool daycare centers (Hadler et al. 1980). Handlers of nonhuman primates may be at risk for similar reasons. Not surprisingly, sexual behavior can influence the spread of infection, particularly among male homosexuals (Corey and Holmes 1980). Food- and waterborne transmission of HAV is also common, facilitated by the stability of the HAV virion and its relative resistance to drying (Siegl et al. 1984). Foodborne transmission of HAV may follow contamination of uncooked foods by infected food handlers, and is not infrequently implicated in common source outbreaks of disease. However, fresh produce may also be contaminated at its source, before distribution (Rosenblum et al. 1990). Finally, infection may occur following ingestion of raw or partially cooked filter-feeding shellfish collected from polluted waters, as these organisms have the ability to concentrate the virus. All these modes of transmission pose risks for travelers to HAV-endemic regions.

Although uncommon, parenteral transmission of the virus is also possible. Injecting drug users have represented a substantial proportion of cases of hepatitis A in some studies, and there is little doubt that they are at increased risk of HAV infection (Widell et al. 1983; Centers for Disease Control 1988). These infections are probably related to sharing of contaminated needles and thus to parenteral transmission of the virus, given that a relatively high level viremia is present for several weeks throughout the asymptomatic incubation period of the hepatitis A (Lemon et al. 1990). This conclusion is strongly supported by remarkable concurrent declines in the incidence of drug use-associated cases of hepatitis A, hepatitis B, and hepatitis C in the USA since 1988. This would be unexpected if cases of hepatitis A among drug users related primarily to poor sanitation. Transmission of virus by blood and blood products is also well documented, although it is much less common than with other hepatitis agents. Many such infections have been recognized in neonates who may receive split units of blood (Rosenblum et al. 1991), but transfusion-related infections have also been observed rarely in adults (Hollinger et al. 1983; Sherertz et al. 1984). Parenterally transmitted infections have been described in hemophi-

liacs receiving high-purity, solvent-detergent inactivated factor VIII (Mannucci et al. 1994; Robertson et al. 1994b), and cancer patients who received IL-2 produced in LAK cells maintained in 'normal human serum' (Weisfuse et al. 1990). With the possible exception of infections among drug users, however, parenteral transmission of HAV does not contribute significantly to the overall spread of the infection.

PREVALENCE OF HEPATITIS A

The prevalence of HAV infection varies widely by geographical region and depends on factors such as population density and the quality of public health sanitation and sewage disposal (Lemon and Shapiro 1994). It may be greatly increased during periods of social upheaval and war. The poorest of developing countries are characterized by the type I seroprevalence curve shown in Figure 6. In these countries, including many in Africa, Asia, and Central America, infections occur predominantly in very young children and are thus generally clinically inapparent. As a result, most children have antibodies against HAV by the age of 5–10 years, and disease is very infrequent in older people. With improved sanitary conditions, as found in the emerging economies of eastern Europe, the republics of the former Soviet Union and China, HAV infections tend to occur at a somewhat older age, resulting in the type II seroprevalence curve in Figure 6. In these regions, the probability of exposure and infection remains relatively high, but an increase in the mean age at infection results in a greater disease burden as adolescents and young adults are more likely to experience clinical symptoms when infected (Szmuness et al. 1977; Frosner et al. 1979; Lemon 1985a). In recent decades, improving economic conditions have resulted in changing epidemiological patterns in many developing nations (Innis et al. 1991), with the result that epidemics of hepatitis A among older children, adolescents, and young adults, previously unheard of, are now becoming apparent. Older adults and the elderly are protected from infection by virtue of the antibody they carry from infections acquired in earlier, more endemic periods.

This trend continues in relatively well developed countries such as the USA and much of western Europe, where young children are no longer commonly infected (except in the setting of daycare centers), and the burden of disease is found among adolescents and young adults (Szmuness et al. 1977; Frosner et al. 1979; Lemon and Shapiro 1994). In these countries, symptomatic HAV infections in older individuals result in substantial absence from work and associated medical expenses. The major sources of infection in these populations are community-wide outbreaks, daycare centers, and common source outbreaks. Relatively high seroprevalence in the older age groups (Figure 6) signifies not continued risk of infection over time, but rather a cohort effect from infection in previous decades when HAV infections were more prevalent (Frosner et al. 1978). Finally, in highly developed regions such as the Scandinavian countries, seroprevalence tends to follow the type IV curve shown in Figure 6. There is little endemic transmission of the virus, and disease occurs primarily in travelers to other regions and in certain high risk groups such as intravenous drug users (Frosner et al. 1979; Siebke et al. 1982; Widell et al. 1983). Despite this convenient classification, it is important to note that prevalence patterns do not follow political as much as socioeconomic borders. For example, within the USA there are communities that would fit each of the type II, III, and IV patterns.

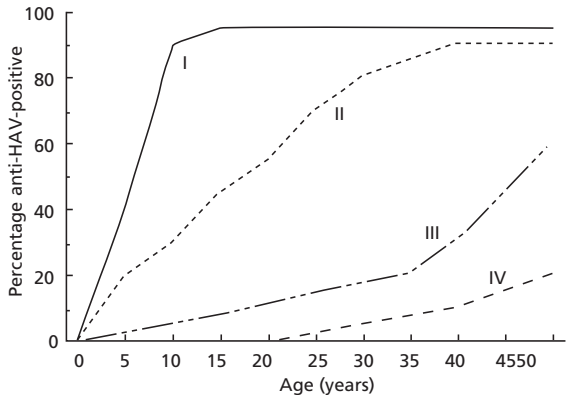

Figure 6 *Typical age-related seroprevalence curves found in populations residing in regions with high (I), intermediate (II) or low (III) endemicity for HAV infections, and in regions such as Scandinavia where endogenous transmission of HAV is now very uncommon (IV).*

Prevention of hepatitis A

To a considerable extent, hepatitis A can be prevented by good personal hygiene, adequate disposal and treatment of human waste, and provision of safe drinking water. As indicated above, HAV is rarely transmitted endemically in countries where these standards are met. However, specific measures are also available for the prevention of hepatitis A. These include passive immunoprophylaxis with pooled human immunoglobulin (IG) and active immunization with hepatitis A vaccines.

POOLED HUMAN IMMUNOGLOBULIN

Postexposure prophylaxis is generally accomplished with human IG (0.2 ml/kg), which should be given to people who are household members or sexual contacts of an infected individual (Gellis et al. 1945; Winokur and Stapleton 1992 Immunization Practices Advisory Committee 1990). Postexposure prophylaxis with IG may not prevent infection but it is remarkably effective in reducing or eliminating symptoms. It probably exerts

this effect by reducing the level of viremia, thereby reducing spread of virus within the liver (Lemon 1985a). To be optimally effective, it must be given within 2 weeks of exposure to the virus. IG is also useful for pre-exposure prophylaxis (0.2–0.5 ml/kg) and has been administered routinely to individuals traveling to HAV-endemic regions. If given before exposure, IG prevents disease for up to 4–6 months (Conrad and Lemon 1987). In this setting it is more likely to prevent infection as well as symptoms of hepatitis A, but this depends on the dose administered, the time elapsed between administration of IG and exposure to the virus, as well as the magnitude of the viral inoculum. Except for very limited travel, the use of inactivated hepatitis A vaccine is preferable and is largely replacing pre-exposure prophylaxis with IG.

HEPATITIS A VACCINES

Inactivated whole virus vaccines contain purified HAV particles (both complete virions and empty capsids) produced in cell culture and inactivated with formalin (Binn et al. 1986; Andre et al., 1990; Lewis et al. 1991). Several inactivated vaccines are licensed in their countries of origin and elsewhere, making inactivated HAV vaccine available worldwide. Most of these vaccines are adsorbed with alum (aluminium hydroxide) and all seem to be very immunogenic when administered by intramuscular injection. They are generally safe, and two have been shown in well designed clinical trials to provide a high level of protection against symptomatic hepatitis A in children (Werzberger et al. 1992; Innis et al. 1994; Lemon 1994). Antibody levels exceeding that produced by a single injection of IG are often present within 2–4 weeks of the first vaccine dose. Booster doses, given as early as one month following primary immunization, enhance the titer of neutralizing antibody and thus are likely to extend the duration of protection. Although the minimal protective level of antibody is not well defined, it is very low (<45 mIU/ml) (Stapleton et al. 1985; Werzberger et al. 1992). Although inactivated vaccines do not produce detectable secretory antibody, the prevention of intrahepatic virus replication is likely to prevent or substantially reduce the fecal shedding of virus. Thus, in contrast to inactivated poliovirus vaccines, immunization with inactivated hepatitis A vaccines should render an individual unable to transmit the infection if exposed to the virus.

The major shortcoming of inactivated HAV vaccines is that they are quite expensive and thus not available for the control of hepatitis A on a population-wide basis in countries where immunization is most needed. Although inactivated vaccines are likely to be more effective than IG in controlling community-wide outbreaks of disease (Werzberger et al. 1992; Lemon and Shapiro 1994; Prikazsky et al. 1994), the use of the vaccine in this setting is also likely to be limited by cost. Although data are limited, immunization may provide some level of protection against hepatitis A if it is administered immediately after exposure to the virus (Werzberger et al. 1992; Robertson et al. 1994a).

Several candidate attenuated HAV vaccines have been evaluated in clinical trials (Provost et al. 1986; Midthun et al. 1991; Sjogren et al. 1992). The virus strains included in these vaccines have been attenuated by passage in cell culture and require parenteral injection to initiate infection uniformly in human recipients. In general, the immune response to these candidate vaccines has been disappointing with slow, low magnitude antibody responses. This probably reflects the fact that these virus strains are highly restricted in their ability to replicate in human hosts. Although they seem quite safe in clinical trials involving limited numbers of people and are likely to be effective clinically, these candidate attenuated vaccines have generally been abandoned by commercial manufacturers in favor of the development of more profitable inactivated vaccines. However, one such vaccine has been used extensively in China (Mao et al. 1989, 1991).

A fresh approach to the selection of candidate attenuated HAV vaccine strains is likely to be required for the development of highly immunogenic attenuated vaccines. One such approach has been the creation of large deletion mutations within the 5′ NTR of a virulent, but minimally cell culture-adapted, variant of HAV (Shaffer et al. 1994). Some of these mutants have a strongly temperature-sensitive replication phenotype. However, there is no evidence thus far that these large 5′ NTR deletions result in significant attenuation of the virus in primates (Shaffer et al. 1995). A more promising alternative approach is to consider the use of simian strains of HAV, which seem to be naturally restricted in their ability to cause disease in chimpanzees (Purcell 1991), or virus chimeras containing selected sequences of human and simian HAVs. Recent data using chimeras derived from cell-adapted HM-175 (HAV/7) and the simian AGM-27 strain suggest that chimeras containing the HAV/7 background and the C terminus of the AGM-27 2C are attenuated for chimpanzees and may provide an alternative for development of an attenuated vaccine (Raychaudhuri et al. 1998).

Similarly, there has been little success in developing recombinant hepatitis A vaccines. This reflects the fact that the protective epitopes present on the surface of this picornavirus are conformationally defined by interactions between the individual capsid proteins in the assembled virus particle. However, Winokur and colleagues (1991) have demonstrated that it is possible to produce immunogenic, assembled viruslike capsids following expression of the P1 protein precursor and $3C^{pro}$ by recombinant vaccinia virus. Moreover, preliminary studies with synthetic peptide mimotopes (Mattioli et al. 1995) indicate that certain peptide motifs may successfully mimic the conformational, immuno-

dominant antigenic site of HAV, suggesting the ultimate feasibility of a synthetic peptide-based vaccine.

HEPATITIS E VIRUS

Classification

On the basis of the morphology of the hepatitis E virus (HEV) particle, the absence of a lipid envelope, the type and length of its nucleic acid and the general organization of its genome, HEV was originally classified within the *Caliciviridae* (Cubitt et al. 1995) (Table 3). However, a phylogenetic analysis of the nucleotide sequence of HEV shows that it is related more closely to the alphavirus superfamily of positive-strand RNA viruses, in particular the rubiviruses (Koonin et al. 1992) and it has subsequently been removed from the *Caliciviridae* and reassigned to an unclassified genus termed 'hepatitis E-like virus' (Berke and Matson 2000). Hepatitis E-like viruses have been identified in humans, swine, and chickens and all have similar genetic arrangements. The swine derived virus does not appear to cause any overt clinical symptoms in the pigs; in contrast, the avian HEV-like virus is associated with a hepatitis-splenomegaly syndrome in chickens within the United States. (Haqshenas et al. 2001)

Morphology and structure

As with many other features of HEV, the exact structure of the virion remains elusive owing to the absence of a reliable cell culture system that is permissive for its replication and to difficulties in obtaining large quantities of stable particles from human and nonhuman primate samples. The HEV particle is chloroform-resistant and has a morphology resembling that of human caliciviruses and Norwalk virus (Figure 7; and see Table 1). Although early reports suggested the diameter of HEV particles to be ca. 27 nm (Balayan et al. 1983), subsequent studies have shown the average diameter to be closer to 32 nm (Bradley et al. 1988). Smaller particles may result from proteolytic degradation as the virus passes through the intestine, as both particle sizes have been observed in single stool suspensions (Bradley et al. 1987). HEV-specific antibodies recognize both forms. The characteristic cup-like surface of caliciviruses is less prominent in HEV, but Markham rotational enhancement clearly indicates surface projections and valleys (Ticehurst 1991). Cryoelectron microscopy of a recombinant baculovirus expressed ORF2 product (amino acids 112–660) revealed spherical structures approximately 27 nm in diameter. These structures contained 60 copies of the recombinant ORF2, with a T = 1 lattice of icosahedral symmetry (Xing et al. 1999). However, X-ray diffraction data on the surface structure of the virus itself which is predicted to have a T = 3 lattice composed of 180 molecules is not available since sufficient amounts cannot be obtained from cell culture growth.

GENOME ORGANIZATION

The genome of HEV is a single-stranded, 7.5-kb, positive-sense RNA that is polyadenylated at its 3′ terminus (Reyes et al. 1990; Tam et al. 1991). It contains three separate ORFs flanked by short 5′ and 3′ NTRs of 27 and 68 nt, respectively (Figure 8). The presence of a methyltransferase motif within the nonstructural proteins encoded by the most 5′ ORF (ORF1) closest to the 5′ terminus is consistent with the presence of a methylated cap structure (Koonin et al. 1992) on the 5′ end of the RNA. Experimental studies have confirmed the presence of such a structure (Zhang et al. 2001b;

Table 3 *Properties of Hepatitis E virus, Calicivirus, and Rubivirus*

	Calicivirus	Hepatitis E virus	Rubivirus
Morphology	Icosahedral	Icosahedral	Spherical
Envelope	No	No	Yes

Kabrane-Lazizi et al. 1999a), identified the viral encoded capping enzyme (Magden et al. 2001) and verified that the capped structure is necessary for infectivity (Emerson et al. 2001). The ORF closest to the 3′ terminus (ORF2) is thought to encode the major structural protein. There is an additional short ORF (ORF3), which overlaps ORF1 by a single nucleotide and ORF2 by most of its length. ORF3 encodes a small protein that appears to be phosphorylated and is associated with the cytoskeleton (Zafrullah et al. 1997). The 5′ end of HEV RNA may contain a secondary structure analogous to that predicted to be present in alphaviruses. In addition, the sequence between 150 and 208 nt of HEV resembles a conserved 51 nt alphavirus sequence, whilst homology at 3602–3632 nt of HEV and junction sequences of alphaviruses suggests that this region may contain a promoter for transcription of a subgenomic RNA.

HEV PROTEINS

Most information about the proteins of HEV has been obtained from analysis of the nucleotide sequence of the virus. ORF1 encodes a relatively large polyprotein that contains consensus motifs for a methyltransferase, a papain-like cysteine protease, a helicase (NTP-binding site), and an RNA-dependent RNA polymerase similar to those found in the alphaviruses (Koonin et al. 1992).

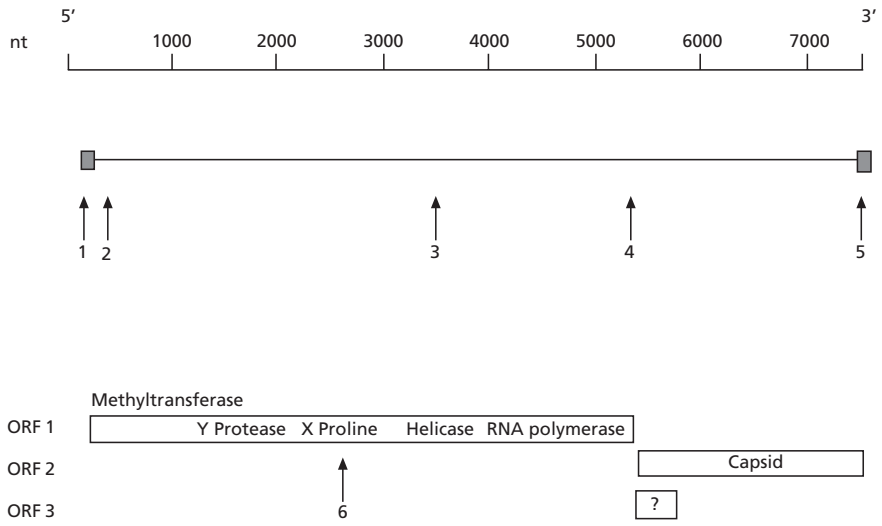

Figure 8 *Organization of the 7.5-kb single-stranded RNA genome of HEV.*

Also present in the ORF1 polyprotein is a polyproline 'hinge,' which is also found in rubiviruses, and a conserved 'X' domain, which is of unknown function but is found flanking the papain-like protease domain in other positive-strand RNA viruses. Although this polyprotein is almost certainly proteolytically cleaved into 4–5 individual polypeptides with distinct functions in replication, the details of this process are not understood and a preliminary study was unable to detect self-cleavage products using two different expression systems (Ropp et al. 2000). Several unusual features of this polyprotein distinguish HEV from members of the *Alphavirus* genus (Koonin et al. 1992). For example, a peculiar domain ('Y' domain) located downstream of the methyltransferase motif has no equivalent in the alphaviruses, although a similar domain is found in the plant virus, beet necrotic yellow vein virus. The function of this domain is unknown. Near the 'proline hinge' region, a 'hypervariable' region has also been noted whose function is not known (Fry et al. 1992, C.-C. Huang et al. 1992; Tsarev et al. 1992; Yin et al. 1993).

ORF2 encodes a 72 kDa capsid polypeptide and contains a signal peptide sequence and three potential glycosylation sites (Tam et al. 1991; Yarbough et al. 1991). The amino half of the ORF2 protein is rich in arginine residues, suggesting that it may associate with viral RNA. Cloning and expression of this product indicate that it is translocated in the endoplasmic reticulum, cleaved by signal peptidase and glycosylated (Jameel et al. 1996; Zafrullah et al. 1999). Subsequent studies have determined that ORF2 is present in both glycosylated and nonglycosylated forms but only the nonglycosylated form is stable in mammalian cells (Torresi et al. 1999). A portion of this molecule lacking the first 100 amino acids self assembles into viruslike particles (Li et al. 1997; Xing et al. 1999), and generates antibodies that are protective (Tsarev et al. 1994a; Zhang et al. 2001a). From an immunologic perspective, the ORF2 amino acids 452–617 are responsible for generating neutralizing antibodies that react with all four genotypes (Meng et al. 2001). An additional immunoreactive site is located at the amino terminus, but this site is not accessible using intact virions (Schofield et al. 2003). Although the ORF2 protein is found on the cell surface (Zafrullah et al. 1999), it is important to note that any surface lipid components of the virus would be unstable and almost certainly removed during passage of the virus through the bile.

Overlapping ORF1 and ORF2 is a small open reading frame (ORF3) that encodes a 13 kDa, cysteine-rich polypeptide that is immunoreactive with many patient sera. The genotype I ORF3 product has been shown to be a cytoskeleton-associated phosphoprotein (Zafrullah et al. 1997), with Ser^{80} serving as the phosphorylation site. Subsequent studies using a yeast two hybrid system suggests that the phosphorylated form of this protein associates with the nonglycosylated form of the ORF2 product and therefore may be involved in capsid assembly (Tyagi et al. 2002). However, the analogous product for genotype III does not contain a Ser^{80}, and large deletions have been described within this ORF in viruses recovered from two separate epidemics in India (Ray et al. 1992).

REPLICATION OF HEV

Although there are reports of HEV replication in conventional cell cultures (Huang et al. 1992; Kazachkov et al. 1992), they have not been confirmed. However, replication has been documented recently in primary cultures of hepatocytes taken from cynomolgus monkeys infected in vivo (Tam et al. 1996). The absence of a well characterized and readily available permissive cell culture system has severely limited studies of the molecular mechanisms of replication. The nonstructural proteins are presumably translated from newly uncoated RNA by a 5′ cap-dependent mechanism, providing the enzymes required for subsequent synthesis of both negative- and positive-strand RNAs. The 3′ end of the viral genome binds the viral RNA dependent RNA polymerase thereby providing a mechanism for viral RNA replication (Agrawal et al. 2001) while the ORF2 protein binds to the first 76 nt of the 5′ region of the viral RNA (Surjit et al. 2004). Two 3′ co-terminal, subgenomic messenger RNAs of 3.7 and 2.0 kb seem to be transcribed from the full-length negative-strand RNA, with the 2.0-kb message present in greater abundance than the 3.7-kb product (Tam et al. 1991). However, the role of these subgenomic RNAs in directing translation of the ORF2 and ORF3 proteins remains unclear. There is no understanding of how these processes are regulated.

GENETIC AND ANTIGENIC VARIANTS OF HEV

HEV strains seem to comprise a single serotype of antigenically related viruses, as all well-characterized strains share cross-reacting epitopes. Several studies have examined the reactivity of acute or convalescent sera with synthetic peptides or recombinant proteins expressed from ORF2 and ORF3 of different HEV strains (Yarbough et al. 1991; Kaur et al. 1992; Khudyakov et al. 1993; Li et al. 1994). Antigenic epitopes have been identified at the carboxy termini of both ORF2 and ORF3 protein products. The ORF3 epitope seems to differ between eastern and western hemisphere strains (Yarbough et al. 1991), however, the biological relevance of this finding is unclear. Multiple studies have identified that the carboxy terminal portion of ORF2 (approximately amino acids 270–660) is responsible for generating neutralizing antibodies, and that recombinant constructs containing these amino acids self assemble into viruslike particles (Li et al. 1997; Xing et al. 1999). Riddell et al. (2000), were the first to identify amino

acids 394–457 as part of the immunodominant capsid epitope using mouse monoclonal antibodies. Subsequently, Meng et al. (2001) used a PCR-based in vitro neutralization assay to evaluate the ability of synthetic peptides to inhibit binding of virus to PLC/PRF/5 cells and identified amino acids 452–617 as part of the neutralization epitope. A subsequent study characterized monoclonal antibodies derived from a chimpanzee experimentally infected with a construct including amino acids 112–607 (Schofield et al. 2003). Two antigenic reactive sites were identified in this study. One site, associated with neutralization, was localized to amino acids 452–617, while the second site was located between amino acids 112 and 150.

Despite the homogeneous antigenic reactivity, this group of viruses has a wide range of genetic diversity. Four distinct genotypes can be defined based upon complete genome sequences. Up to nine genotypes have been proposed based upon limited sequencing of 287 nucleotides within the OFR1 region (Schlauder and Mushahwar 2001) although this region has not been demonstrated to be representative of the complete genome. Genotype I contains human HEV strains recovered from endemic regions in the Far East and Central Asia – India, Myanmar, Nepal, Pakistan, China, Uzbekistan (Arankalle et al. 1999; Tam et al. 1991; Nakai et al. 2001; Gouvea et al. 1997; Shrestha et al. 2003; van Cuyck-Gandre et al. 2000; Li et al. 2002; Chatterjee et al. 1997) and African nations – Namibia, Algeria, Morocco, Chad, Egypt, and Tunisia (He et al. 2000; van Cuyck-Gandre et al. 1997; Meng et al. 1999; Tsarev et al. 1999; Chatterjee et al. 1997). These strains form a monophyletic cluster with individual branches being much more closely related genetically to each other (about 90 percent identity) than to strains representing viruses from other parts of the world. Genotype II is represented by a single sequence from Mexico (C.-C. Huang et al. 1992), although limited sequence of strains from Nigeria also appear to belong to genotype II (Buisson et al. 2000). Genotype III has been identified from human and swine sources in the United States, Japan, and the The Netherlands (Schlauder et al. 1998; Meng et al. 1997; Takahashi et al. 2001, 2003a, b; Okamoto et al. 2001; van der Poel et al. 2001; Widdowson et al. 2003); sporadic human cases in Greece, Spain, Italy, and the United Kingdom (Schlauder et al. 1999; Pina et al. 2000; Wang et al. 2001) and in swine populations in India and New Zealand (Arankalle et al. 2002, 2003; Garkavenko et al. 2001). Genotype IV strains have been characterized from human and swine sources in Taiwan, Japan, and China (Hsieh et al., 1998, 1999; Nishizawa et al. 2003; Takahashi et al. 2001, 2003a, b; Li et al. 2002; Wang et al. 2002), while human cases with this genotype have been identified in Vietnam (Hijikata et al. 2002). The tight genetic clustering observed within genotype I is not seen in the available sequences from these other strains.

Many of these sequences are derived from swine sources, and it has become obvious that there is a wide array of swine HEV sequences all over the world. However, the direct relationship between swine HEV and human disease is not obvious. Individuals with occupational exposures to swine do have a higher seroprevalence of antibodies against HEV, but this does not reflect disease (Drobeniuc et al. 2001; Meng et al. 2002). Other animal reservoirs including rats, mice, cows, sheep, goats, dogs, cats, wild boar, and deer have also been proposed based upon seroprevalence studies or virological studies (Balayan et al. 1990; Favorov et al. 1996, 2000; Kabrane-Lazizi et al., 1999b; Wang et al. 2002; Matsuda et al. 2003; Tei et al. 2003). In addition, avian HEV strains genetically related to swine and human HEV, have been characterized from chickens with hepatitis – splenomegaly syndrome in the United States (Haqshenas et al. 2001) and Australian big liver and spleen disease virus (Payne et al. 1999; Haqshenas et al. 2001).

Clinical and pathological aspects of HEV infection

PATHOGENESIS OF HEPATITIS E

Chimpanzees and several species of monkeys are susceptible to HEV infection and have served as experimental models of hepatitis E in humans (Bradley et al. 1987; Ticehurst et al. 1992; Tsarev et al. 1993a). In addition, swine, rats, and possibly other mammalian species may support replication of the virus as discussed above. The most reliable experimental animal models have been the rhesus and cynomolgus macaques, and much of our understanding of the pathogenesis of this disease is derived from experimental infections of these animals. Following intravenous inoculation of cynomolgus macaques, there is an incubation period of 2–6 weeks, which precedes the development of raised liver enzymes (Figure 9). During this period there are viremia and fecal excretion of virus, reflecting replication of virus within hepatocytes. Antibodies to HEV develop just before elevations of liver enzymes, coincident with resolution of the viremia and fecal virus shedding and reductions in the quantity of viral antigen present in the liver. A biphasic pattern of liver disease has been observed in some animals, the initial period of enzyme elevation occurring within the first 2 weeks after inoculation. Pathological changes in the liver are consistent with acute viral hepatitis (Longer et al. 1993), but not specific for any etiological agent, and include hepatocyte necrosis and inflammatory cell infiltration. In general, the overall pattern and severity of disease do not seem to be as dramatic as in humans. Although limited evidence supports the theory of replication of the virus within the gastrointestinal tract of swine, an inoculum containing $10^{6.8}$ infectious units by intravenous inocula-

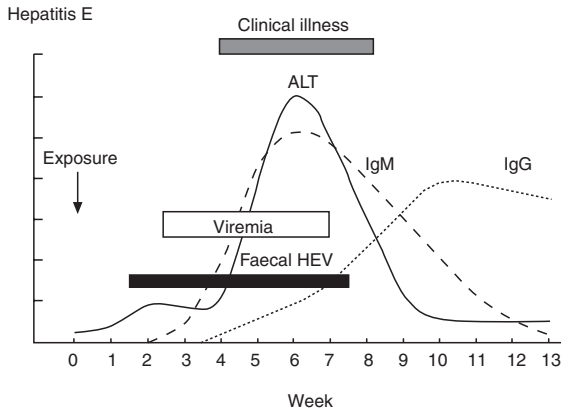

Figure 9 *Typical course of virological and pathological events during infection with HEV.*

tion failed to initiate infection when administered orally to macaques (Tsarev et al. 1994b).

There are few data about virological events in infected humans. In one of two reported human volunteer infections, raised liver enzymes and jaundice persisted for 3 months (Chauhan et al. 1993). Viremia was first detected at day 22, and terminated at day 46 when liver enzymes reached their peak value. Antibodies against HEV were first detected at day 41; their appearance was followed by declining levels of liver enzyme. Excretion of virus in stool samples was detected by RT-PCR between 30 and 50 days after ingestion. Disease was limited to a 1 month period in the other reported experimental human infection (Balayan et al. 1983). Examination of liver specimens from patients involved in outbreaks of disease attributed to HEV in Delhi, the Kashmir and (putatively) Ghana have revealed two general types of histopathological change (Gupta and Smetana 1955; Morrow et al. 1968; Khuroo 1980). A cholestatic pattern is characterized by prominent bile stasis within canaliculi and a unique glandlike transformation of parenchymal cells. There is portal and, to a lesser extent, parenchymal infiltration of lymphocytes and polymorphonuclear leucocytes. A second histopathological pattern is similar to that found in other types of acute hepatitis, and includes ballooning degeneration of hepatocytes and formation of acidophilic bodies.

IMMUNE RESPONSE TO HEV INFECTION

Antibodies to HEV develop during convalescence from the disease and are reactive with both linear and conformational epitopes of the virus. A wide variety of assays has been developed for detection of these antibodies, including various ELISAs using recombinant proteins (Goldsmith et al. 1992; He et al. 1993; Tsarev et al. 1993b) or combinations of peptides and recombinant antigens (Sallie et al. 1992; Paul et al. 1994) as antigen synthetic peptides (Coursaget et al. 1994; Favorov et al. 1994). In addition, immunoblot assays have been developed using recombinant antigens (Favorov et al. 1992; Li et al. 1994). These assays seem to vary considerably in their sensitivity and specificity, with relatively low overall concordance between results in a recent collaborative study. Synthetic peptides representing linear epitopes within the protein products of all three ORFs seem to react with serum from infected individuals (Kaur et al. 1992; Favorov et al. 1994), but peptide-based assays performed poorly over all against a reference panel of anti-HEV serum. A baculovirus-expressed, nearly complete ORF2 product forms viruslike particles and is a superior antigen because it displays conformation-dependent epitopes (Tsarev et al. 1993b). The early antibody response to this antigen includes both IgM and IgG antibodies to the virus (Tsarev et al. 1993b, 1994a), although the IgM response is variable. Antibody to the ORF2 protein was detectable in immunoblots for more than 12 months after infection, whereas antibody to ORF3 disappeared following resolution of the disease (Li et al. 1994). Nothing is known of the cellular immune responses, and there is controversy regarding the longevity of natural immunity after infection with HEV (Bryan et al. 1994; Arankalle et al. 1995). A number of early studies (Paul et al. 1994; Dawson et al. 1992; Mast et al. 1997) suggested that a measurable proportion of the population within nonendemic regions had evidence of antibodies to HEV (1.2–13 percent). Subsequent seroprevalence studies have revealed that individuals who are exposed to pigs in an occupational setting (farm workers, veterinarians) are more likely to be anti-HEV positive than a control population unexposed to pigs (Drobeniuc et al. 2001; Meng et al. 2002); likewise individuals who have increased exposure to rats have increased seropositivity against HEV (Smith et al. 2002).

CLINICAL MANIFESTATIONS OF HEPATITIS E

HEV, like HAV, causes an acute, self-limited disease that does not progress to a chronic phase. As shown in Figure 9, the incubation period is somewhat longer than that for HAV, averaging ca. 40 days. The prodromal symptoms of infection are similar to hepatitis A, including malaise, anorexia, and abdominal discomfort. A 15–20 percent case-fatality rate has been observed among women who become infected during the third trimester of pregnancy (Khuroo et al. 1981), although the clinical features of fatal disease are not well described. Fulminant disease also occurs in other settings. About 60 percent of sporadic cases of fulminant hepatitis in India are due to HEV infection (Nanda et al. 1994). The much less frequent involvement of HEV in fulminant hepatitis in developed countries (Liang et al. 1993; Sallie et al. 1994) reflects the rarity of the infection in these regions.

DIAGNOSIS

Serological diagnosis of acute infection is relatively straightforward with the assays currently available.

Detection of IgG anti-HEV in the absence of markers of other types of acute viral hepatitis is generally indicative of HEV infection. Tests for IgM antibodies have marginal sensitivity and are therefore of limited usefulness. In the past, lack of standardization and poor concordance between peptide based and recombinant ORF2 based assays for IgG anti-HEV severely limited their usefulness in population-based studies and epidemiological investigations. However, it is currently accepted that assays using the recombinant ORF2 antigen most clearly indicate evidence of infection in humans and other species.

Epidemiology of HEV

The earliest documented outbreak of hepatitis E occurred in Delhi, India, in 1955, after heavy flooding of the Yamuna River (Viswanathan 1957). Subsequent outbreaks of disease and sporadic cases of hepatitis E have been confirmed in a wide variety of tropical and developing regions, including India, China, Nepal, Pakistan, Myanmar, Indonesia, the Central Asian region of the former Soviet Union, Egypt, Ethiopia, Jordan, Algeria, the Ivory Coast, Chad, Sudan, Somalia, Ethiopia, and Mexico. In most outbreaks, contaminated drinking water has been incriminated as the source of infection. However, sporadic cases of hepatitis E also occur in these regions (Hyams et al. 1992a, b; Bile et al. 1994), suggesting that the virus is endemic. Clinically apparent hepatitis E generally occurs in individuals 25–40 years of age (Bradley 1992; Jameel et al. 1992), and the mean age at infection with HEV seems to differ markedly from the mean age of infection with HAV in regions that are endemic for both viruses. Surveys of sera collected over an interval of 10 years from an HEV-endemic region of India demonstrated that most HAV infections occurred before the age of 5 years, whereas HEV infections generally occurred after the age of 16 years (Arankalle et al. 1995). The reason for this difference is not known; serologically determined rates of infection are similar in children and adults during disease outbreaks, although adults are more likely to develop clinical evidence of hepatitis (Mast et al. 1993). Hepatitis E is an extraordinarily rare disease in the USA and Europe, although seroprevalence studies with currently available assays indicate that limited exposure to HEV or a closely related virus may indeed occur. In these regions of the world, almost all reported cases have been in travelers who have recently returned from endemic regions.

The apparent low level, endemic circulation of the virus in some regions contrasts with the fact that person-to-person transmission of HEV is unusual during epidemics (Mast et al. 1993; Aggarwal and Naik 1994). The recent data indicating markers of HEV infection in multiple animal species (pigs, deer, boar, rats, macaques) suggests that this family of viruses is ubiquitous in many parts of the world. This has led to speculation that HEV may represent a zoonotic pathogen, confined to its ecological niche until adverse circumstances, such as flooding, result in fecal contamination of the water supply (Bile et al. 1994). Another possibility is that certain individuals may shed virus for extended periods and thereby serve as reservoirs of infection (Nanda et al. 1995).

Control of hepatitis E

As with HAV, primary prevention of HEV infection rests with the provision of safe drinking water and the sanitary disposal of human waste (Bile et al. 1994), but most cases of hepatitis E occur in regions of the world where these conditions are difficult to achieve. Data concerning the protective efficacy of IG are limited and difficult to interpret (Joshi et al. 1985; Khuroo and Dar 1992). However, it is likely that anti-HEV is not present in significant titers in IG prepared from plasma collected in well developed, industrialized countries. Passive immunoprophylaxis of nonhuman primates with hyperimmune globulin has prevented biochemical and histological evidence of hepatitis although it did not prevent infection (Tsarev et al. 1994a). Both viremia and fecal virus excretion were documented in animals receiving hyperimmune globulin.

Because HEV cannot be propagated efficiently in cell culture, vaccine development has focused on recombinant immunogens. Preliminary studies suggested that immunization of cynomolgus monkeys with a recombinant, partial ORF2 protein product may have provided protection against disease, but not virus replication following challenge with a heterologous inoculum (Purdy et al. 1993). Subsequent studies have revealed that the partial recombinant ORF2 product with a molecular weight of 53 kd provides protection against disease (Tsarev et al. 1994a; Zhang et al. 2001a, 2002; Purcell et al. 2003), but not necessarily infection (depending upon the titer of the challenge inoculum) (Tsarev et al. 1997). These data are encouraging for the development of a vaccine.

INTRODUCTION

Since its discovery 15 years ago (Choo et al. 1989; Kuo et al. 1989), hepatitis C virus (HCV) has been the subject of intense research and clinical investigations as its major role in human disease emerged. Globally, HCV is estimated to infect 170 million people, 3 percent of the world's population, and creates a huge disease burden from chronic progressive liver disease. HCV has become a major cause of liver cancer and one of the most common indication for liver transplantation (reviewed in Pawlotsky (2003b), Hoofnagle (2002), and Seeff (2002)). HCV infection can be treated, but currently requires long-term medical support and follow up; current therapies are impractical for the majority of HCV carriers worldwide. The development of a protective vaccine remains a distant prospect.

Discovery of HCV

The discovery of HCV in 1989 was the dramatic end to a major research endeavor to find the causes of post-transfusion hepatitis. In the 1970s, several groups produced evidence for an infectious agent, distinct from the hepatitis A virus (HAV) and hepatitis B virus (HBV), that caused chronic hepatitis and was frequently transmitted by blood and blood products (Prince et al. 1974; Feinstone et al. 1975; Alter et al. 1975). Typically, non-A, non-B hepatitis (NANBH) was a mild disease that caused jaundice in fewer than half of cases, and was frequently asymptomatic. In its clinical features, it differed in several respects from acute HAV and HBV infection with a longer incubation period from exposure to liver function abnormalities, around 8 weeks, than is usually observed for HAV (4 weeks), but shorter than that for HBV (12 weeks). There was a high rate of chronicity following acute infection (at least 50 percent of cases, compared with around 5 percent for adult HBV infection). While chronic infection was almost invariably asymptomatic at first, a large proportion of cases eventually progressed to cirrhosis.

Progress towards identifying the cause of NANBH was hampered by the difficulty in culturing the agent in cell or organ culture, and the eventual characterization of the infectious agent of NANBH was made possible after the successful transmission of the agent into chimpanzees. Experimental data were then obtained that the agent passed through a 80-nm filter and was inactivated by lipid solvents such as chloroform; together these data suggested a small enveloped virus. Examination of liver biopsies from patients with NANBH and of experimentally infected chimpanzees helped to define the histologic features of acute and chronic disease and to differentiate it from other causes of hepatitis. Passaging and titration of the NANBH agent in chimpanzees eventually provided high titer stocks of virus that were necessary for the eventual cloning and sequence analysis of the infectious agent (Bradley et al. 1979; Bradley and Maynard 1986).

Nucleic acid (both DNA and RNA) was extracted following ultracentrifugation from a large volume of a

plasma sample with a high infectivity titer in chimpanzees (approximately 10^6 infectious units/ml). The nucleic acid was reverse-transcribed and the resulting DNA fragments cloned into the λ-gt11 bacteriophage. The DNA sequences in the resulting library were expressed as fusion proteins during replication of the bacteriophage in *Escherichia coli*. Immunoscreening of large numbers of bacteriophage plaques with antisera from patients with NANBH led to the eventual identification of an immunoreactive clone (designated 5-1-1) that appeared to be specific for the NANBH agent (Choo et al. 1989). This clone showed no similarity with any human or *E. coli* genomic sequences and produced a protein that was consistently recognized by sera from patients with NANBH, but not by sera from control individuals, or those with hepatitis of other etiologies (Kuo et al. 1989).

The 5-1-1 clone was then used as a probe to identify overlapping sequences in the λgt-11 library and this led to the assembly of a nearly complete nucleotide sequence of the NANBH agent (Choo et al. 1991). Knowledge of the length, nucleic acid composition, and genome organization of HCV has led to its classification in the *Flaviviridae* family (see Relationship of HCV to other flaviviruses) and its method of replication (see Replication of the HCV genome). From the sequence of HCV it was possible to design hybridization probes and primers for amplification of the HCV genome by polymerase chain reaction (PCR) that can be used to detect HCV RNA in sera and liver biopsies from hepatitis patients (see Diagnostic tests for HCV infection). The original 5-1-1 clone, together with an overlapping clone, c100-3, and more recently with clones from other parts of the genome, has been used to manufacture recombinant proteins for assays for antibody to HCV. This has enabled effective screening of blood donors for HCV infection to be adopted worldwide.

RELATIONSHIP OF HCV TO OTHER VIRUSES

Relationship to positive-strand RNA viruses

The sequence of the HCV genome shares several features with other positive-strand RNA viruses. Most striking is the existence of a single continuous open reading frame that occupies almost the entire genome. After translation, this is cleaved into individual proteins that are enzymes necessary for virus replication or are structural components of the virion (Figure 1). In overall genome organization and likely method of replication, HCV is most similar to members of the *Flaviviridae*, and indeed the roles of the different proteins encoded by HCV have been inferred by comparison with homologues in other flaviviruses. Although there is still no suitable method developed for the in vitro culture of HCV, expression of cloned HCV sequences in prokaryotic and eukaryotic systems, and the recently developed replicon has also allowed the replication functions of several nonstructural proteins of HCV to be identified (Figure 1) (described in detail below in the section Nonstructural proteins).

Other members of the *Flaviviridae* have many features in common with HCV. They have a similar genome size to HCV (YFV: 10 862 bases (Rice et al. 1985), compared with 9 379 of HCV (Choo et al. 1991)), and the virus envelope contains a viral encoded glycoprotein (E1). However, the homologue of HCV E2 in flaviviruses (also a membrane-bound glycoprotein: NS1) is not incorporated into the virion, being expressed only on the infected cell surface. Like HCV, the polyprotein of flaviviruses is cleaved by a combination of viral and host-cell proteases. Although there is no close sequence similarity between HCV and other flaviviruses, there are at least two regions with conserved amino acid residues that demonstrate enzymatic functions. The NS5B protein of HCV contains the GDD (glycine–aspartate–aspartate) motif that forms part of the active site in virus RNA-dependent RNA polymerases (RdRp) of positive-strand RNA viruses (Miller and Purcell 1990; Koonin 1991). Similarly, the NS3 protein contains domains associated with helicase and serine protease activity (Miller and Purcell 1990) (see Nonstructural proteins).

Shared features of HCV with pestiviruses

An important difference between members of the *Flaviviridae* is the structure of the 5′ and 3′ untranslated regions (UTR). These parts of the genome are involved in replication (see below), and in the initiation of translation of the virus genome by cellular ribosomes. Both pestiviruses and HCV have highly structured 5′ UTRs, in which internal base-pairing produces a complex set of stem–loop structures that interact with various host-cell and virus proteins during replication and translation (Smith et al. 1995; Tsukiyama Kohara et al. 1992; Wang et al. 1994; Poole et al. 1995). In both viruses, there is evidence for internal initiation of translation, in which binding to the host-cell ribosome directs translation to an internal methionine (AUG) codon (see HCV translation). This contrasts strongly with translation of flavivirus genomes which act much like cellular mRNAs, in which ribosomal binding occurs at the capped 5′ end of the RNA, followed by scanning of the sequence in the 5′ to 3′ direction with translation commencing at the first AUG codon.

Structurally, HCV is also more similar to the pestiviruses than flaviviruses, with a low buoyant density in sucrose (see Physicochemical properties), similar to that reported for pestiviruses and attributable in both cases

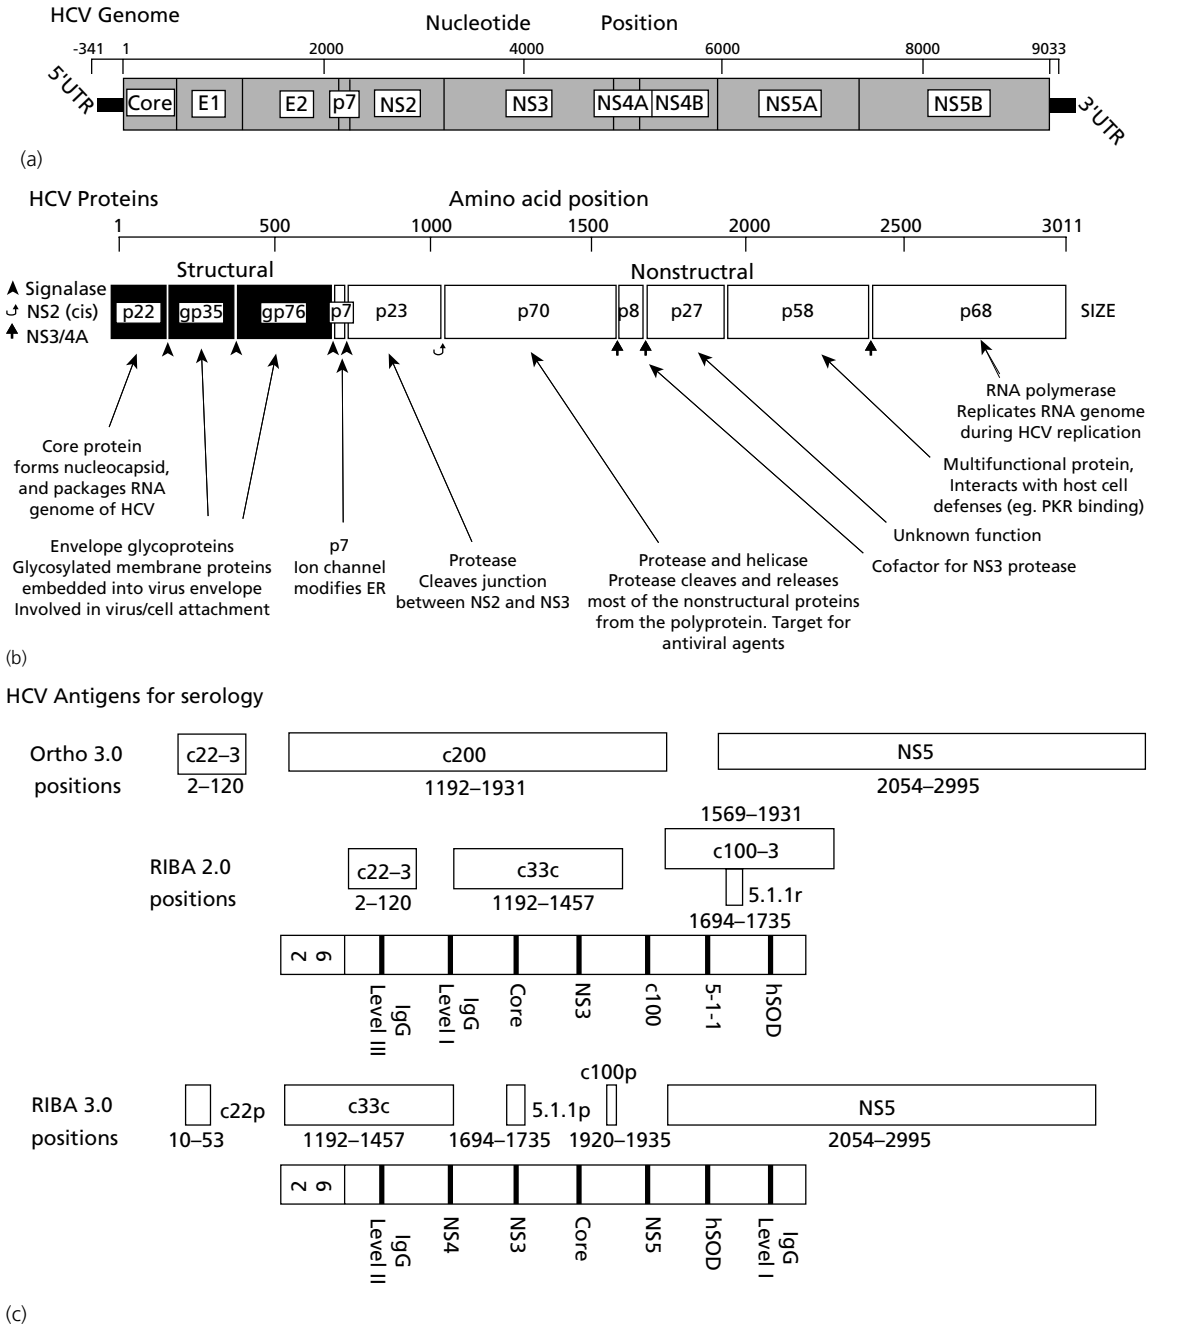

Figure 1 *Organization of HCV genome.* **(a)** *The coding sequences from structural and nonstructural proteins, and the 5′ and 3′ untranslated regions.* **(b)** *The sizes and summaries of functional properties of the mature proteins cleaved from the translated polyprotein, with the positions and enzymes responsible for the cleavage reaction indicated.* **(c)** *Regions of the genome expressed as recombinant antigens for serological assays. Nucleotide and amino acid positions numbered as in Choo et al. (1991).*

to extensively glycosylated proteins in the virus envelope. By contrast, flavivirus envelope glycoproteins contain few sites for *N*-linked glycosylation, and the virion itself is relatively dense (1.2 g/cm^3). Finally, the arrangement and number of cleavage sites of the HCV polyprotein is more similar to pestiviruses, particularly in the cleavage of NS5 into two subunits, with NS5B corresponding to the RNA polymerase.

Relationship of HCV to other flaviviruses

Shortly after the discovery of HCV, a number of new flaviviruses was found to infect humans, old and new world primate species. The most closely related virus to HCV was GB virus B (GBV-B), found to cause acute, resolving infections in captive tamarins (*Sanguinis* spp.),

which had been inoculated with a transmissible agent originally passaged from a plasma sample from a surgeon who had developed a hepatitis of unknown etiology (Simons et al. 1995). Remarkably, tamarins exposed to this in vitro passaged material were also found to be infected with a second, largely unrelated flavivirus, described as GB virus A (GBV-A). While a range of wild caught South American primate species show frequent evidence for infection with species-specific variants of GBV-A (Leary et al. 1997; Erker et al. 1998; Bukh and Apgar 1997), current surveys had not provided clear evidence for either active or past infection with GBV-B in New World primates, and its origin in the passaged material is therefore currently unclear. What has become apparent is that neither virus infected the human whose plasma originated the passaged material (both GBV-A and GBV-B were probably picked up at some point during passage through a number of different New World primate species), and they therefore do not represent human viruses. However, with knowledge of the sequences of GBV-A, it has proved possible to detect viruses distantly related to GBV-A found in humans and chimpanzees; two groups independently but simultaneously discovered in 1995 the human homolog, described as hepatitis G virus (HGV) or GB virus-C (Leary et al. 1996; Linnen et al. 1996). Shortly afterwards, a virus related to HGV/GBV-C was found to be widely distributed in chimpanzees (Adams et al. 1998; Birkenmeyer et al. 1998).

The evolutionary relatedness of HCV, GBV-B, GBV-A, HGV/GBV-C, and other flaviviruses can be shown by comparison of a region of the highly conserved RdRp (Figure 2). Flaviviruses fall into four distinct genetic groups, corresponding to (1) HCV; (2) pestiviruses; (3) an expanded group of tick and mosquito-borne viruses and nonvector-transmitted viruses infecting rodents; and finally (4) HGV/GBV-C and GBV-A. The affiliation of GBV-B remains somewhat uncertain, although most methods of phylogenetic analysis place it within the HCV group, and it resembles HCV more closely than other flaviviruses in genome structure. Using both phylogenetic information and comparisons of genome organization, the International Committee on the Taxonomy of Viruses (ICTV) has now formally classified these genetic groups into three named genera, the flaviviruses, the pestiviruses, and the hepaciviruses (containing HCV and GBV-B), and a fourth, currently unnamed and provisional genus that contains HGV/GBV-C, GBV-A, and other primate homologues (Thiel et al. 2000).

PROPERTIES OF THE VIRUS

Genome

The genome of HCV is single-stranded RNA of positive (protein coding) polarity. As with other positive-strand

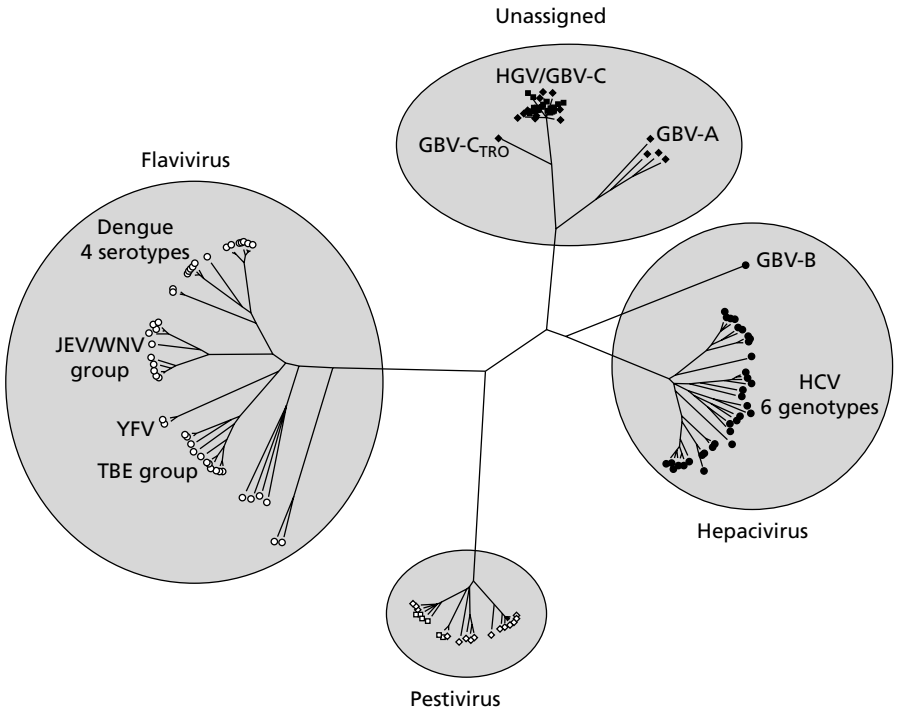

Figure 2 *Genera within the family* Flaviviridae. *Phylogenetic analysis of a conserved region of the RNA polymerase gene of flaviviruses reveals four well-defined genetic groups. These correspond to three of the current classified genera of flaviviruses, while the fourth group contains the currently unassigned HGV/GBV-C viruses and homologues in New World primates.*

RNA viruses, genomic RNA of HCV is infectious on experimental inoculation into chimpanzees (Yanagi et al. 1997). More than 98 percent of the HCV genome codes for virus proteins (9 033 of 9 397 bases of the HCV-PT genome (Choo et al. 1991)), with noncoding regions at both 5′ and 3′ ends. The 5′ UTR is 341–344 bases long, with no evidence for chemical modification of the ends, such as capping with a methyl^{7}guanosine residue as found in members of the genus *Flavivirus* and in eukaryotic mRNAs.

The 3′ untranslated region contains three domains, 25–30 poorly conserved nucleotides. a homopolymeric region comprising mainly uridine/cytosine residues, and finally, a highly conserved 'X-region' that forms a stable RNA structure comprising three juxtaposed stem–loops. There is no evidence for any covalent modifications to the genomic RNA of HCV.

Morphology

HCV remains difficult to visualize by electron microscopy. Without an efficient in vitro culture system for HCV, most attempts at visualization have used negative-staining of HCV of high titer plasma (Figure 3). In the example shown (Kaito et al. 1994), HCV forms viruslike particles of diameter 55–65 nm (Figure 3) with 6-nm spikelike projections that may correspond to the envelope glycoproteins on the virion surface. The envelope glycoproteins of HCV show several potential sites for *N*-linked glycosylation (four sites in E1, 11 sites in E2) and it is likely that the addition of relatively large carbohydrate groups contribute structurally to the outer surface of the virion, and influences the ability of antibody to neutralize infectivity.

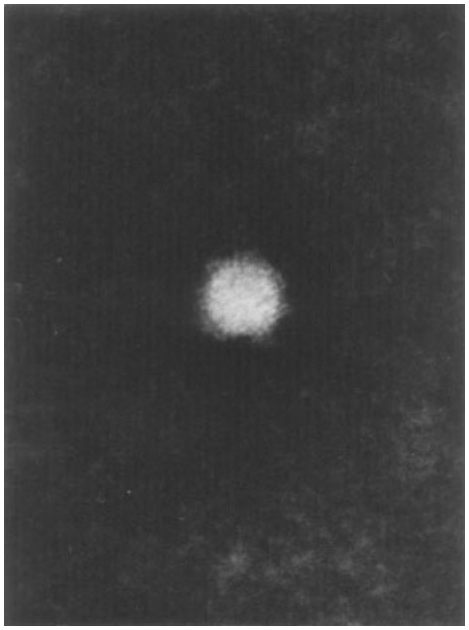

Figure 3 *Morphology of HCV virions. Visualization of an isolated virus particle of HCV by surface staining using 2 percent phosphotungstic acid, pH 6.5 (Kaito et al. 1994). Fine spikelike projections can be seen around the edge of the virus particle of approximate measured diameter of 60 nm. This figure was kindly provided by the authors.*

Physicochemical properties

The density of HCV is difficult to measure accurately because of its binding to various factors in plasma (the only available source of virion particles to study). For example, it associates to a variable extent with β-lipoprotein that reduces its density (Bradley et al. 1991; Thomssen et al. 1992). In samples from seropositive individuals, it may also be immune complexed with antibody creating a second density band of up to 1.20–1.25 g/cm^3 (Bradley et al. 1991; Miyamoto et al. 1992; Hijikata et al. 1993b; Carrick et al. 1992).

HCV is inactivated by exposure to chloroform, ether, and other organic solvents and by detergents. It is inactivated by dry heat treatment at 80°C or wet-heat treatment at 60°C, organic solvents (n-heptane) and detergents used in the manufacture of plasma-derived blood products (Mannucci 1993).

REPLICATION OF HCV

Culture of HCV in vitro

Despite considerable efforts, little progress has yet been made towards the development of a system for the culture of HCV in vitro. HCV does not produce obvious cytopathology, and the amounts of HCV released from cells infected in vitro are often low (Shimizu et al. 1992, 1993; Carloni et al. 1993; Shimizu and Yoshikura 1994; Kato et al. 1995). This may be because the cells used for culture are not representative of those infected in vivo, or because productive infection requires a combination of cytokines and growth factors found in the liver that is not reproduced in cell culture.

Transfection of full length DNA sequences of the HCV genome might be expected to initiate the full replicative cycle of HCV, as it does when similar experiments are carried out with picornavirus sequences. However, while HCV proteins are translated and can be processed into structural and nonstructural proteins, there is no evidence for replication of genomic RNA, nor the assembly of virion particles. Despite considerable efforts, the reason for this block is still not understood, and has led to alternative strategies to study the HCV replication cycle. Of these, the most successful has been the development of subgenomic or full-length genomic replicons of HCV (Lohmann et al. 1999; Ikeda et al. 2002; Blight et al. 2003; Pietschmann et al. 2002). The original clone

was constructed as a dicistronic vector containing the nonstructural genes (NS3–NS5B) and the 3′ UTR from a genotype 1b clone whose expression was driven by a powerful IRES from encephalomyocarditis virus (EMCV). Upstream was a selectable marker (*neo*) and a 5′ terminus comprising the HCV 5′ UTR (Lohmann et al. 1999). Under neomycin selection, this replicon replicates at selfsustaining levels, although this is limited to specific cell lines such as certain clones of the Huh-7 hepatoma cell line. Replication is enhanced by the appearance of a number of 'adaptive' amino acid changes in the NS3 and NS5B regions (Bartenschlager et al. 2003), even though these play no role in natural infections and actually attenuate replication in experimentally infected chimpanzees (Bukh et al. 2002).

Since this pioneering work was carried out, several groups have developed replicons based on other genotype 1b isolates (Ikeda et al. 2002) and other genotypes (e.g. 1a, 2a; (Blight et al. 2003; Kato et al. 2003)). It is also possible to create viable replicons containing the structural proteins (Pietschmann et al. 2002; Blight et al. 2003), even though these still require selection and do not generate infectious viral particles. Clearly much remains to be discovered about the cell line restrictions, the requirement for 'adaptive,' nonphysiological sequence changes, and the underlying reasons why infectious virus does not appear to be produced in any of the available systems. Nevertheless replicons are useful in studying many aspects of the replication of HCV genomic RNA; they are also increasingly used to discover more about the mode of action of interferons used for human therapy (see Antiviral treatment), and the action and development of resistance to other antiviral agents, such as protease and RNA polymerase inhibitors (Blight et al. 2000; Frese et al. 2001; Lanford et al. 2003; Wang et al. 2003; Lu et al. 2004).

Animal models

The chimpanzee is the only animal model for HCV with demonstrated susceptibility to HCV infection, and which show a course of infection resembling that in humans. In particular, exposed chimpanzees may become persistently infected, with incubation periods, seroconversion profiles, and elevation of liver enzymes (such as alanine aminotransferase) broadly similar to that of human infections. Unfortunately, the later events in HCV infection in humans, such as the development of cirrhosis and hepatocellular carcinoma typically occurring over periods of 20–30 years, make it difficult to conduct natural history studies of the main disease outcomes of HCV infection in chimpanzees (Walker 1997).

One frequently observed difference between humans and chimpanzees lies in the immune response to infection. Inoculated chimpanzees generally show a delayed, weaker, and less broadly reactive antibody response to infection (Choo et al. 1994), while the appearance of strong T-cell responses is associated with clearance of infection (Cooper et al. 1999). These differences complicate the use of the chimpanzee as a model for vaccine development (see Immunization).

With the possible exception of the gorilla (for which there are few or no data available), HCV does not infect other primates in the wild (Makuwa et al. 2003), nor can they be infected experimentally (Bukh et al. 2001; Abe et al. 1993). There is, however, one report of the unexpected ability of HCV to replicate in the tupaia (Xie et al. 1998). It is not known whether the apparent species-specificity of HCV for human and higher apes is determined at the level of entry, by intracellular blocks in the replication cycle of HCV in cells of other species, or by missing cellular factors for virus assembly and release. The current problems associated with establishing HCV in a cell culture system make this issue experimentally difficult to resolve at present.

Replication of the HCV genome

In common with other positive-strand RNA viruses, HCV replicates its RNA genome through the production of a minus-strand replication intermediate, that is an RNA copy of the complete genome that is synthesized by the activity of a virus encoded RdRp (NS5B) (Figure 1). The minus-strand copy becomes the template for the generation of positive-strand copies. Because template can be transcribed several times, many minus-strand copies can be copied from the infecting positive strand, and each of these transcripts used several times to produce positive-strand progeny sequences. In this way, a single input sequence could be amplified several thousand-fold during the course of replication within a cell.

Using a highly strand-specific PCR method, antisense HCV RNA sequences have been detected in the liver of HCV-infected individuals, directly demonstrating replication of HCV via its replication intermediate (Lanford et al. 1994). Transcription initiation is dependent on possession of intact termini to the 5′ and 3′ UTRs. It has also been recently shown that replication in the replicon system requires RNA structures in the NS5B coding region (You et al. 2004; Lee et al. 2004). While the details of its role and of adjacent RNA structures in NS5B remain to be established, it is clear from other virus systems that transcription initiation and its regulation with translation are likely to be complex, and to involve multiple long-range interactions within HCV genomic RNA and with a range of cellular proteins and RNA sequences.

HCV translation

The 5′ UTR is an essential component in the initiation and regulation of translation of the large open reading

frame (ORF) of HCV. The region is between 341 and 344 bases in length, and a combination of computer analysis, nuclease mapping experiments, and studies of covariance has allowed the RNA secondary structure to be accurately predicted (Tsukiyama Kohara et al. 1992; Wang et al. 1995; Smith et al. 1995). Similar structures have been predicted for pestiviruses (Smith et al. 1995; Wang et al. 1995) and GBV-B (Grace et al. 1999) despite their frequent lack of nucleotide sequence similarities with HCV.

Evidence that the 5′ UTR can direct the internal initiation of translation was originally obtained by in vitro translation of reporter genes downstream from the 5′ UTR sequence placed in mono- or dicistronic vectors (Wang et al. 1993, 1994; Fukushi et al. 1994). The IRES activity of the 5′ UTR directs translation from the AUG methionine codon at position 341, through binding to the 40S ribosomal subunit (Pestova et al. 1998). There is no evidence for translation from any of the variable number of AUG triplets upstream from this site. As the structure of the IRES extends into the coding region, its activity is influenced by these downstream sequences. For example, the efficiency of IRES-mediated translation is inversely related to the stability of a short stem loop (designated stem–loop IV; nucleotides −12 to +12 with respect to the initiation codon) (Honda et al. 1996). It has also been demonstrated that the first 28–42 nucleotides of the core sequence must lack RNA secondary structure to allow positioning of the ribosome at the start of the coding sequence (Rijnbrand et al. 2001).

The synthesis of HCV proteins occurs through translation and cotranslational or subsequent proteolytic cleavage of the large potential polyprotein encoded by the open reading frame (Figure 1), and is intimately connected to the formation of a replication complex of HCV that remains closely associated with the endoplasmic reticulum (ER). Initial translation of the core gene leads to a protein on the cytoplasmic side of the ER with an amino terminus embedded in the ER membrane. This hydrophobic tail is subsequently cleaved to release the core protein, and directs synthesis of the E1 glycoprotein to the luminal side of the ER. A second hydrophobic region sequence embeds E1 to the ER membrane by forming a trans-membrane anchor. A second, host-cell signal peptidase (signalase)-mediated cleavage reaction separates it from E2. Signalase subsequently mediates cleavage of E2 from p7 and p7 from NS2. The remainder of the HCV proteins are produced on the cytoplasmic side of the ER. Cleavage of NS2 from NS3 is carried out autoproteolytically by a *cis*-acting zinc-dependent protease formed by the uncleaved NS2/NS3 precursor protein (Figure 1). Subsequent translation leads to the synthesis of NS3/NS4A serine protease that mediates cleavage between NS3 and NS4A in *cis*, and *trans*-cleavage of sites between NS4A and NS4Bb, between NS4B and NS5A, and between NS5A and NS5B (Figure 1).

Virus entry, uncoating, assembly, and release

Currently there is uncertainty about the nature of the cellular receptor for HCV and the mechanism by which it enters the cell. It has been found that CD81, a tetraspanin molecule that plays a role in the conformational ordering of signaling complexes, bound to the E2 protein of HCV, and that this interaction was blocked by neutralizing antibodies to HCV (Pileri et al. 1998). More recently, using a pseudotype system in which HCV envelope proteins were co-expressed with enveloped–deleted proviral clones of human immunodeficiency virus type 1 (HIV-1) to generate infectious particles, it was shown that expression of CD81 was absolutely required for infection of hepatocytes by HCV (Zhang et al. 2004). However, CD81 is widely distributed on a variety of human cell types, and does not therefore account for apparent highly specific cellular tropism of HCV for primary hepatocytes of the HCV/HIV-1 pseudotype. It is therefore likely that CD81 represents a coreceptor for HCV and that other cell surface molecules, perhaps with a liver-specific pattern of expression, are required for essential steps in HCV-binding or -fusion reactions. Of several candidate molecules, most attention has been paid to the low density lipoprotein (LDL) receptor, as its expression is restricted to the liver, and HCV purified from plasma of HCV-infected individuals is known to associate with LDL (Agnello et al. 1999; Wunschmann et al. 2000).

Replication of HCV within the cell occurs in the cytoplasm, in membrane-bound replication complexes, containing most of the nonstructural proteins of HCV and viral RNA (Lin et al. 1997; Ishido et al. 1998; Egger et al. 2002; El Hage and Luo 2003). At present, there is little information on the process of HCV virion assembly, maturation, and release from the cell, because virus particle formation is not achievable with currently used replicons of HCV, even those that express the full complement of structural proteins. However, core, E1, and E2 proteins expressed from transfected expression vectors have been shown to localize to the endoplasmic reticulum, intermediate compartment, and the *cis*-Golgi, likely representing steps in their maturation (such as glycosylation), and ultimately, particle assembly (Martire et al. 2001; Blanchard et al. 2002). There is currently no evidence for expression of HCV proteins on the surface of infected cells.

PROTEINS OF HCV

The genome of HCV is thought to encode at least ten proteins, of which three are structural (core, E1, and E2) and six nonstructural (NS2, NS3, NS4A, NS4B, NS5A, and NS5B) (Figure 1). HCV also expresses p7, a membrane-associated ion channel that may function

during virus assembly or infection. Most information about the function and enzymatic activities of the nonstructural proteins has been obtained by expression of DNA sequences corresponding to the different proteins, and by direct observations of the cellular distributions and properties of HCV proteins detected in liver or plasma in vivo.

Structural proteins

The structural proteins of HCV are encoded by sequences at the 5′ end of the genome and so are translated first (Figure 1). Expression of this part of the genome in cells (Selby et al. 1993; Ralston et al. 1993; Grakoui et al. 1993c), or in reticulocyte lysate containing microsomal membranes (Hijikata et al. 1991b; Santolini et al. 1994) leads to the synthesis of a polyprotein followed by proteolytic cleavage into the core, E1, and E2 proteins. Cleavage between the capsid protein and E1, E1 and E2, and E2 and NS2 are dependent upon the addition of microsomal membranes, implying the role of the host-cell signalase in these processing steps.

CORE

The core or capsid protein has a size of 21–22 kDa, smaller than predicted from its coding sequence of 191 amino acids, the result of cleavage of the final 17–18 amino acids post-translationally to produce the mature protein. The N terminus contains several positively charged amino acid residues, that bind to viral RNA and which are presumably involved in the virus packaging reaction. It is not known how core proteins bind together to form the HCV nucleocapsid, although nucleocapsid formation is thought to drive the budding process in the ER that leads to the formation of fully-assembled virions. It has been proposed that the core protein of HCV can be functionally divided into three domains (Hope and McLauchlan 2000): domain 1 (amino acids 1–117) forms the nucleocapsid of the virus, while domain 3 represents the final 10–12 amino acid hydrophobic leader sequence that is cleaved after translation. Domain 2 has been shown to be the region of core responsible for its targeting to lipid droplets, a process which potentially interferes with lipid metabolism within the infected hepatocyte, and which may play a role in the development of steatosis as a complication of HCV infection (Perlemuter et al. 2002). Interestingly, domain 2 is highly conserved between HCV and GBV-B, while only the capsid region (domain 1) is obviously homologous with the capsid regions of pesti- and flaviviruses (Hope et al. 2002).

ENVELOPE (E1, E2)

The envelope proteins of HCV (E1, E2) are synthesized in mammalian cells as proteins with sizes ranging from 31–35 kDa and 68–72 kDa, respectively (Hijikata et al. 1991b; Selby et al. 1993; Grakoui et al. 1993c; Ralston et al. 1993; Santolini et al. 1994). E1 and E2 are extensively glycosylated after translation at a large number of *N*-linked glycosylation sites in the extracellular domains of the proteins. Interactions between E1 and E2 have been demonstrated by immunoprecipitation experiments, in which antibody to E1 or E2 could precipitate both proteins under nondenaturing conditions (Ralston et al. 1993; Grakoui et al. 1993c; Dubuisson et al. 1994). E1 and E2 are thought to form heterodimeric structures in the virus envelope through a noncovalent interaction (Dubuisson et al. 1994; Matsuura et al. 1994; Selby et al. 1994).

The envelope proteins are likely to form the principal target of antibody-mediated neutralization of virus infectivity, although investigation of this phenomenon has been hampered by the lack of an in vitro infectivity assay, and of a suitable animal model. Recently, however, it has been possible to demonstrate neutralizing antibody responses directed at the E1 and E2 glycoproteins through the use of pseudotyped virus, comprising the envelope glycoproteins from HCV and a capsid from either HIV or a murine retrovirus (Bartosch et al. 2003; Logvinoff et al. 2004). The E2 protein contains hypervariable regions (HVR) in the N-terminal region, which evolve much more rapidly during the course of persistent infection than other regions of the genome. This variability may arise through selection of amino acid changes that allow immune escape from neutralizing antibody; persistence may therefore be accompanied by continuous virus sequence change to keep ahead of developing B-cell responses (Kumar et al. 1993; Taniguchi et al. 1993; Weiner et al. 1992; Farci et al. 2000; Kantzanou et al. 2003) (see Immune escape).

P7

The small p7 protein lies between E2 and NS2 proteins of the virus polyprotein and is thus at the junction of the structural and nonstructural gene regions (Lin et al. 1994; Mizushima et al. 1994), although it is not known whether p7 is a virion component. The 63 amino acid protein is highly hydrophobic and remains embedded in the ER membrane on translation through a transmembrane anchor of two predicted alpha helices (Carrere-Kremer et al. 2002). Recently it has been shown that p7 oligomerizes to create ion channels within membranes (Griffin et al. 2003). These pores allow transport of cations across membranes, comparable to the activity of viral viroporins, such as M2 in influenza virus. Similarly, to M2, the activity of p7 is inhibited by amantadine (Carrere-Kremer et al. 2002), an observation that suggests a new strategy to treat HCV infection. It is currently unknown at what stage in the replication cycle p7 is active or required, nor whether it is an integral component in the envelope of the mature virus particle.

Nonstructural proteins

In vitro translation of the rest of the genome leads to the production of proteins of sizes 23, 70–72, 4, 27, 56–58, and 66 kDa, corresponding to NS2, NS3, NS4A, NS4B, NS5A, and NS5B, respectively (Figure 1).

NS2

The NS2 protein is cleaved from p7 at its N terminus by ER-associated signalase. NS2 remain membrane bound, with its C terminus located through the ER membrane, and the N terminus in the cytoplasm (Santolini et al. 1995). The only function assigned to NS2 is to form one domain of a protease in combination with the first 180 amino acid residues at the N terminus of NS3 (Hijikata et al. 1993a; Grakoui et al. 1993a). This protease activity autocatalytically excises the NS2 protein from NS3 in a *cis*-cleavage reaction through a currently unclear mechanism. The dependence of the NS2/NS3 protease on Zn^{++} and its inhibition by ethylenediaminetetraacetic acid (EDTA) (that chelates divalent cations) suggests that it might be a zinc protease. However, mutation of what would be functionally cysteine and histidine amino acids in the catalytic dyad of a cysteine protease also abolished protease activity of NS2/NS3 (Hijikata et al. 1993a). The NS2 protein is widely conserved across the flavivirus family; it is possible that it plays other roles in virus replication or assembly beyond that of a self-excising protein that detaches itself from the rest of the replication complex.

NS3

The NS3 protein has a variety of enzyme activities that participate in both RNA replication and in processing of the viral polyprotein. The mature form of NS3 migrates as a protein of 67 kDa, and is generated through NS2/NS3-mediated cleavage from NS2, and NS3/NS4B-mediated cleavage from NS4A. Although not cleaved internally when expressed in mammalian cells or during virus replication, the NS3 protein can be conceptualized as comprising two independent domains with different enzymatic activities.

The first 181 amino acid residues at the N terminus of NS3 show two different protease activities. As described in the previous section, it forms part of the NS2/NS3 protease, and forms a separate, functionally distinct serine protease after cleavage (Tanji et al. 1994). The serine protease shows *cis*-acting activity in cleavage of the NS3/NS4A junction, and *trans*-activity in the cleavage of NS4A from 4B, 4B from 5A, and 5B from 5A (Eckart et al. 1993; Hijikata et al. 1993a; Grakoui et al. 1993b; Bartenschlager et al. 1993; Tomei et al. 1993). The *trans*-activity of NS3 requires NS4A as a cofactor; recent crystallographic studies have shown that NS3 and NS4A form a tightly bound protease complex (Kim et al. 1996), with extensive interactions between residues 21 and 32 of NS4A with the β-sheet of the NS3 protease core. This interaction with NS4A may chaperone or stabilize the folding of NS3 into an active conformation. The hydrophobic, predicted membrane spanning N terminus of NS4A may, in turn, anchor the protease complex to membranes and thus link it to other components of the viral replication complex. NS3 contains a structural zinc-binding site through binding with a histidine and three cysteine residues, and which supplies electrons to the catalytic site in the enzyme complex.

The substrate specificity and mechanism of action of the NS3/NS4A protease has been extensively investigated because of the possibility of developing inhibitors that could be used to treat HCV infection (see Antiviral treatment). Each of the cleavage sites in different variants of HCV conform closely to the consensus sequence D/E – X–X–X–X–C/T // S/A (where // represents the cleavage site) (Komoda et al. 1994; Kolykhalov et al. 1994; Bartenschlager et al. 1995; Leinbach et al. 1994). There is some evidence for a less stringent requirement for specific amino acids around the *cis* cleavage site (NS3/NS4A) than those cleaved in *trans* (Bartenschlager et al. 1995). Inhibitors of NS3/NS4A have now been developed that mimic the recognition sequence, and competitively inhibit the processing of the HCV polyprotein (De Francesco et al. 2003); BILN 2061 is currently in clinical trials (Lamarre et al. 2003). While the primary function of the protease domain of NS3 is processing of the HCV polyprotein, it has recently been shown that the NS3/4A protease blocks the phosphorylation and signaling function of the antiviral interferon regulatory factor 3 (Foy et al. 2003). Blocking of this cell defense pathway may contribute to the ability of HCV to persist in vivo, and to resist exogenous interferon therapy.

The much longer second enzymatic domain of NS3 shows helicase and NTPase activities. Helicases displace base-paired RNA or DNA sequences from a template strand usually in a 3′ to 5′ direction. This process requires the presence of Mg^{++} ions and energy provided by hydrolysis of ATP by a NTPase activity of the enzyme and these are combined in an energy-dependent unwinding process of template and copied RNA sequences during virus genome replication (Gwack et al. 1997; Tai et al. 1996). Several sequence motifs in NS3 (such as the DEXH box) are shared with corresponding proteins in other positive-strand RNA viruses, suggesting a degree of functional equivalence on which the HCV helicase might be modeled (Suzich et al. 1993).

NS4A

As described above, NS4A functions as part of the NS3/NS4A protease complex, with an additional role in localizing the complex to membranes. No other function of NS4A has been determined to date.

NS4B

The function of NS4B is not fully understood. After cleavage, NS4B is membrane-associated in the ER

(Hugle et al. 2001) with at least two predicted membrane-spanning domains (Hugle et al. 2001; Lundin et al. 2003), and participates in the formation of a membranous web that may act as a structural platform for HCV replication complex (Egger et al. 2002). Recently, NS4B has been shown to possess a GTPase activity that is required for replication of the HCV replicon; this finding suggests an additional enzymatic role for NS4B in the replication complex (Einav et al. 2004; Piccininni et al. 2002).

NS5A

The NS5A protein is a 56–58-kDa nonstructural protein. Although for many years after the discovery of HCV the function of NS5A was unknown, more recent research has revealed a key role for NS5A in a variety of interactions with host-cell defense mechanisms that may be associated with the ability of the virus to persist in vivo and to resist interferon therapy. On cleavage from NS4B and NS5B, NS5A is bound to the ER by the N-terminal amphipathic helix (Figure 4) and becomes associated with the viral replicase complex on the cytoplasmic side of the ER; binding to NS5B may be required for the RNA polymerase activity of the replication complex (Shimakami et al. 2004). NS5A becomes phosphorylated after translation, at one or more of several targeted serine or threonine residues at the center and C terminus of the protein. The number and position of NS5A phosphorylation sites varies between genotypes (Hirota et al. 1999; Reed et al. 1997). NS5A may additionally become hyperphosphorylated within a serine-rich region at the center of the protein (Figure 4), although this form of NS5A is not present in the replication complex, and mutations that prevent phosphorylation at positions 2 197 and 2 204 actually enhance the replication ability of the HCV replicon (see Replication of the HCV genome).

While NS5A is a necessary part of the viral replication complex, it shows a number of additional activities that are broadly aimed at combating the innate cell defenses, thus potentially contributing to the persistence of HCV and its resistance to interferon. These include the binding to and inactivation of PKR (Gale et al. 1997), blocking apoptotic pathways through sequestering p53, modulation of intracellular calcium levels, and binding to growth factor receptor-bound protein 2 (Grb-2) (Majumder et al. 2001; Gong et al. 2001; Tan et al. 1999), and induction of anti-inflammatory interleukin-8 (IL-8) secretion (Polyak et al. 2001) (recently reviewed in Macdonald and Harris 2004). Many of these interactions block the apoptotic cellular response to persistent HCV infection, while the induction of IL-8 may potentiate viral replication and inhibit intracellular IFN-responsive antiviral pathways. These different functions have been mapped to a number of different domains in the NS5A protein (Figure 4).

Interferon therapy has been shown to lead to the appearance of a number of amino acid changes in the region of NS5A that interacts with PKR (Figure 4). An association was also found between treatment response and possession of the so-called 'prototype' NS5A sequence in the region where mutations occurred (Enomoto et al. 1995). These original findings have since been confirmed in recent meta-analyses of all the available data which demonstrated a clear correlation between possession of the prototype interferon-sensitivity determining region (ISDR) sequence and treatment resistance, and a large number of diverse amino acid changes in nonresponders (Witherell and Beineke 2001; Pascu et al. 2004). It has also been shown that the same differential response exists in genotype 2a and 2b infections (Murakami et al. 1999). Prototype ISDR sequences have also been shown to be associated with higher circulating virus loads in untreated patients (Watanabe et al. 2003). It is therefore possible that PKR evasion is a key determinant in the persistence of HCV and potentially other aspects of the virus/host interaction.

NS5B

NS5B is an RNA-dependent RNA polymerase, and is responsible for the copying of the HCV genome during replication. NS5B is cleaved at its N terminus from the rest of the HCV polyprotein by the NS3/NS4A protease. NS5B remains membrane bound through a hydrophobic,

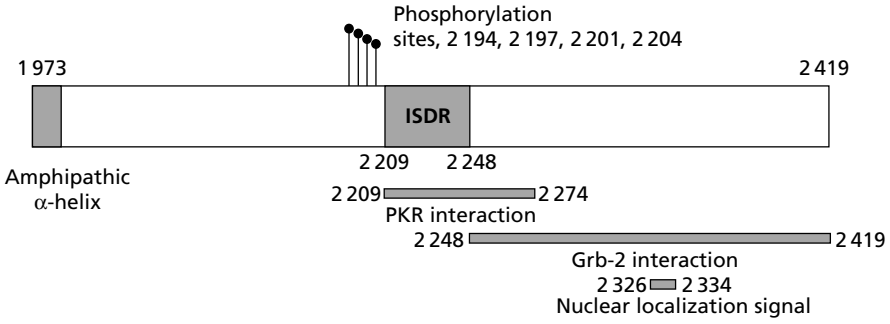

Figure 4 *Diagram of the* NS5A *gene. This shows the positions of the ER-binding amphipathic helix, the interferon-sensitivity determining region (ISDR), and regions of the protein known to interact with PKR and other cellular pathways associated with innate cell defenses against viruses. Identified sites of hyperphosphorylation found in the 58-kDa form of the protein localize to the ISDR.*

membrane-inserted anchor sequence at the carboxyl terminus of the protein. The mature form of NS5B is 68 kDa in size, is phosphorylated, and forms part of the replication complex along with other nonstructural proteins that participate in genome replication. The recently determined crystal structure (Lesburg et al. 1999) has shown NS5B to have a typical thumb/palm/finger arrangement of domains that encircle the RNA template strand, and that contains catalytic residues, such as the GDD motif characteristic of RNA polymerase of other positive-strand RNA viruses. Determining the structure of NS5B has been important for the design and optimization of activity of new classes of antiviral agents that inhibit RNA polymerase function (see Antiviral treatment). In vitro, NS5B requires a nucleic acid primer to initiate polymerization (Oh et al. 1999). The mechanism of strand initiation during genome copying is unknown, although it has recently been demonstrated that replication required one or more RNA stem–loops in the terminal NS5B region (You et al. 2004), to which NS5B directly binds (Lee et al. 2004; Cheng et al. 1999). Whether strand initiation of the opposite strand occurs through a similar mechanism, and whether there is post-transcriptional editing or modification of the newly synthesized genomic and antigenomic strands is unknown.

HCV GENETIC VARIABILITY

Nucleotide sequence variation

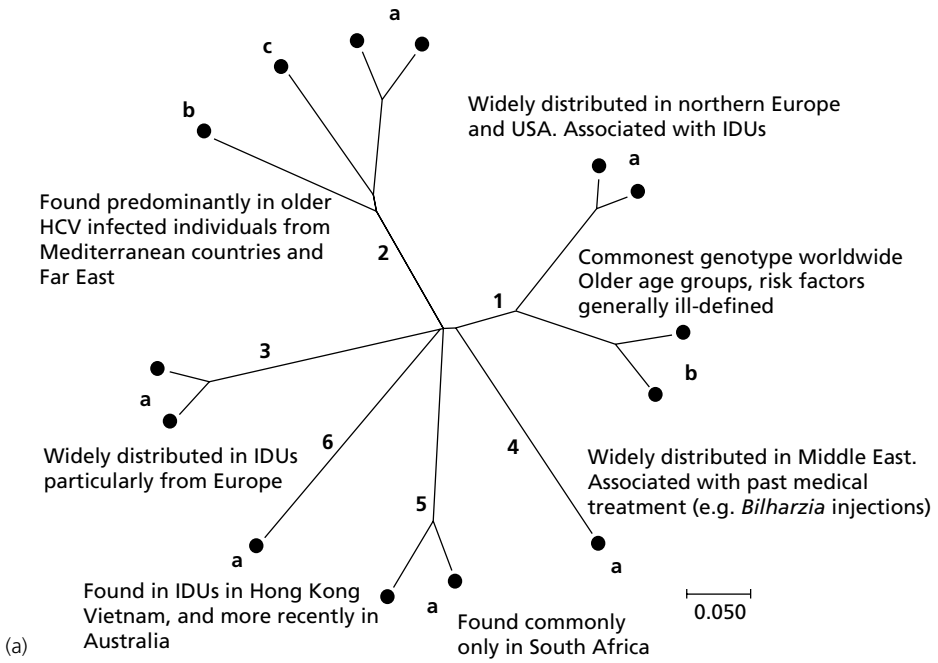
The first indication of the genetic heterogeneity of HCV came from comparisons of nucleotide sequences of HCV variants from Japan with that of the prototype HCV variant obtained from the USA, HCV-PT (Choo et al. 1991). For example, the complete genome sequences of HCV-J (Kato et al. 1990) and -BK (Takamizawa et al. 1991) from Japan showed 92 percent similarity to each other, but only 79 percent with HCV-PT. At that time, the former were referred to as the 'Japanese' type (or type II), while those from the USA (HCV-PT and -H) were classified as type I. However, far more divergent variants of HCV have since been found in Japan (Okamoto et al. 1992b, 1991) and elsewhere (Mori et al. 1992; Chan et al. 1992), leading to the adoption of an extended classification of HCV into types and subtypes.

Comparison of nucleotide sequences of variants recovered from infected individuals in different risk groups for infection and from different geographical regions has revealed the existence of six major genetic groups. Over the complete genome, these differ in 30–35 percent of nucleotide sites, with more variability concentrated in regions such as the E1 and E2 glycoproteins, while sequences of the core gene and some of the nonstructural protein genes, such as NS3, are more conserved. Least sequence variability between genotypes is found in the 5′ untranslated region, the 5′ end of the core gene and the 99 base pair X-tail in the 3′ UTR, where specific sequences and RNA secondary structures are required for replication and translation functions. Despite the sequence diversity of HCV, all genotypes share an identical complement of colinear genes of similar or identical size.

Each of the six major genetic groups of HCV contain a series of more closely related subtypes, typically different from each other by 20 percent in nucleotide sequences compared with the >30 percent between genotypes (Figure 5) (Simmonds et al. 1993a). Some, such as genotypes 1a, 1b, and 3a have become very widely distributed as a result of transmission through blood transfusion and needle sharing between infecting drug users (IDU) over the past 30–70 years, and now represent the vast majority of infections in western countries (Figure 5a) (see Geographical distribution of HCV genotypes). These are the genotypes most commonly encountered clinically, and for which most information has been collected on response to interferon and other antiviral treatments (see Biological differences between HCV genotypes).

A different pattern of sequence diversity is observed in parts of Africa and South East Asia. Here, there are close associations between genotypes and specific geographical regions (Figure 5b). For example, infections in western Africa are predominantly by genotype 2 (Jeannel et al. 1998; Mellor et al. 1995; Wansbrough Jones et al. 1998; Ruggieri et al. 1996; Candotti et al. 2003), while those in central Africa, such as the Democratic Republic of Congo (DRC) and Gabon are by genotype 1 and 4 (Bukh et al. 1993a; Fretz et al. 1995; Stuyver et al. 1993b; Menendez et al. 1999; Xu et al. 1994; Ndjomou et al. 2003; Mellor et al. 1995). In both regions, there is a remarkable diversity of subtypes; for example, 20 of 23 HCV-seropositive blood donors in Ghana (west Africa) were infected by genotype 2, but each corresponded to different and previously undescribed subtypes (Candotti et al. 2003). Similar diversity was found in Guinea, Benin, and Burkina Faso (west central Africa), where 18 different subtypes of genotypes 1 and 2 infected 41 HCV-infected individuals (Jeannel et al. 1998). These field observations reflect both the huge genetic diversity of genotypes 1, 2, and 4, and also its likely long-term presence in human populations in these parts of Africa. Taking this geographical mapping further, genotypes 3 and 6 show similar genetic diversity in south and eastern Asia (Tokita et al. 1994a, b, 1995; Mellor et al. 1995).

The model suggested by these genotype distributions is that HCV has been endemic in sub-Saharan Africa and South East Asia for a considerable time, and the occurrence of infection in western and other nontropical countries represents a relatively recent emergence of infection in new risk groups for infection (Simmonds



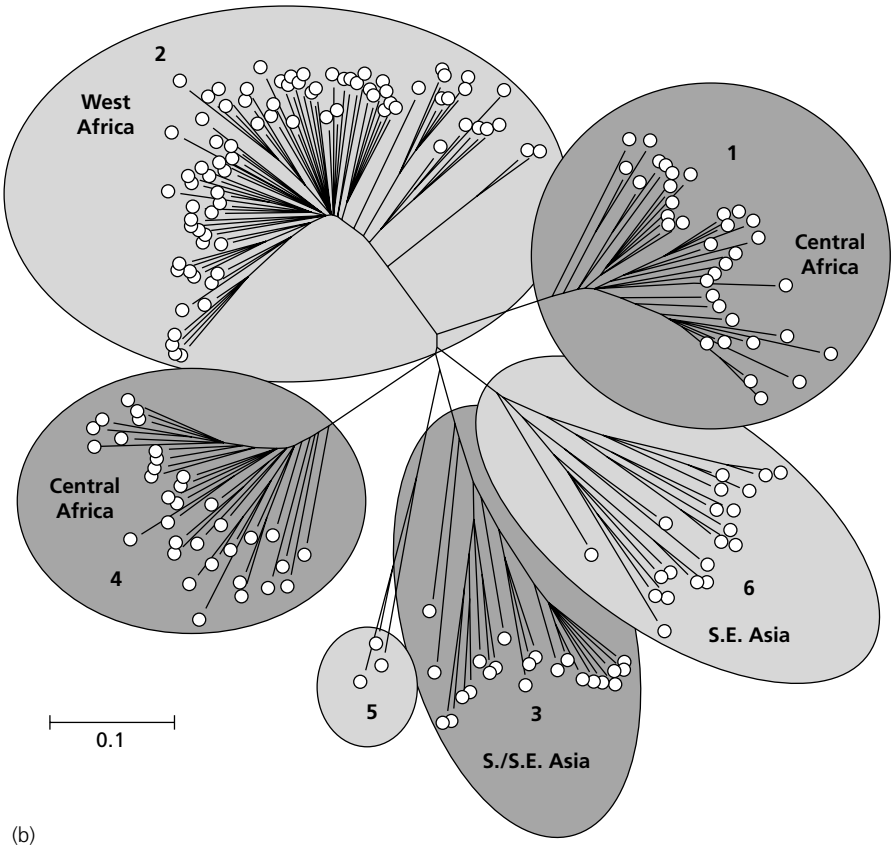


Figure 5 (a) *Evolutionary tree of the principal genotypes of HCV found in industrialized countries. Phylogenetic analysis was carried out on complete genome sequences of genotypes of HCV found in the main identified risk groups for HCV infection (IDUs, recipients of unscreened blood or blood products, other parenteral exposures). These represent the main variants believed to have become prevalent over the course of the twentieth century.* **(b)** *Evolutionary tree of all available NS5B sequences for different subtypes and genotypes HCV. This phylogenetic analysis demonstrates that HCV variants still fall into six distinct genotypes, but each contains numerous novel variants discovered in high diversity areas in sub-Saharan Africa and South East Asia. (The trees were constructed using the phylogeny program neighbor-joining implemented in the MEGA package, using Jukes-Cantor corrected distances.)*

2001; Ndjomou et al. 2003). In the twentieth century, parenteral exposure to bloodborne viruses became frequent through the widespread adoption of blood transfusion since the 1940s, the medical use of often unsterilized needles for injections and vaccinations (a practice that continues in many developing countries) and most specifically to industrialized countries, injecting drug use, and the sharing of injection equipment. These new routes for transmission plausibly account for the epidemiological and genetic evidence for recent epidemic spread of HCV over the past 50 years in Europe, Egypt, and elsewhere (Cochrane et al. 2002; Pybus et al. 2001, 2003; Ndjomou et al. 2003). However, the original routes of HCV transmission in endemic, high diversity areas are not understood, as transmission by either sexual contact or from mother to child is inefficient (Wasley and Alter 2000; Pradat and Trepo 2000; Thomas 2000), and there is little evidence historically for the widespread parenteral exposure that fueled the recent epidemic in western countries.

Nomenclature of HCV genotypes

The six main genetic groups or 'clades' of HCV have been designated as genotypes (Figure 5). Following previous proposals (Mellor et al. 1995; Mizokami et al. 1996; de Lamballerie et al., 1997), 'new' genotypes (such as 7a, 8a, 9a, and 11a) have been assigned as members of genotype 6, and genotype 10a into genotype 3. An advisory group is currently cataloging a full listing of recognized genotypes and subtypes, and resolving any inconsistencies (such as the labeling of two HCV variants with the same subtype name) for publication in 2005. The new standardized nomenclature will be adopted by public access databases that allow access to fully annotated sequences deposited on GenBank, EMBL, or DDBJ. It has also been decided not to pursue the designation of all variants within genotypes as individual subtypes. In high diversity areas such as central Africa, there may an indefinite number of 'subtypes' that would be of little value to catalog. Future assignment of subtype names will only be carried out for those where a new variant is found in three or more epidemiologically unlinked infections, thus restricting formal classification to those that are more widely distributed, and which may show specific geographical, risk group, or other epidemiological associations.

Recombination

Recombination occurs in many families of RNA viruses, its occurrence requiring both epidemiological opportunity and biological compatibility. Recombination occurs within cells infected with two or more genetically distinct variants of HCV, and thus requires both coinfection of the same individual with more than one such variant, and substantial overlaps in their geographical distributions of different genotypes to enable recombinant forms to be detected. The wide range of genotypes circulating in the main risk groups for HCV in western countries, such as 1a and 3a in IDUs, provides opportunities for recombination, as does the nature of HCV risk behavior, frequently involving multiple exposures around the time of primary infection (e.g. repeated needle-sharing with several infected individuals). Recombination may also be facilitated by the absence of protective immunity from reinfection in chronic HCV infection (Farci et al. 1992; Kao et al. 1993; Jarvis et al. 1994; Lai et al. 1994).

A convincing example of a viable, and rapidly spreading recombinant form of HCV contains structural genes from genotype 2k, a recombination point in NS2 and nonstructural genes from genotype 1b, and has been recovered from several IDUs in St Petersburg (Kalinina et al. 2002, 2004). The existence of widespread recombination would place a considerable limitation on the use of genotyping assays for HCV, as the genotype identified in the region used in the assay, such as the 5′ UTR or core gene may not correspond to the genotype of other parts of the genome which may be more relevant for determining treatment response (see Biological differences between HCV genotypes).

Biological differences between HCV genotypes

The major features of HCV structure, replication, transmission, and ability to establish persistent infection are shared between all known variants. Infection with each genotype has become widespread in human populations, and indicates that they are equally capable of maintaining infections in human populations. Despite this obvious evidence for phenotypic similarity, there is growing evidence for genotype-specific differences in persistence and interactions with innate cell defenses and the immune system that have important repercussions for current and likely future therapy.

The extensive amino acid sequence variability found in both structural and nonstructural proteins would be expected to modify profoundly immunological recognition by both antibody and T-cell receptors. For example, the envelope proteins of different genotypes differ in amino acid sequence from each other by between 34–40 and 26–29 percent for E1 and E2. By analogy, this degree of sequence variability would be sufficient to prevent neutralization of one subtype by antibody elicited by a heterologous serotype, a prediction that has been borne out in recent studies using HCV chimeras (see Replication of the HCV genome). There is also clear evidence for antigenic differences between recombinant proteins or peptides from different genotypes in enzyme-linked immunosorbent assays (McOmish et al.

1993; Simmonds et al. 1993c; Tsukiyama Kohara et al. 1993; Mondelli et al. 1994). Antigenic differences between genotypes have implications for the development of vaccines for HCV and for the optimal design of serological screening and confirmatory assays for HCV (see Diagnostic tests for HCV infection).

The most clinically apparent difference between genotypes is in their susceptibility to treatment with interferon (IFN) monotherapy or IFN/ribavirin (RBV) combination therapy. Typically, only 10–20 and 40–50 percent individuals with chronic infection with genotype 1 on monotherapy and combination therapy, respectively, exhibit complete and permanent clearance of virus infection. This long-term response rate is much lower than the 50 and 70–80 percent observed on treatment of genotype 2 or 3 infections (comprehensively reviewed in Zeuzem (2004) and Pawlotsky (2003a)). This difference has proved to be highly significant in patient management, and has led to the use of higher doses and longer durations of treatment for type 1 (and type 4) infections to achieve acceptable efficacy. In numerous multivariate analyses, genotype-specific differences in treatment response have been shown to be independent of host variables, such as stage of disease progression, age, duration of infection, sex, and HIV and other virus coinfections. It is similarly independent of virus-specific factors, such as pretreatment viral load, although this also independently correlates (inversely) with response. The underlying mechanism of these differences in response is currently unknown.

Enzymatic studies and preliminary data from clinical trials provide consistent evidence for frequent genotype-specific differences in susceptibility to recently developed protease and RNA polymerase inhibitors for HCV therapy (De Francesco et al. 2003). Antiviral agents whose modeling, screening, and optimization was based on enzymatic studies of genotype 1 protease or RNA polymerase have since been found to be poorly inhibitory against other genotypes (Holland-Staley et al. 2002). For example, the protease inhibitor, BILN 2061, showed nearly 2 logs weaker binding affinity to genotype 2 and 3 proteases than to genotype 1 (Thibeault et al. 2004). These enzymatic differences may be clinically significant; in a recent efficacy trial, nongenotype 1-infected individuals were nonresponsive or only weakly responsive to short-term treatment with the BILN 2061 protease inhibitor (Reiser 2004), in contrast to its efficacy in genotype 1 (Lamarre et al. 2003).

In contrast to the clear-cut differences between genotypes in their response to antiviral therapy, it has proven much more difficult to obtain reliable data on the differences in the natural history and pathogenicity between HCV genotypes. This is because it is difficult to obtain prospective and/or case–controlled data on the outcomes of HCV infection over the exceptionally long time over which complications of HCV infection present clinically. Biased recruitment of study cohorts towards the minority with clinically apparent disease lack the community denominator and information on durations of infection with which to estimate the time course of disease development. Longitudinal studies have shown that genotype 1 invariably appeared more likely to establish persistence, and in carriers, to be associated with more severe liver disease compared with genotypes 2 and 3 (Mazzeo et al. 2003; Yee et al. 2000; Resti et al. 2003; Franchini et al. 2001). The underlying mechanism for the greater persistence of genotype 1 infections may be related to the greater treatment resistance of this genotype (see above). Most evidence supports the hypothesis that genotype 1 is more likely to cause hepatocellular carcinoma (Di Bisceglie 1997). However, infections with genotype 3 are associated with a higher incidence of steatosis (Adinolfi et al. 2001; Rubbia-Brandt et al. 2000), thought to result from direct cytopathic damage to hepatocytes from a block in lipoprotein secretion (Serfaty et al. 2001).

CLINICAL AND PATHOLOGICAL ASPECTS

Clinical and pathological features of HCV infection

Hepatitis C infection causes an indolent and slowly progressive liver disease that is asymptomatic until the development of decompensated liver disease and, often, liver cancer. The following sections review the clinical and pathological features associated with acute and chronic hepatitis, the replication of HCV in liver and possibly at extrahepatic sites, and describes proposed mechanisms of liver damage and of persistence.

Acute hepatitis

Percutaneous exposure to HCV usually results in an asymptomatic infection (not associated with jaundice), and most people become chronic carriers of the virus (Figure 6). This contrasts strongly with the observation that few adults infected with HBV become chronically infected. The period from exposure to the development of hepatitis has been measured in a number of investigations of post-transfusional hepatitis. Most studies have reported an interval of about 8 weeks to the development of abnormal liver function tests (such as alanine aminotransferase (ALT) levels), although viremia can be detected earlier (Figure 6). Only 5 percent of individuals with acute HCV infection have symptomatic disease, although in some cases it may be severe. HCV is very rarely associated with acute fulminant hepatic failure (Wright et al. 1991; Mutimer et al. 1995a). HCV may be more likely to cause acute liver failure in the patient who is a carrier of hepatitis B and in those who acquire hepatitis B and HCV

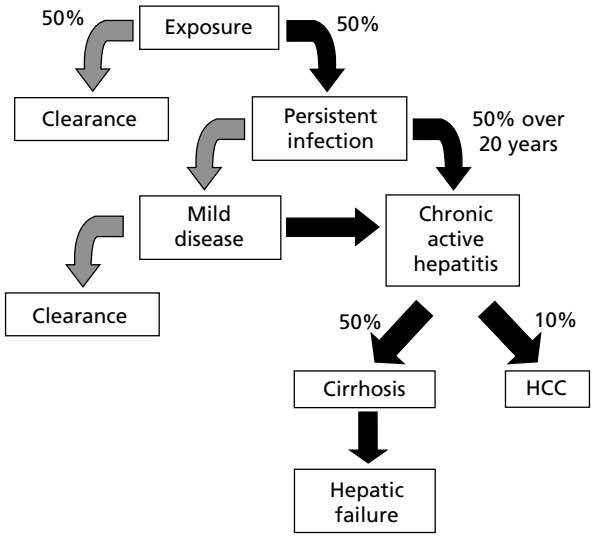

Figure 6 *Outcome of infection with HCV. Hepatitis can be detected by blood tests approximately 2 months after exposure to HCV. Most infections are asymptomatic, and a minority of patients develop jaundice. Approximately 50 percent of infected patients have persistent infection, i.e. they become HCV carriers. Of these, a proportion will progress to chronic active hepatitis, and may eventually progress to cirrhosis or hepatocellular carcinoma. The frequencies of the various outcomes are provided only as a very approximate guide, and are greatly influenced by host (particularly patient age) and viral factors (such as infecting genotype).*

simultaneously. Clinically, hepatitis caused by HCV is indistinguishable from that caused by other hepatitis viruses; jaundice may develop, but more usually symptoms are nonspecific such as fatigue, anorexia, and nausea. Most HCV-infected individuals cannot recall a history of jaundice, and HCV accounts for a small proportion of clinically apparent hepatitis cases in the community.

Viremia can be detected by PCR in the early stages of acute hepatitis, appearing at the same time or slightly earlier than abnormal levels of ALT (Figure 7). In contrast, seroconversion for antibody may be delayed for several weeks or months after the onset of hepatitis (Lelie et al. 1992), although second- and third-generation assays have closed this 'window' period to some extent. Nevertheless, reliable identification of HCV as a cause of acute hepatitis depends on the use of PCR, in contrast to acute HAV infection where IgM is generally detectable at the onset of clinical hepatitis. Histological features of acute HCV are similar to those associated with acute HAV and HBV infection; liver biopsy is rarely indicated to make a diagnosis of acute HCV infection.

Chronic hepatitis

The frequency of chronic infection following exposure to HCV is high, although there are difficulties in estimating a precise figure. For example, HCV may be identified more frequently in those with symptomatic primary infection or those with post-transfusion hepatitis (Kiyosawa et al. 1990; Gilletterver et al. 1995), both of which may be associated with an increased likelihood of chronic infection (Gordon et al. 1993; Mutimer et al. 1995b).

Individuals infected through blood transfusion and hemophiliacs, many of whom have been repeatedly exposed to HCV through the use of nonvirally inactivated clotting factor concentrates, have a high rate of persistent infection associated with active liver disease (60–80 percent). In contrast, lower rates of chronic infection and more slowly progressive disease are observed in individuals with lesser exposure to HCV. For example, only 50 percent of women exposed to a particular batch of anti-D immunoglobulin had persistent infection (Meisel et al. 1995), whereas in a similar outbreak in Ireland, also associated with the use of anti-D (Power et al. 1994), viremia was detected by PCR in only 50 percent of people remaining seropositive 17 years after exposure. Given the tendency for antibody to become undetectable following clearance of viremia, the true frequency of persistent infection in these two cohorts may be even lower.

Persistent infection with HCV is generally associated with persistent and progressive hepatitis. Chronically infected individuals generally have fluctuating or continuously abnormal levels of ALT and are viremic. However, it has been difficult to establish a correlation between the level of viremia and the severity of liver disease. For example, HCV RNA levels in asymptomatic blood donors are similar to those found in patients treated for liver disease (Smith et al. 1996; Lau et al. 1995a). Moreover, several studies have failed to document any association between the degree of viremia and level of ALT or other biochemical abnormalities associated with hepatitis.

Histological features

HCV infection causes a range of characteristic histological changes in the liver, although none allows a specific diagnosis of HCV infection to be made. The most striking feature of HCV infection of the liver is the presence of lymphoid follicles within the portal tracts (Figure 8); these are less often observed in hepatitis from other viral causes. Biopsies also typically reveal a dense periportal inflammatory process, associated with the infiltration of lymphocytes and plasma cells. Bile duct damage is often found in association with the infiltration, with vacuolization and ballooning of epithelial cells lining small bile ducts. Another common observation is the appearance of lobular hepatitis, with lymphocyte infiltration within sinusoids surrounding the hepatocytes. Steatosis is a frequent histological feature of HCV infection. It may be more commonly observed in those patients with HCV genotype 3 infection and

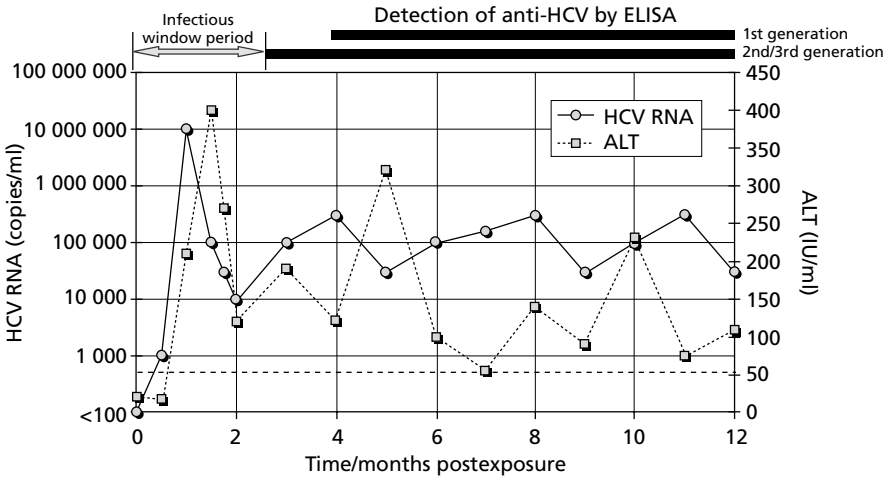

Figure 7 *Virological and biochemical markers of acute HCV infection. HCV RNA (solid line) and abnormal ALT levels (dotted line) appear approximately 50 days after exposure to HCV in a typical individual. The subsequent development of chronic hepatitis is indicated by persistent viremia and by fluctuating abnormal ALT levels. Antibody to HCV first appears after the onset of acute hepatitis, in this example leading to 'infectious window periods' of up to 60–80 days in currently used serological assays. The antibody profile elicited by infection is highly variable between individuals, although antibody to c33c is normally the first to appear.*

may resolve (along with other features of chronic hepatitis) in response to successful antiviral therapy.

The extent of histological abnormalities within biopsies can be summarized by descriptions such as lobular, chronic persistent hepatitis (CPH), and chronic active hepatitis (CAH), with or without cirrhosis, although more informative scoring systems such as the Knodell and Ishak scores have also been devised (Knodell et al. 1981; Ishak 1994). A spectrum of milder disease is generally observed in studies of asymptomatic individuals, such as those identified by blood donor screening, possibly reflecting a shorter duration of infection.

Despite sporadic publication of in situ histological demonstrations of HCV RNA and/or encoded proteins, most histopathologists struggle to demonstrate HCV in tissue sections and convincing reproducible studies using commercially available reagents are lacking.

Progression of disease

The percentage of chronically infected individuals who progress to cirrhosis and liver failure is not known. Progression to clinically significant liver damage is almost invariably very slow, although it may be faster in the context of immunosuppression. Particularly aggressive liver disease associated with HCV has been observed in immunosuppressed recipients of organ transplants and in patients with inherited immunodeficiency states (Healey et al. 1994). Studies of post-transfusion HCV highlight the following important clinical features. Many transfusion recipients are elderly (often suffering significant nonhepatic diseases) and die within two decades of infection, but not as a consequence of HCV infection. HCV-related mortality is rare within 20 years of infection; in one study, no excess mortality of HCV-infected individuals was observed over a period of 17 years (Figure 9) (Seeff et al. 1992). Cirrhosis is rarely observed within 10 years of infection, and as few as 20 percent of infected patients have cirrhosis after 20 years' follow-up. Risk factors for progression of chronic hepatitis to cirrhosis include age at time of infection (more rapid progression observed when infection occurs at older age), male gender, and concurrent alcohol consumption (Poynard et al. 1997). Recent analyses have highlighted the potential adverse impact of hepatic steatosis (and patient body mass index (BMI)) on fibrosis progression and on response to antiviral therapy. Cirrhosis may be complicated by hepatocellular carcinoma, but this rarely develops within 15 years of HCV infection (see Hepatocellular carcinoma). Some patients have asymptomatic infection, with normal liver function tests and mild hepatitis, despite 30 years of infection.

HCV may be associated with more aggressive liver disease in older than in younger people. Prognosis may also depend on viral genotype, although this is interrelated with other factors such as age at acquisition. For example, most transfusion recipients are elderly, and HCV genotype 1b is most commonly isolated from the serum of patients with transfusion-associated infection (Mahaney et al. 1994). Although it is not possible to estimate long-term prognosis at the time of infection, it is more feasible for patients with a known long duration of infection. For instance, when a 30-year-old patient has cirrhosis within 10 years of infection, there is a high likelihood that liver failure will eventually develop. However, for a 70-year-old patient with mild hepatitis despite 30 years' duration of infection, HCV is unlikely to cause death. Assessment of prognosis is an important aspect of selecting patients for treatment.

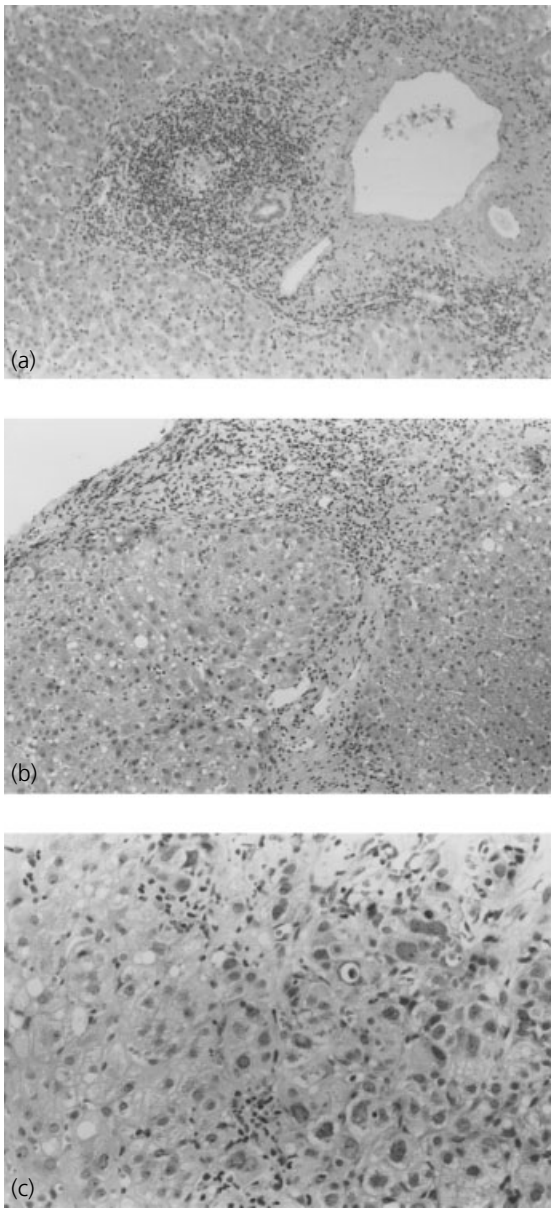

Figure 8 *Typical histopathological feature of HCV infection of the liver.* **(a)** *Typical HCV hepatitis with a large lymphoid aggregate within a portal tract showing reactive germinal center formation. Although the aggregate is close to a bile duct and adjacent to the limiting plate of the tract, there is little evidence of bile duct damage and none of interface hepatitis (piecemeal necrosis). Plasma cells and macrophages are also commonly present.* **(b)** *Cirrhosis. This is characterized by coarse fibrous septa separating nodules of regenerating hepatocytes.* **(c)** *Hepatocellular carcinoma. Tumor cells (right) are pleomorphic and hyperchromatic adjacent to regenerating hepatocytes in a cirrhotic nodule. There is a patchy chronic inflammatory infiltrate at the interface between them (sections kindly provided by Professor D.J. Harrison, Department of Pathology, University of Edinburgh).*

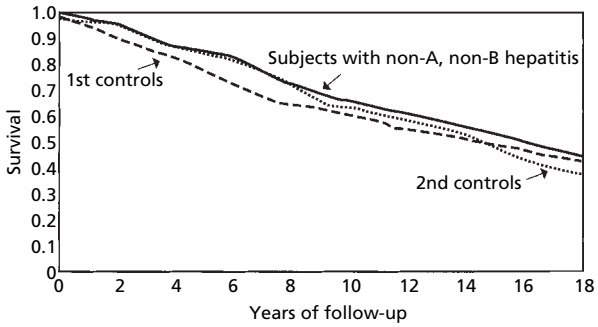

Figure 9 *Mortality associated with chronic post-transfusion hepatitis. The authors studied patients with transfusion-related non-A, non-B hepatitis (principally hepatitis C) who had been identified in five major prospective studies conducted in the USA between 1967 and 1980. Each index case was matched with two groups of noninfected transfusion recipients (first and second), and mortality rates from all causes were determined during an average follow up of 18 years. Mortality from all causes was high (about 50 percent in all groups), and the survival curves for the three groups were the same (reproduced from Seeff et al. (1992). Death from liver disease was low in all three groups, but was significantly higher in those originally given a diagnosis of non-A, non-B hepatitis (data not shown).*

After many years, liver failure may develop in patients with cirrhosis (also known as decompensated cirrhosis) (Fattovich et al. 1997). Decompensation may be manifest as hepatic encephalopathy, variceal hemorrhage, or ascites. Clinical manifestations of liver failure are not specific for HCV-induced liver disease, but are common to all forms of cirrhosis. Hepatocellular carcinoma may develop in an HCV-infected liver, but is very rarely observed in the absence of cirrhosis (see below).

In summary, most HCV infection is asymptomatic; when symptoms do develop, they are the nonspecific symptoms of liver failure.

Hepatocellular carcinoma

Hepatocellular carcinoma (HCC) is a frequent complication of long-standing HCV infection. In many western countries such as Spain and Italy, as well as in Japan, HCV infection is found in 60–90 percent of cases of HCC. HCC develops slowly, typically appearing 30 years after infection, and being rare within 15 years (Kiyosawa et al. 1990). In most studies, HCC usually, although not invariably (Demitri et al. 1995), occurs in patients with pre-existing cirrhosis.

For these reasons, the mechanism by which HCV causes HCC is generally considered to be indirect, arising as a consequence of chronic damage and inflammation of liver cells. Unlike HBV, replication of HCV does not produce DNA sequences that could be integrated into the host genome, nor is there any evidence for transforming activity of any of the HCV gene products. Treatment of hepatitis C patients with interferon-α has been reported to greatly reduce the subsequent risk of developing HCC, even in those conventionally regarded as 'non-responders,' in whom long-term normalization of ALT was not achieved (Nishiguchi et al. 1995).

B-cell responses to HCV infection

Infection with HCV elicits humoral and T-cell-mediated immune responses. Antibody reactivity to several HCV proteins can be detected in most infected individuals, although the response is highly variable and generally weak compared with antibody responses to other viruses. There seems to be no specific pattern of antibody response that is predictive of the long-term outcome of infection.

HCV antibody has been found to rapidly decline in titer after clearance of viremia in those who spontaneously resolve infection and in those who respond to HCV therapy. For example, ten women with documented exposure to HCV infection through treatment with contaminated anti-D immunoglobulin in East Germany were found to be seropositive 10 years after exposure, but five became completely seronegative in the following 10 years, while antibody titers in the remainder fell to close to the cut-off the HCV serological assay (Takaki et al. 2000).

Until recently it has been difficult to assess the protective effect of the serological response to HCV infection. It is now possible to investigate neutralization of HCV in vitro through the production of virus pseudotypes, in which a different virus from HCV is packaged inside an HCV envelope, and whose infectivity can be more readily quantified than HCV (Flint et al. 2004; Bartosch et al. 2003; Hsu et al. 2003) (see Structural proteins). Neutralizing antibody responses can be detected in HCV-infected individuals; titers are initially low and highly strain-specific, but increase and broaden in reactivity on development of chronic infection (Logvinoff et al. 2004). Neutralizing antibody was found targeted to epitopes in the hypervariable region of the E2 envelope protein and elsewhere in the viral envelope (Bartosch et al. 2003). Neutralizing antibodies elicited by infection with genotype 1a was able to cross-neutralize pseudotypes generated from other strains of genotype 1a, as well as of genotype 1b. Despite these new observations, it remains unclear whether B-cell responses are important in controlling HCV replication in vivo, and contribute to virus clearance on initial infection or subsequently.

T-cell responses to HCV infection

A vigorous cellular immune response to HCV can be detected in infected individuals. T-helper cells obtained from peripheral blood of most HCV-infected people proliferate when exposed to recombinant HCV proteins, such as core, E1, E2, NS3, NS4, and NS5 (Botarelli et al. 1993; Ferrari et al. 1994; Schupper et al. 1993). Indeed, unlike B-cell responses, recovery from infection is associated with stronger and more sustained cytotoxic T lymphocyte (CTL) responses around the time of primary infection than in those who become persistently infected (Cooper et al. 1999; Thimme et al. 2001; Lechner et al. 2000). Proliferative responses were detected more frequently in individuals who had cleared infection, suggesting that the cellular immune response is important in the control of virus replication in vivo. In the East German women who lost HCV antibody reactivity on resolution of active infection (see previous section), all retained HCV-specific helper and cytotoxic T-cell responses more than 10 years after clearance of viremia (Takaki et al. 2000).

Proliferative responses of T-helper cells obtained from the liver showed a highly restricted reactivity to NS4, compared with the responses found in mononuclear cells of peripheral blood (Minutello et al. 1993). CTLs from the liver and peripheral blood of HCV-infected individuals react with a wide range of epitopes from both structural and nonstructural proteins (Koziel et al. 1992, 1993; Cerny et al. 1995b; Battegay et al. 1995). CTLs are likely to be important in both the control of, and recovery from, HCV infection and in the pathogenesis of liver disease.

Mechanism of persistence

Although humoral and cellular immune responses to HCV occur upon infection, these seem to be unable to clear the infection (see Chronic hepatitis) or to protect an individual from reinfection. For example, it is possible to reinfect chimpanzees repeatedly with the same strain of HCV (Prince et al. 1992; Farci et al. 1992), producing hepatitis de novo similar to that observed on primary infection. However, chimpanzees who have cleared previous infection are partly or completely resistant to reinfection with the homologous or heterologous genotypes of HCV (Lanford et al. 2004), possibly the result of strong T-cell memory responses characteristic of resolved infections. Repeated exposure of humans to HCV may also produce recurrent episodes of infection, observed for example in thalassemic patients transfused with HCV-contaminated blood (Lai et al. 1994). Infection with more than one HCV genotype is frequently observed in other multiply exposed individuals, such as hemophiliacs (Jarvis et al. 1994). Persistence of HCV and the observed susceptibility of individuals to reinfection occur despite the existence of neutralizing antibody responses to HCV, that which often shows cross-reactivity to other HCV genotypes.

Immune escape

Several observations suggest that many of the amino acid changes that occur during HCV infection are driven sequentially by selection pressures that prevent peptide binding to MHC class I or II alleles, or prevent

neutralization by antibody responses to the virus. The envelope proteins are the principal targets of humoral immune responses, and it has been hypothesized that changes in E1 and E2 alter the antigenic properties of the proteins, thereby allowing the virus to 'escape' from neutralizing antibodies (Weiner et al. 1992). In this model, persistent virus replication is achieved by continuous diversification of HCV in regions particularly sensitive to neutralizing antibody; this hypothesis is supported by the observation that much of the variability in the *E2* gene is concentrated in discrete 'hypervariable' regions (Weiner et al. 1992; Hijikata et al. 1991a; Kato et al. 1992), that may be in close proximity to parts of the protein involved in virus/cellular receptor interactions, as in influenza A virus. Supporting this hypothesis is the observation that sequence change was slower in individuals with defects in B-cell immunity (Booth et al. 1998), where there would be reduced immune selection on B-cell epitopes. Similarly, the strong and sustained CTL responses in primary HCV infection may drive sequence change in those who became chronic carriers (Chang et al. 1997; Cantaloube et al. 2003; Sheridan et al. 2004). Immune selection may also underlie the high degree of sequence variability between and within genotypes in the envelope and other regions of the genome such as NS5A.

Mechanism of liver damage

It is likely that direct cytopathic infection of cells in the liver, as well as damage secondary to the inflammatory process contributes to HCV-associated liver disease. Evidence that HCV replication itself is directly cytopathic includes the clinical observation of more severe and rapidly progressive liver disease in individuals who are immunosuppressed and who have high levels of viremia. Secondly, there is generally a direct correlation between clearance of viremia and normalization of ALT levels in people who respond to interferon treatment (see Progression of disease), implying that it is virus replication itself that is responsible for the hepatitis. These observations contrast with HBV, in which successful treatment with interferon is thought to result from augmenting CTL activity in the liver and is associated with elevated ALT levels and a transient exacerbation of hepatitis.

Immunopathology may result from cytotoxic T cell reactivity against HCV-infected cells, or the process of HCV infection might trigger an autoimmune disease in which uninfected cells become the targets. The development of an immune response to the cellular protein, GOR, in association with HCV infection could be an example of this process (Mishiro et al. 1991). Understanding the mechanism of liver disease would assist the rational development of HCV treatment (see Antiviral treatment). Standard antiviral treatment schedules including interferon-α have been shown to clear hepatitis in some individuals (Davis et al. 1989; Di Bisceglie et al. 1989), although it is not known whether it acts as a virucidal agent or if its action depends on its immunomodulatory properties such as the upregulating expression of MHC class I on hepatocytes.

Extrahepatic manifestations

In a few infected patients, HCV may be responsible for extrahepatic clinical manifestations and disease (Martin 1993). The underlying pathogenic mechanisms for these extrahepatic manifestations are varied and often poorly understood. There are at least three mechanisms by which HCV could cause such disease. First, it is possible that HCV is capable of cytopathic replication in cell types outside the liver. Secondly, HCV may trigger an autoimmune process that is directed against antigens expressed on nonhepatic cells. Thirdly, persistent HCV infection could lead to immune-complex formation with antibodies followed by deposition in small vessels.

Methods to detect extrahepatic replication of HCV include the detection of HCV protein expression by immunocytochemistry and the detection of replication intermediates by strand-specific PCR. Simple detection of HCV RNA sequences is generally insufficient evidence, as HCV may nonspecifically associate or bind to cells such as macrophages or B lymphocytes in the peripheral circulation. The detection of HCV in tissues may reflect a process of immune-complex deposition rather than replication.

Many published studies reporting the detection of replication intermediates (complementary RNA sequences) in a range of cell types used methods that were insufficiently specific. However, using a PCR-based method for detection of sequences from the core region, Lerat and co-workers (1996) reported that replication may occur in certain lymphoid cells. In contrast, no evidence for extrahepatic replication was observed in chimpanzees, using a similar assay (Lanford et al. 1995). In other studies, HCV was detected in lymphocytes infiltrating the liver by immunocytochemical and hybridization methods (Blight et al. 1994).

HCV infection is clearly associated with certain types of vasculitis and glomerulonephritis, which are caused by immune complex deposition. In southern Europe, HCV infection seems to be associated with porphyria cutanea tarda, a potentially disfiguring skin condition associated with an acquired deficiency of the liver enzyme uroporphyrinogen decarboxylase (Herrero et al. 1993). There is a putative association of HCV with other nonhepatic conditions, including Sjögren's syndrome, rheumatoid arthritis, pulmonary fibrosis, corneal ulceration, aplastic anemia, and non-Hodgkin's lymphoma. Vasculitis and glomerulonephritis are more frequent in patients with established cirrhosis.

HCV is classically associated with the small vessel vasculitis known as 'essential mixed cryoglobulinemia' (Agnello et al. 1992) (also observed in patients with chronic HBV infection). Laboratory features include the presence of rheumatoid factor activity in serum, the presence of a cryoprecipitate, complement activation, and proteinuria/hematuria. The most important clinical manifestation is purpura, which is nearly always present, and 25–50 percent of patients have renal disease. Most patients have constitutional symptoms, especially weakness and arthralgia; Raynaud's phenomenon, Sjögren's syndrome, and neuritis may also be present. Purpura may resolve with interferon-α therapy (Misiani et al. 1994).

HCV infection is also associated with membranoproliferative glomerulonephritis (MPGN) type 1 (Johnson et al. 1993), which is a consequence of immune complex deposition in the glomerular capillaries. It is associated with serum rheumatoid factor positivity, with complement activation, and with cryoglobulinemia. MPGN is classically associated with heavy proteinuria, often in the nephrotic range (more than 3.5 g per 24 h), whilst creatinine clearance is modestly impaired. Treatment with interferon-α reduces urinary protein loss, but the impact of treatment on renal outcome is uncertain (Johnson et al. 1993). It should be emphasized that HCV infection is a relatively common cause of mixed essential cryoglobulinemia and MPGN, but that HCV infection is rarely complicated by these conditions.

EPIDEMIOLOGY

Parenteral routes of transmission

In western Europe, Australia, and North America, most HCV-infected patients have a history of percutaneous exposure to the virus, and most are (or have been) injecting drug users. The seroconversion rate of IDUs has been estimated at 20 percent per year, so long-term drug users are almost invariably HCV-infected. Drug use was uncommon before the 1960s, so drug users tend to be younger than patients infected through transfusion and are also more likely to be infected with genotypes other than type 1b. Most drug users have asymptomatic infection with no history of jaundice, but have chronic hepatitis whereas some have developed cirrhosis and a few have progressed to liver failure. Since drug use is usually associated with HCV acquisition at a fairly young age (in comparison with transfusion-acquired infection) and thus with a slower rate of progression to cirrhosis, few IDUs would progress to liver failure within two (or even three) decades of infection. However, because of the lower average age of IDUs, their life expectancy from the time of infection is five or six decades; despite less aggressive infection, many will survive long enough to develop significant liver disease.

In the 1960s, clotting factor concentrates became more widely used and most patients with coagulation disorders became infected with HCV. Thousands of donors contribute to each factor concentrate, so contamination with HCV and HIV was very likely. Many recipients were young, and most developed liver disease. Some have progressed to liver failure, and died or undergone liver transplantation (Telfer et al. 1994), although for many the prognosis may have been affected by HIV coinfection. Since the introduction of effective virus inactivation for blood products in the 1980s, factor concentrates have not transmitted HCV infection.

Repeated exposure to blood and blood products (in the absence of serological screening and/or heat treatment) is clearly associated with a high risk of HCV exposure and infection. The risk associated with exposure to a single donor product (e.g. one unit of blood) was already diminishing before the availability of specific serological tests for HCV, but varied significantly from country to country. Mercenary donors are more likely to be HCV-infected, and the prevalence of donor seropositivity was significantly reduced when 'self-exclusion' policies were introduced to combat the risk of HIV transmission. For example, by the mid-1980s fewer than 1 percent of UK donors were HCV-positive (Contreras et al. 1991).

Screening of blood donors for antibodies to HCV was introduced by most blood transfusion services in 1990 and 1991. Blood donors are clearly not representative of the entire population, but scrutiny of HCV-positive donors provides some insights into the epidemiology of this infection (Alter 1995; Mansell and Locarnini 1995). The lowest seroprevalence is observed in Scandinavia and in the UK with slightly higher prevalence in North America, western Europe, and Australia. Prevalence is intermediate in eastern and southern European countries, even higher in Japan, and most prevalent in Middle Eastern (especially Egyptian) blood donors. When donor seroprevalence is low, the seropositive donor is more likely to have an identifiable risk factor for parenteral exposure (Mutimer et al. 1995b), but as donor seroprevalence increases, prior parenteral exposure becomes more difficult to identify (Esteban et al. 1991).

In countries of low and intermediate seroprevalence, seropositive donors frequently admit to prior intravenous drug use; sometimes a single exposure, 20–30 years previously. Investigation of seropositive donors confirms that the majority are viremic, and that many have chronic hepatitis and cirrhosis (Esteban et al. 1991; Irving et al. 1994; Mutimer et al. 1995b). As seropositive donors are excluded from the blood donor panels, the frequency of seropositivity falls; in the UK, for instance, true seropositivity fell from an initial rate of 0.60 to 0.15 percent. To further reduce the already small risk for transfusion-associated infection, some blood transfusion organizations have introduced nucleic acid testing of

donated products for HCV RNA (see Blood donor screening by PCR and related methods).

Transplanted organs may also transmit HCV infection, and studies in the USA and UK suggest that organ donors have a higher seropositivity rate than blood donors (Pereira et al. 1992; Wreghitt et al. 1994). The majority of high-risk blood donors are subject to self-exclusion, an option that is not available to the brain-dead organ donor. In one study, six of 554 (1.08 percent) British organ donors were HCV-seropositive in the screening assay, and four of these six infected an organ recipient.

Other routes of transmission

Most studies (and this discussion) have focused on groups at risk for HCV infection as a result of percutaneous exposure. These groups include IDUs, transfusion recipients (especially recipients of pooled plasma products such as factor VIII, anti-D) (Power et al. 1995), immunoglobulin (Healey et al. 1994), transplant recipients, hemodialysis patients, and healthcare workers (Zuckerman et al. 1994; Klein et al. 1991). Tattooing and acupuncture may also be responsible for some percutaneous exposure, and in countries of high prevalence the use of unsterilized needles for cultural rituals, medical treatment, or vaccination programs may result in HCV infection. For example, bilharzia treatment using reusable and unsterile needles in the past has frequently been suggested as a cause for the very high population prevalence of HCV infection in Egypt.

However, for many people, overt percutaneous exposure cannot be identified. For example, detailed questioning failed to identify such a cause of infection in approximately one-third of HCV-infected Scottish blood donors (Crawford et al. 1994), and this has prompted the search for other routes of transmission. There seems to be a low risk of infection associated with sexual contact with an HCV carrier. Evidence suggesting that sexual transmission may occur includes the observation that HCV seems to be more common in people who have multiple sexual partners, such as prostitutes and male homosexuals (Tedder et al. 1991; Buchbinder et al. 1994). Large-scale studies of sexual partners of HCV-positive people generally show a slightly increased likelihood of HCV infection compared with the background population (Daikos et al. 1994; Soto et al. 1994; Cerny et al. 1995a; Utsumi et al. 1995), although in two studies (both of wives of hemophiliacs) no transmissions were documented (Bresters et al. 1993a; Hallam et al. 1993). Other sexually transmitted diseases may facilitate sexual transmission of HCV, as is the case for HIV.

Barrier methods of contraception/protection are likely to prevent transmission of HCV. For casual sexual contact, such precautions are mandatory (for mutual protection from all sexually transmitted infection). When one member of a long-term sexual partnership is identified as a carrier of HCV, both members should be counseled appropriately. The other partner might request serological testing. It seems likely that most couples will not elect to change their sexual practices. HIV/HCV coinfection may increase the risk for sexual transmission of HCV, and this may be a function of the higher HCV titer which is measured in the blood of HIV coinfected patients. In this setting, barrier methods of protection are clearly appropriate.

Early studies documented a low but detectable rate (5–15 percent) of mother-to-child transmission of HCV (Novati et al. 1992; Lam et al. 1993; Wejstal et al. 1992). However, it remains unclear whether this is true vertical transmission (in utero or during birth) or if it occurs through close contact (and possibly unapparent parenteral exposure) during the postnatal period. The risk of infant infection seems to be increased when the mother is HIV/HCV coinfected, and again this may be secondary to higher virus loads associated with immunosuppression (Ohto et al. 1994). HCV transmission may also occur as a result of 'household' contact. In this setting, it is almost impossible to distinguish vertical and sexual transmission from other 'household' contact. The parents of an index case are most likely to be infected. Relative risk is lower for spouses and siblings, and lowest for children of the index case.

In western Europe, most patients with liver failure will be referred for liver transplantation. Examination of the liver transplant experience during the 1980s and 1990s suggests that HCV has been an uncommon cause of liver failure in the UK. This observation suggests the relatively recent introduction of this virus into the western European population. It is evident that HCV infection was rare in western Europe and in North America before the emergence of intravenous drug use in the 1960s. However, it is calculated that the USA experienced an annual incidence of 15 cases per 100 000 population during the 1980s (Alter 1995), predicting a national reservoir of HCV carriers of as many as 3.5 million people. That HCV currently poses less of a clinical problem in the USA and northern Europe than in southern Europe, Japan, and the Middle East is probably due to its later introduction in these populations. In the future, all countries can expect higher rates of significant liver disease from HCV, including liver cancer.

Geographical distribution of HCV genotypes

Some genotypes of HCV (types 1a, 2a, 2b) show a broad worldwide distribution, while others such as type 5a and 6a are only found in specific geographical regions. HCV infected blood donors and patients with chronic hepatitis from countries in western Europe and the USA is frequent with genotypes 1a, 1b, 2a, 2b, and 3a, although

the relative frequencies of each may vary, such as the trend for more frequent infection with type 1b in southern and eastern Europe. In many European countries, genotype distributions vary with age of patients, reflecting rapid changes in genotype distribution with time within a single geographic area.

A striking geographical change in genotype distribution is apparent between south east Europe and Turkey (both mainly type 1b) and several countries in the Middle East and parts of north and central Africa where type 4 predominates. For example, a high frequency of HCV infection is found in Egypt (20–30 percent (Saeed et al. 1991; Darwish et al. 1993; Kamel et al. 1992)), of which almost all correspond to type 4a (Simmonds et al. 1993b; McOmish et al. 1994). HCV genotype 5a is frequently found amongst NANBH patients and blood donors in South Africa, but is found only rarely in other parts of Africa or elsewhere.

In Japan and Taiwan and probably parts of China, genotypes 1b, 2a, and 2b are the most frequently found. Infection with type 1a in Japan appears to be confined to hemophiliacs who have received commercial blood products, such as factor VIII and IX clotting concentrates, provided in the USA. A genotype with a highly restricted geographical range is type 6a which was originally found in Hong Kong, where approximately one-third of anti-HCV-positive blood donors are infected with this genotype, as are an equivalent proportion in neighboring Macau and Vietnam.

Molecular epidemiology of HCV infection

Persistent infection with HCV entails continuous replication of HCV over years or decades and the large number of replication cycles, combined with the relatively error-prone RNA-dependent RNA polymerase leads to measurable sequence drift of HCV over time. For example, over an 8-year interval of persistent infection in a chimpanzee, the rate of sequence change for the genome as a whole was 0.144 percent per site per year (Okamoto et al. 1992a), similar to the rate observed in the 5′ half of the genome over 3 years in a human carrier (0.192 percent (Ogata et al. 1991)). Using this molecular clock, it is in principle possible to calculate times of divergence between HCV variants, and therefore establish their degree of epidemiological relatedness. Similarly, phylogenetic analysis of sequences from individuals exposed to HCV can be used as evidence for a common source of infection. Sequence comparisons in variable regions of the HCV genome, such as E2 and NS-5, have been used to document transmission between individuals, and to explore the possibility of nonparenteral routes of transmission such as mother to child (Weiner et al. 1993), within families (Honda et al. 1993), and by sexual contact (Rice et al. 1993; Setoguchi et al. 1994; Healey et al. 1995). For example, clustering of HCV sequences into a single phylogenetic group amongst recipients of an HCV-contaminated blood product (anti-D immunoglobulin) was still apparent 17 years after exposure (Power et al. 1995).

DIAGNOSTIC TESTS FOR HCV INFECTION

Antigens

Antibody reactivity can be detected to several linear and conformational epitopes present on both structural and nonstructural proteins of HCV. Recombinant proteins or peptides containing these antigenic regions are used for serological tests for antibody to HCV (see Figure 1), and much of our current knowledge of antibody responses to HCV has arisen from research aimed at improving antibody tests to enable effective screening of blood donors and diagnosis in patients. Cytotoxic T-cell and proliferative responses have also been detected to several peptides or recombinant proteins.

NS4

The original HCV-specific clone isolated from chimpanzee plasma was expressed in *E. coli*, the derived protein of 42 amino acids (1 694–1 735) being encoded by the NS4 region of the genome (see Figure 1). A larger clone (c100-3) assembled from several overlapping clones was expressed in yeast and formed the basis of the first commercial tests for HCV antibody. The antigen was derived from amino acids 1 569–1 931, thus spanning a small section of the NS3 region, as well as almost all of 4a and 4b. Despite its being a somewhat unnatural hybrid, use of the antigen in screening assays provided the first evidence of the importance and widespread occurrence of HCV infection. Antigen from NS4 is present in all current screening enzyme-linked immunosorbent assays (ELISA), whether singly, in combination with NS3 or in synthetic peptide form. Likewise, all commercial supplementary immunoblot assays contain NS4 components either as recombinant antigens (Chiron RIBA-2, Murex western blot, Abbott Matrix) or as synthetic peptides (Chiron RIBA-3, Organon Liatek III), which show improved specificity.

Many of the antigenic determinants in the NS4 region show considerable amino acid sequence variability between genotypes of HCV; serological reactivity to the 5-1-1 protein is absent or weak in samples from individuals infected with types 2 or 3 (Chan et al. 1991; McOmish et al. 1993). Indeed, type-specific reactivity to NS4 forms the basis for serological typing assays that can differentiate between the antibody responses elicited

by different genotypes (Simmonds et al. 1993c; Tanaka et al. 1994; Bhattacherjee et al. 1995).

CORE

Infection with HCV elicits a strong humoral antibody response to the core protein, predominantly to a series of linear epitopes at the N terminus of the protein (Nasoff et al. 1991; Sallberg et al. 1992). The incorporation of either recombinant proteins or synthetic peptides from the core region led to a great improvement in the sensitivity of HCV screening assays for HCV antibody (Chiba et al. 1991; Hosein et al. 1991; Ishida et al. 1993). Commercial screening assays have mainly used recombinant antigen (c22) comprising a major portion of the core region (Ortho 3.0, amino acids 2–120; Abbott 3.0 amino acids 1–150, Murex VK47/48), but the Sanofi Pasteur New Antigen ELISA instead uses two synthetic peptides. Similarly the most recent version of the Chiron RIBA supplementary test, RIBA-3, replaces the recombinant antigen of RIBA-2 with one synthetic peptide utilizing amino acids 10–53 resulting in much improved specificity. Liatek III incorporates two peptides from the core region, while the Murex and Matrix blots retain recombinant antigen. The amino acid sequence of the core region is highly conserved between different genotypes of HCV and consequently, most epitopes are cross-reactive, with similar reactivity observed for individuals infected with different genotypes. Those differences that do exist have been exploited in a typing assay to distinguish antibody to type 1 and type 2 (Tsukiyama Kohara et al. 1993), although the core proteins of types 1, 3, 4, 5, and 6 are probably too similar to allow this assay to be extended further.

NS3

Antibody to epitopes in the NS3 region of HCV is produced early in infection and is the first detectable in many seroconversions while in established infections, it is as common as core antibody and more frequently seen than antibody to c100 or NS5. Several manufacturers were slow to realize the benefits of incorporating antigen from this region in their screening tests and some early tests had either none or too little to be effective, thus missing viremic samples (Dow et al. 1993; Courouce et al. 1995). All current screening assays contain recombinant antigen either singly or in combination with NS4 sequences (Ortho 3.0) or c22 sequences (Abbott 3.0). In Ortho 3.0, the NS3 antigen has been modified biochemically to give increased sensitivity for NS3 antibody enabling earlier detection of seroconversions (Courouce et al. 1994) and the detection of chronically infected patients with low levels of NS3 antibody (Dow et al. 1996). All supplementary immunoblots utilize recombinant antigen from the NS3 region. Changes in the concentration of the coating antigen, c33c, in RIBA-3 have made this test particularly sensitive to NS3 antibody (Courouce et al. 1994).

NS5

Recombinant antigen from the NS5 region was incorporated in the first Wellcozyme/Murex ELISA, but appeared in the Abbott and Ortho tests only with the third generation. Both Abbott and Ortho tests use recombinant antigen from almost the whole NS5 region (amino acids 2 054–2 995), whereas in the Murex assay the size of the recombinant protein has been reduced with each succeeding test and the present Murex test contains protein from only a small segment of the NS5a region. Of the current supplementary tests, RIBA-3 and Murex blot incorporate recombinant antigen, whilst in Liatek III it is a peptide. The contribution of NS5 antigens to improved specificity and sensitivity in screening tests has been difficult to quantify. Seroconversions in which antibody to NS5 occurs first are rare, and no chronically infected patient has been found with NS5 antibody as the only marker. Specificity is not enhanced, as these tests produce significant numbers of a new population of RIBA-3, NS5 indeterminates, that are all PCR-negative; it is generally agreed that improvements in sensitivity with third generation ELISAs are associated with improved NS3 antibody detection. Inclusion in supplementary tests may have value in providing extra evidence of positivity, but the poorer specificity of NS5 antigens in these tests may compromise interpretation.

The battery of antigens used in current screening and supplementary tests will detect the vast majority of chronic, established infections. Where improvement is required is in earlier detection of seroconversion. In addition, manufacturers will need to address the problems associated with antigenic variation between different genotypes. All current screening tests are based on genotype 1 antigens, and while this genotype is widely distributed throughout the world, it is not the only, nor predominant, genotype in many countries. Diminished sensitivity to genotype 3 is seen in RIBA-2 (Damen et al. 1995) and to a lesser extent RIBA-3 (Dow et al. 1996), and this may also be reflected in the sensitivity of screening ELISAs (Neville et al. 1997). Future tests will need to incorporate antigens from various genotypes to ensure an optimal sensitivity for all (response to all).

First generation tests

The first test to specifically detect antibody to HCV was based on the c100-3 antigen (Kuo et al. 1989). Use of this simple, single antigen test in ELISA format confirmed that HCV was the major cause of post-transfusion non-A, non-B hepatitis in the USA and elsewhere (Alter et al. 1989; Esteban et al. 1990; Hopf et al. 1990; van der Poel et al. 1990), and that prevalence of

antibody to the c100-3 antigen was high in hemophiliacs (Brettler et al. 1990), drug abusers (Esteban et al. 1990), and in patients with hepatocellular carcinoma (Colombo et al. 1989; Bruix et al. 1989; Nishioka et al. 1991). The simple first generation tests for anti-HCV were valuable in establishing the importance of HCV infection worldwide, its identity with non-A, non-B hepatitis and its wider spread in the community usually via drug abuse.

Second generation tests

Once the HCV genome had been fully sequenced and the structural and nonstructural regions identified (Choo et al. 1991), several manufacturers developed second generation tests which included antigen to the core region (c22c) and one or more further nonstructural regions NS3 (c33), NS4 (c100-3), or NS5. The most widely used tests, those manufactured by Ortho Diagnostics and Abbott Laboratories, contained four antigens (5-1-1, c100-3, c22, and c33c). These tests were significantly more sensitive and specific than their first generation equivalents and their use for screening blood donations virtually eliminated post-transfusion HCV infection as a complication of transfusion (Aach et al. 1991). The improved sensitivity allowed earlier detection of seroconverting patients by some weeks (van der Poel et al. 1992) (Figure 7), and the detection of HCV antibody positivity in donors and patients previously screened as negative in the first generation assays (Yuki et al. 1992; Aoki et al. 1994).

The same series of antigens present in the second generation Ortho and Abbott tests were incorporated in an improved RIBA test by Chiron, RIBA-2 – often referred to as 4-RIBA in early reports. In this test, two bands were required for positivity, one band was termed an indeterminate result. This test was very effective in identifying ELISA false positives in first generation tests where it represented a truer confirmatory test in that it incorporated new antigens (c33c and c22) not present in the ELISA screening test (van der Poel et al. 1991; Courouce et al. 1991). There was a strong correlation between RIBA-2 positivity and viremia as detected by PCR tests (Garson et al. 1992; Larsen et al. 1992; Bresters et al. 1993b; Yun et al. 1993). The interpretation of the RIBA-2 indeterminate result, of which there were significant numbers in low risk populations such as blood donors, and the advice to give the patient/donor has proved controversial. Only PCR testing could clearly define the association with HCV infection, but few PCR-positive indeterminate individuals were found in low risk groups (Follett et al. 1991), and these were almost always associated with the c22 or c33 band (Bresters et al. 1993b). Most of the indeterminate reactivity to c22 could be shown to be due to nonspecific cross-reactivity to restricted N-terminal regions of the core antigen (Tobler et al. 1994). RIBA-2 is less likely to 'confirm' samples from individuals infected with type 1 genotypes (Damen et al. 1995; Dow et al. 1996) due to the predominantly type-specific reactivity to the NS3 and particularly NS4 proteins.

Third generation tests

Current tests for HCV antibody omit the original 5-1-1 antigen and include the NS5 antigen, although the value of this addition is questionable. Third generation ELISAs are more sensitive and detect seroconversions significantly earlier (Courouce et al. 1994; Uyttendaele et al. 1994; Vrielink et al. 1995b), but this improvement is associated with an improved reactivity of the c33 antigen component, and not with the presence of the NS5 antigen (Barrera et al. 1995; Lee et al. 1995; Courouce et al. 1995). Counterbalancing this improvement in sensitivity is some loss in specificity related to a new population of indeterminate samples associated with the NS5 antigen; NS5 indeterminate samples are invariably PCR-negative.

Significant changes were made in the updated RIBA test, RIBA-3 introduced in Europe in 1994. As well as incorporating NS5 recombinant antigen, RIBA-3 incorporates synthetic peptides for c22 and c100 replacing the recombinant antigens of RIBA-2. Improved sensitivity is again apparent and associated with the NS3 component (Courouce et al. 1994; Zaaijer et al. 1994). Specificity is greatly enhanced and use of RIBA-3 resolves many of the nonspecific problems associated with RIBA-2 (Dow et al. 1993; Zaaijer et al. 1994). Viremia and RIBA-3 positivity are strongly associated when three and four bands are present but much less so for two-band positives (Dow et al. 1996). Care is required with all PCR-negative, two-band positives, and further ELISA and supplementary tests are necessary before equating such reactivity with HCV infection, as false positives are known (Damen et al. 1995; Dow et al. 1996). Although RIBA-3 has improved sensitivity for genotypes 2 and 3 compared to RIBA-2, some lack of sensitivity to type 3 is still apparent (Dow et al. 1996).

Alternative antigen tests

Manufacturers of HCV serological assays use recombinant proteins and peptides from type 1a, although some in the USA and Europe have cloned HCV independently and produced commercial products based upon differently sourced HCV antigens. These produce tests which show different nonspecific reactivity on screening from that produced by the Chiron-based tests. Consequently, using one such test to screen ELISA reactives from an alternatively sourced antigen test could help to resolve many of the specificity problems associated with HCV ELISAs (Craske et al. 1993). However, patent

regulations have forced the removal of these tests from the marketplace and only two commercially available ELISAs with independently sourced antigen are widely available (Murex, Sanofi-Pasteur).

Alternative supplementary tests to the Chiron RIBA products are produced by several manufacturers based either on the Chiron isolate (Abbott Matrix) or independently sourced antigen (Murex Western Blot, Organon Liatek line immunoassay, Diagnostic Biotechnology blot assay). The Liatek assay most closely approaches RIBA-3 for sensitivity and specificity (Zaaijer et al. 1994). A new antigen from the E2/NS1 region of the genome incorporated into this test did not contribute to earlier detection of HCV antibody in seroconversion. Whether use of recombinant envelope antigens is helpful must await further studies. All these supplementary tests can be valuable when investigating a doubtful ELISA or RIBA result.

Genome detection

Detection of the HCV genome is indispensable for the accurate diagnosis and the complete characterization of HCV infection in a patient. Our knowledge of HCV infection has benefited immensely from use of the PCR for HCV RNA. A PCR test or equivalent is the only method of confirming HCV infection in equivocal ELISA reactives such as RIBA indeterminates, and is the only method for distinguishing between chronic and resolved infections. Retrospective studies on recipients of blood donations known to be RIBA positive or indeterminate indicate that transmission is only associated with PCR positivity (Vrielink et al. 1995a).

Detection of the virus genome is the only reliable method of following the effect of treatment with antiviral drugs on patients with chronic infection since normalization of biochemical liver function tests is not always associated with virus clearance. Similarly, chronic HCV infection with associated disease is known in patients with normal liver functions tests (Nalpas et al. 1995). Patients in early seroconversion and patients with an impaired immune response can appear falsely negative in current HCV ELISA tests and PCR is necessary for complete diagnosis in such cases (Bukh et al. 1993b). In chimpanzees, viremia can be detected by PCR within the first week after infection (Beach et al. 1992; Shimizu et al. 1990) providing a long window period when the blood is infectious but no antibody can be detected.

Blood donor screening by PCR and related methods

One of the most used applications for HCV PCR and related nucleic acid amplification tests (NAT), such as transcript-mediated amplification (TMA), has been its adoption for routine testing of blood donors in addition to serological tests. The introduction of NAT allows acutely infected donors to be detected before their seroconversion for antibody to HCV (Figure 57), and thus further reducing or eliminating the potential for transfusion-transmitted HCV infections. The introduction of NAT screening was prompted by estimates that between one in 100 000–200 000 donations would be intercepted by NAT in this 'window' period, thus preventing large numbers of transfusion-transmitted infections (Courouce and Pillonel 1996; Schreiber et al. 1996). The introduction of very large-scale NAT screening in the USA, other western countries, and Japan has led to impressive progress in establishing the infrastructure and laboratory facilities for testing, as well as driving the evolution of pooled testing in which donations are combined into small pools before testing, and positives resolved by the creation of cross-pools. In practice, donor yield has proved divergent from original estimates, with incidences of less than one per million HCV NAT-positive, seronegative donations being found in most countries. Despite the scope for HCV NAT to be combined with NAT-detection methods for other viruses currently screened for in blood donors by serology methods, the cost-effectiveness of this further testing is highly questionable (Roth and Seifried 2001; Marshall et al. 2004; Jackson et al. 2003; Simmonds et al. 2002).

HCV viral load measurement

A large number of methods have been developed in-house and commercially for the measurement of HCV viral loads in plasma, and potentially in other samples such as liver biopsy. The PCR can be made semi-quantitative by 'limiting dilution' of the test sample, in which titration of nucleic acid yields an endpoint that reflects the original concentration of HCV sequence in the original sample. These techniques require calibration against agreed HCV RNA standards (Saldanha et al. 1999), and can be time-consuming and impractical for large numbers of samples. Improvement in accuracy and practicality has been achieved through the development of competitive PCR, where the test sample is co-amplified with known amounts of a separate target sequence; the ratio of amplified HCV sequences to those of the competitive target can provide an accurate quantitation of HCV (Ravaggi et al. 1995). Because of the limited quantitative range of most tube-based quantitation methods, and the rapid plateauing of product quantity when amplification proceeds beyond the exponential phase, HCV quantitation may be more effectively carried out by real-time PCR methods (such as the LightCycler from Roche, and the TaqMan method from Perkin Elmer). These assays quantify target sequences through monitoring of product accumulation at each cycle of the amplification reaction. Product detection methods generally involve the specific detection of

amplified target sequences through hybridization to fluorimetric probes. For example, in the Lightcycler assay, two hybridization probes bind to adjacent sequences within the amplicon leaving one base in between, thus allowing fluorescence resonance energy transfer (FRET) between the donor fluor on the 3′ end of one probe and the acceptor fluor on the 5′ end of the other one. The TaqMan assay uses a single hybridization probe labeled with a reporter dye and an adjacent 'quencher' molecule that absorbs fluorescence. On binding to amplified sequences during PCR, the probe becomes degraded by exonuclease activity of *Taq* polymerase during copying, and releases the quencher and the reporter dyes into solution. Increases in the amount of amplified target therefore destroy quenching of the reporter dye, and lead to increases in fluorescent emission intensity.

For HCV, a non-amplification based method is widely used that uses highly sensitive branched DNA (bDNA) synthetic oligonucleotide probes which binds to viral RNA in the test sample that has been immobilized on a solid phase. The bDNA probes enable multiple copies of the alkaline phosphatase-labeled probe hybridize to each amplifier probe on the immobilized complex, which is detected by addition of a chemiluminescent substrate. Viral loads in the range from 1 000–10 million RNA copies/ml can be detected by this method.

The measurement of HCV viral load in plasma has a number of clinical applications and commercially available assays are widely used for prediction of treatment response, in combination with genotype determination (see Antiviral treatment). However, HCV viral loads do not predict the current severity of liver disease in infected individuals, or their likelihood of progression to clinically significant liver disease (Poynard et al. 1997). Viral load is, however, predictive of transmission risk in certain settings; for example, mother-to-infant transmission is strongly associated with higher viral loads. In the original study (Ohto et al. 1994), women who transmitted infection showed a significantly higher viral load ($10^{6.4\pm0.5}$ RNA copies/ml) than nontransmitters ($10^{4.4\pm1.5}$ RNA copies/ml).

HCV genotyping assays

Genotyping of HCV has become important in the treatment of infection (see Antiviral treatment), and for epidemiology tracing in studies of virus transmission. Genotyping assays are usually based upon the analysis of an amplified segment of the genome (such as the 5′ UTR, commonly used for virus detection and viral load monitoring; see Genome detection and HCV viral load measurement). The sequence of the 5′ UTR is highly conserved between genotypes, but genotype-specific differences comprising one or more substitutions can detected by probe hybridization (Stuyver et al. 1993a; Maertens and Stuyver 1998), by changes in restriction endonuclease sites (McOmish et al. 1993; Davidson and Simmonds 1998), or by direct sequencing of the 5′ UTR (Ross et al. 2000). As described above (see Recombination), few recombinant forms have been described to date, and for practical purposes it can be assumed that the 5′ UTR sequence predicts the genotype of the whole virus. Should more circulating recombinant forms be detected, then this assumption may have to be re-examined.

In general, the 5′ UTR is highly predictive of the genotype of the rest of the virus, reflected by the high concordance between the results of genotyping assays that use the 5′ UTR and the genotype identified by nucleotide sequencing in NS5B or other coding regions of the genome (Simmonds et al. 1993c; Tanaka et al. 1994; Lau et al. 1995a; Bhattacherjee et al. 1995; Zheng et al. 2003; Gault et al. 2003; Dansako et al. 2003). However, 5′ UTR-based assays have some limitations. For example, some genotype 6 variants found in South East Asia have 5′ UTR sequences identical to those of genotype 1a or 1b (Tokita et al. 1994a, 1995; Mellor et al. 1996), although their geographical restriction is therefore not a major problem for assays carried out for clinical purposes in the USA, other western countries, and Japan. More problematic is the inability of 5′ UTR-based assays to reliably differentiate different subtypes, such as 1a from 1b, and 2a from 2c. While such information may be relevant for epidemiological purposes, the major clinical use of genotyping assays is, however, for pretreatment prediction of response and dose scheduling of interferon therapy (see Antiviral treatment). For this application, differentiation of genotype 1 from 2 or 3 is generally all that is required, and existing assays are acceptably accurate. Serological typing methods are based upon the detection of type-specific antibody to epitopes of HCV that differ between genotypes (Bhattacherjee et al. 1995; Simmonds et al. 1993c). Such assays may show high sensitivity and reproducibility, although antigenic similarity currently precludes the separate identification of subtypes, such as 1a and 1b or 2a and 2b using the NS4 peptides alone. Serological typing assays provide the only method to determine the originally infecting genotype of individuals who have cleared viremia.

Commonly used commercially available assays for HCV genotype include the VERSANT HCV genotype assay, the TRUGENE HCV 5′ NC genotyping kit (both from Bayer) and the Murex HC03 serotyping assay. The VERSANT assay is a hybridization assay using line probes immobilized on to nitrocellulose strips that capture labeled target sequences in a number of simultaneous highly sequence-specific hybridization reactions (InnoLipa II) (Stuyver et al. 1993a; Maertens and Stuyver 1998). The TRUGENE assay automates the direct sequencing of amplicons from the 5′ UTR, although this approach can in principle be extended to

other regions of the genome that may be more informative if reliable identification of different subtypes is required. The HC03 serotyping assay identifies type-specific antibody to genotypes 1–6 by ELISA using peptide from regions in the NS4A and 4B regions.

CONTROL OF HCV INFECTION

Antiviral treatment

Since the introduction of serological screening of blood products, acute HCV infection is seldom encountered in clinical practice. Small studies show that treatment with interferon (interferon-α and -β have been used) during the acute phase may be beneficial, and substantially reduces the risk of chronic infection (Omata et al. 1991; Lampertico et al. 1994; Jaeckel et al. 2001).

Combination antiviral therapy with interferon-α and ribavirin can cure a substantial proportion of patients with chronic HCV infection (Figure 10). Most clinicians now use a pegylated form of interferon-α. 'Pegylation' involves the covalent attachment of a molecule of polyethylene glycol to an interferon-alpha molecule. This alters the pharmacological properties of the interferon-alpha to prolong the plasma half-life. As a consequence, pegylated interferons are administered only once weekly. In comparison to the combination of nonpegylated interferon and ribavirin, the use of pegylated interferon and ribavirin is associated with significantly enhanced cure rates (Manns et al. 2001; Fried et al. 2002). Favorable predictors of response to antiviral treatment include HCV genotype (good response for types 2 and 3, inferior for type 1), low pretreatment viral titer, no or minimal liver fibrosis, female gender, and low BMI. In clinical trials, cure rates of approximately 50 percent have been achieved for genotype 1 patients and 80 percent for genotypes 2 and 3. Response to treatment can be monitored by quantitative HCV serum measurements.

Interferon-α and ribavirin may also be indicated for the treatment of extrahepatic manifestations of HCV infection, such as essential cryoglobulinemia and glomerulonephritis.

The mechanism by which different genotypes might differ in responsiveness to treatment remains obscure, particularly as it is still unclear whether interferon acts as an antiviral or as an immunomodulatory agent. Infection with genotypes 1, 2, and 3 all cause progressive liver disease with no evidence that type 1 is significantly more pathogenic than other variants. Similarly, studies of both blood donors and patients have indicated that virus loads are similar among individuals infected with different genotypes (Lau et al. 1995b). It is therefore unlikely that the greater response rates achieved with types 2 and 3 are simply secondary to differences in disease severity. Sequence comparisons demonstrated a

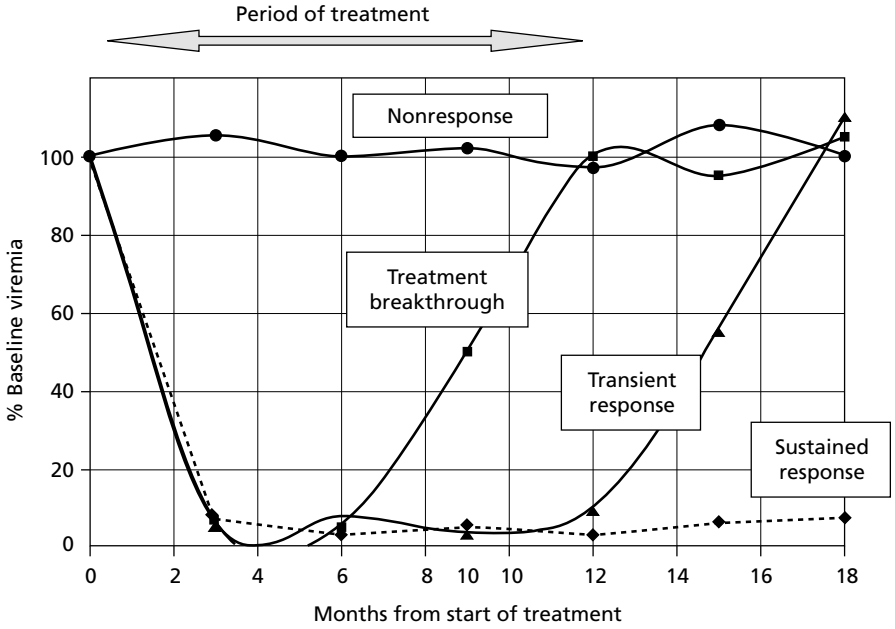

Figure 10 *Pattern of virological responses to interferon-α/ribavirin therapy. The response to HCV therapy is highly variable between individuals. A proportion of individuals, particularly those with genotype 1 infection will show no clearance of viremia after institution of therapy. Of those that clear viremia, three outcomes are commonly observed. Some individuals will relapse during treatment (treatment breakthrough), or after the end of the treatment schedule (transient response). Individuals who clear viremia and remain nonviremic in plasma over 6 months follow up (sustained response, dotted line) have cleared infection permanently. Clearance of viremia is almost invariably associated with normalization of biochemical markers of liver disease, such as ALT.*

cluster of amino acids in the NS5A region that consistently differed between responders and nonresponders to interferon treatment (Enomoto et al. 1995) (see Nonstructural proteins, NS5A).

The prospects for effective treatment of HCV is further enhanced by current progress in the development of several series of new antiviral agents that target the viral protease and RNA polymerase (De Francesco et al. 2003; Carroll et al. 2003; Sarisky 2004). The development of these small molecule inhibitors of HCV replication has been possible following the development of the HCV replicon culturing system, which allows large-scale screening of potential antiviral agents, and structure optimization by chemical modifications. Currently, the protease inhibitor, BILN2061 (Lamarre et al. 2003), and RNA polymerase inhibitors, NM283 and JT003 are in phase II clinical trial, while several more are in phase I or laboratory development. There are many parallels between the development strategy of HCV antivirals with those used for HIV-1 therapy. For example, some inhibitors of HCV RNA polymerase, such as 2-C-methyladenosine (Olsen et al. 2004), may act as chain terminating nucleoside analogue inhibitors, while nonnucleoside inhibitors, such as benzothiadiazines and benzimadoles bind noncatalytic sites in NS5B, and inhibit enzymatic activity though alterations in protein configuration (Sarisky 2004). Unfortunately, parallels with HIV therapy extend to the finding of large numbers of resistance mutations to all of the protease and RNA polymerase inhibitors developed to date (Nguyen et al. 2003; Lu et al. 2004); these spontaneously emerge after relatively short passaging of the replicon in the presence of antivirals in vitro. In the future, therapy with 2 or 3 antivirals targeting different enzymes may be effectively combined to reduce the frequency of treatment resistance.

Liver transplantation

Liver transplantation is indicated for patients with decompensated HCV cirrhosis and for some patients with hepatocellular carcinoma complicating HCV infection. In many countries, HCV-associated liver disease has become the most common indication for liver transplantation. Liver transplantation does not cure HCV infection, and reinfection of the graft is probably inevitable (Wright et al. 1992). Recurrence may be associated with hepatitis of the graft, which typically occurs within 6 months of transplantation. Short- and intermediate-term outcomes of graft infection are excellent, and reinfection has no discernible effect on patient morbidity or mortality during the first 3 years or so after transplantation. Liver disease is more aggressive in the setting of immunosuppression. There is a need to develop strategies for the treatment of HCV reinfection of the transplanted liver, which might also be applied to the treatment of other immunosuppressed patients (e.g. renal transplant patients) with hepatitis due to HCV infection.

It is clear that pegylated interferon and the combination of interferon and ribavirin can cure a proportion of patients with recurrent HCV after liver transplantation (Bizollon et al. 1997). As observed for the nontransplant patient, viral genotype appears to be the most important determinant of response to treatment. Unfortunately, antiviral treatment is poorly tolerated by post-transplant patients who are more likely to experience the adverse hematological side-effects of both interferon and ribavirin. Thus, compliance with therapy may be poor in this setting, and results (on an intention-to-treat analysis) are disappointing.

Prevention

Screening of blood donors has proved to be effective in preventing transmission of HCV infection through blood transfusion. For example, the incidence of post-transfusion hepatitis fell from 10.7 to 1.9 percent in Spain (Gonzalez et al. 1995) and from 7.7 to 2.1 percent in Japan (Japanese Red Cross Non-A, Non-B Hepatitis Research Group 1991) following the introduction of first-generation screening assays. Most of the donations that were missed using this initial test would have been identified as positive by second- or third-generation assays (Aach et al. 1991; Gonzalez et al. 1995; Yuki et al. 1992; Aoki et al. 1994). A combination of blood donor screening and virus inactivation has virtually eliminated HCV transmission by blood products, such as clotting factor concentrates and immunoglobulins.

The main continuing risks for HCV transmission are intravenous drug abuse and the use of unsterile needles for medical and dental procedures, tattooing, and other percutaneous exposures. Much of this could be prevented by education, greater availability of disposable needles and, for drug abusers, needle exchange programs. Many of the public health measures adopted to prevent transmission of HIV by parenteral routes will assist efforts at controling HCV.

Immunization

The development of a vaccine for HCV faces a series of formidable obstacles. HCV is highly heterogeneous, and effective vaccines may need to be multivalent in a way analogous to poliovirus vaccine in order to be protective against multiple serotypes. Furthermore, the high rate of chronicity and the continued susceptibility of HCV-infected individuals to reinfection (see Chronic hepatitis) had suggested that a protective immune response may be difficult to achieve by immunization. However, the protection from rechallenge observed in chimpanzees with resolved genotype 1 infections may be more analogous to the immune status of a vaccine, and

provides some optimism that antigens that provoke T-cell responses of similar intensity to natural infection may be protective, not only from homologous challenge, but also from infections with other genotypes.

Vaccine development has been relatively slow, partly because chimpanzees are the only in vivo model to investigate the efficacy of different putative HCV vaccines, making experiments and trials extremely expensive, and placing severe limitations on the number of immunization and challenge experiments that can be carried out. Despite these difficulties, encouraging results have been obtained using recombinant envelope proteins (E1 and E2) expressed in mammalian cells as immunogens. These induce a short-lived specific anti-E1 and E2 response in immunized chimpanzees, and a partially protective effect from challenge with low titers of the homologous virus (Choo et al. 1994; Houghton et al. 1998). Chimpanzees that became infected showed reduced levels of viremia on seroconversion, and greater likelihood of spontaneously clearing infection. In recognition of the likelihood that effective vaccines may have to contain immunogens that stimulate T-cell responses rather than just neutralizing antibody, many of the more recently developed candidate vaccines have used antigenic components from the core gene in the form of immune-stimulating complexes, virosomes, or liposomes (Polakos et al. 2001; Hunziker et al. 2002). Rather than immunize with viral proteins, T-cell responses may be more effectively induced with live vectors, such as rabies virus (Siler et al. 2002) or the alphavirus, Semliki Forest virus (Brinster et al. 2002). DNA-based vectors have also been used, designed to express HCV core or envelope coding sequences in situ after immunization (Brinster and Inchauspe 2001; Major et al. 1995; Forns et al. 2000; Geissler et al. 1998). These potently induce both T-cell responses and antibody reactivity to the immunizing proteins, and where tested, induce partial protection in experimentally challenged chimpanzees, with comparable modification to the course of infection noted for the original E1/E2 vaccines. While the lack of sterilizing immunity in chimpanzees induced by vaccination is somewhat less than originally hoped for, HCV vaccines do have potential prophylactic value in preventing a significant proportion of exposed individuals from developing chronic infection. If the vaccines can be manufactured on a large scale and at low economic cost, there is clearly future scope for large-scale prevention of HCV-induced liver disease on a worldwide scale.

Hepatitis B

WOLFRAM H. GERLICH AND MICHAEL KANN

Introduction	1	Clinical and pathological aspects	20
Properties of the virus	2	References	36

INTRODUCTION

Epidemic jaundice was described by the Babylonians, but the infectious nature of the disease and the involvement of the liver were not recognized until the late nineteenth century. In general it was believed that bad living conditions, particularly during wars, generated the catarrhal jaundice. In 1885, Lürmann observed an outbreak of jaundice 2–8 months after people had been given smallpox vaccine. This outbreak was probably caused by hepatitis B virus, since the vaccine had been prepared from human lymph. A larger outbreak of hepatitis caused by vaccination occurred in 1937 when soldiers developed severe jaundice after receiving a yellow fever vaccine containing human serum (Findlay and MacCallum 1937). On the basis of epidemiological studies, two types of agents were suggested: type A, causing large outbreaks via the fecal–oral route, and type B, transmitted mainly by human serum. Hepatitis B was therefore also called homologous serum hepatitis. During the 1970s it became apparent that more than one virus species may transmit hepatitis predominantly by the parenteral route (hepatitis C virus and hepatitis delta virus), but the first identified virus of parenterally transmissible hepatitis was called hepatitis B virus (HBV).

Early efforts to identify HBV failed because it did not grow in tissue cultures or the usual experimental animals. Only humans and higher primates (hominoidae), for example, chimpanzees, are reliably susceptible to HBV. Eventually, the surface protein of HBV was accidentally discovered in 1965 during the search by the anthropologist B.S. Blumberg for polymorphic serum proteins as genetic markers in the blood of an Australian aborigine (Blumberg et al. 1965), and was called Australia antigen. Two years later, the association between the occurrence of the Australia antigen and serum hepatitis infection was recognized (Blumberg et al. 1967). Australia antigen was exposed at the surface of pleomorphic, spherical or filamentous particles of 17–25 nm diameters, which did not contain nucleic acid and were therefore most likely not infectious agents. Among these more numerous particles, Dane and colleagues (1970) detected some larger double-shelled viruslike particles 42 nm in diameter (Figure 1). The surface of these so-called Dane particles cross-reacted with antibodies against Australia antigen. Their significance as the potential viral agent of hepatitis B was confirmed by the detection of antibodies against the inner shell, termed core or nucleocapsid, of the Dane particle in patients with acute hepatitis B. The core antigen was called HBcAg; the Australia antigen was called hepatitis B surface antigen (HBsAg). These antigens induce the corresponding antibodies anti-HBc and anti-HBs. Anti-HBc is a serological marker for previous and current HBV infections, whereas HBsAg is a marker for a current HBV infection. Using these epidemiological markers, it became apparent that HBV is a common human pathogen that causes acute and chronic liver disease throughout the world, particularly in Southeast Asia and sub-Saharan Africa. Chronic illness develops in 5–10 percent of infected adolescents or adults, but in up to 90 percent of infected neonates. Chronic HBV infection is a major cause of liver cirrhosis and primary liver cell carcinoma (Beasley et al. 1981). About half of the world's population has had contact with HBV.

PROPERTIES OF THE VIRUS

Classification

In 1973, an endogenous DNA polymerase activity (i.e. an enzyme that incorporates nucleotides into DNA without addition of an exogenous template) was discovered within Dane particles (Kaplan et al. 1973). The endogenous template was a circular partially double-stranded DNA of ca. 3 200 nucleotides (nt) (Landers et al. 1977). It was found that the DNA strand of negative polarity was transcribed inside the core particle from an encapsidated RNA template, suggesting a replication strategy similar to retroviruses (Summers and Mason 1982).

The observation that liver carcinoma occurred in the Eastern woodchuck (a marmot of the North American east coast) led to the discovery of the HBV-like *Woodchuck hepatitis B virus* (WHV), the closely related *Ground squirrel hepatitis virus* (GSHV), and recently in a variety of primates including chimpanzees, orangutans, gorillas, gibbons, and woolly monkeys. HBV-like virus species were also found in Peking ducks (*Duck hepatitis B virus* (DHBV)), gray herons *Heron hepatitis B virus* (HHBV), and other waterfowl. All these viruses are highly species specific; for example, the heron HBV does not infect ducks, and the woodchuck virus does not infect ground squirrels. Some of these animal models are very useful for elucidating the replication and pathogenesis of HBV. The great molecular and biological similarity of these viruses led to the definition of a common virus family, *Hepadnaviridae* (from *hepar*, liver, and DNA, for the type of the genome) (Mason et al. 2005). The mammalian viruses form the genus *Orthohepadnavirus* (HBV, WHV, GSHV). Because of significant structural differences the avian viruses form a separate genus, *Avihepadnavirus* (for example, DHBV, HHBV).

Although the genome organization, biology, and replication of hepadnaviruses are quite different from those of the *Retroviridae*, the common strategy of reverse transcription places them and the *Caulimoviridae* of plants (Toh et al. 1983) into one class of viruses. *Hepadnaviridae* and *Caulimoviridae*, with their DNA genomes, have also been called pararetroviruses, in contrast to the orthoretroviruses with an RNA genome.

Morphology and structure

All well-characterized hepadnavirus species appear after negative staining in the electron microscope as double-shelled particles of ca. 42 nm diameter (Figure 1). In mammalian hepadnaviruses the surface of the virions consists of several hundred (possibly 240) subunits comprising three different membrane-spanning polypeptides, termed L(arge), M(iddle), and S(mall) surface (HBs) proteins (Figure 2; and see Figure 6, below). These proteins are carboxy-terminally co-terminal and differ in additional amino-terminal domains. Thus, LHBs consists of an S domain and a preS domain (i.e. preS1 plus preS2 domain) (Heermann et al. 1984). The preS domain of LHBs can be localized externally or internally (Bruss et al. 1994; Lambert and Prange 2003). MHBs contains only the preS2 and the S domain whereas SHBs consists only of the S domain (Figure 2 and Figure 6). Because all HBs proteins can be glycosylated at one or two positions, six different proteins, GP42, P39, GP36, GP33, GP27, and P24, can be distinguished whereby G indicates glycosylation and the number the molecular weight (kDa). Compared with the amount of core particles, these HBs proteins are

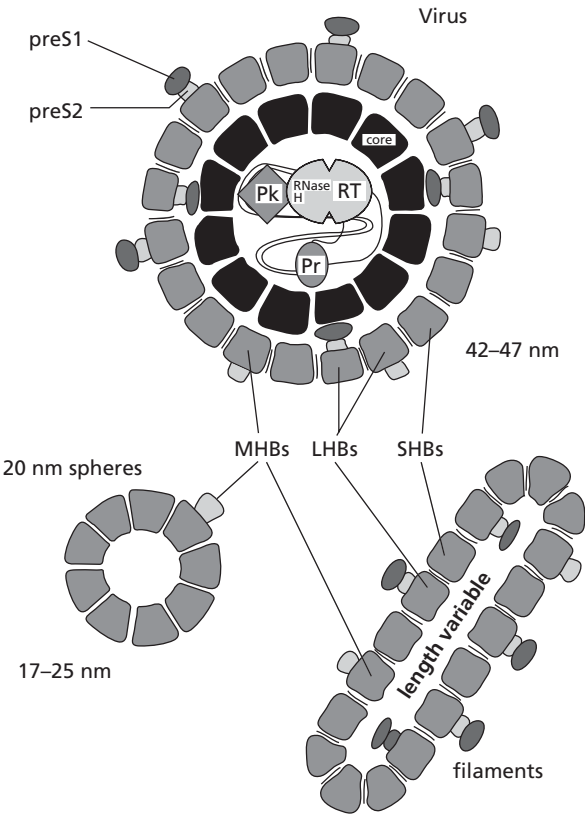

Figure 2 *Schematic presentation of hepatitis B virus and subviral HBsAg particles. DNA is drawn as a single or double line. Structural proteins: the viral polymerase is depicted in gray with a priming domain (Pr), the catalytic domain (RT), and RNase H. The nucleocapsid (core or HBc) is shown in black. Each block represents a dimer; 120 dimers comprise a particle. The surface proteins are shown in gray, with a middle gray S domain, a light gray preS2 domain, and a dark gray preS1 domain. For the topology of the surface proteins, see Figure 6. The virus particles also contain a cellular protein kinase (Pk) and cellular chaperones that are not shown here.*

overexpressed and assemble either to subviral spheres of ca. 20 nm diameter or to filamentous structures, depending on the composition of the different surface proteins (Figure 2). In serum samples of highly viremic individuals, these particles can be found in up to 1 000-fold excess.

In contrast to the mammalian hepadnaviruses, the avian hepadnaviruses are not glycosylated and have only a large (36 kDa) and a small (18 kDa) surface protein and thus do not have division of the preS domain into preS1 and preS2 subdomains. Like the mammalian hepatitis B viruses, these proteins are overexpressed, resulting in the secretion of spherical particles of ca. 40–60 nm diameter.

Both the virion and the surface antigen particles are assembled at the endoplasmic reticulum (ER) and bud to the lumen of a post-ER intermediate compartment. Thus the lipid in the outer protein shell or the HBs particles is derived from an intracellular compartment and not from the plasma membrane. In contrast to other enveloped viruses the lipid content seems to be lower, resulting in a relatively high density of 1.16 g/ml in sucrose. Furthermore, the subunits of blood plasma-derived HBs particles are cross-linked by disulfide bonds and do not disassemble after the addition of detergent.

Within virions the surface proteins enclose the core which encapsidates the viral genome. The core particles interact with the internally localized preS domain of LHBs (Bruss 1997; Ponsel and Bruss 2003) (Figures 2 and 6d). The core protein consists of ca. 185 amino acids (HBV) with a basic carboxyterminus of four arginine-rich clusters. The core molecules form dimers in the cytosol (Zhou and Standring 1992), which are linked by disulfide bridges after release from the reducing environment in the cytosol (Jeng et al. 1991).

Capsid assembly occurs spontaneously. It is initiated by trimerization of the dimer (Zlotnick et al. 1999) and results in two populations of icosahedral core particles, either with a T = 3 or a T = 4 symmetry. They are composed of 180 and 240 core proteins respectively, and show diameters of 32 and 36 nm (Crowther et al. 1994; Kenney et al. 1995). The capsids do not form a closed shell but contain 2-nm holes that allow diffusion of nucleotides into the lumen. They show spikes on their surface, which have been successfully used as carrier sites for foreign epitopes in a highly immunogenic conformation (Pumpens and Grens 2001). Although capsid formation does not require any other viral component, the presence of RNA strongly enhances the assembly. This phenomenon is caused by the stabilizing interaction of RNA and the arginine clusters. Consequently, truncated core proteins lacking the carboxyterminus show a much slower assembly kinetic and are less stable than the wild-type. The localization of the carboxyterminus is, however, flexible. While being internally localized in RNA-containing core particles (Zlotnick et al. 1999) genome maturation results in an exposure on the capsid surface (Rabe et al. 2003).

In a patient's liver or in other eukaryotic cells, but not in bacteria, the assembly of the core particles is combined with the encapsidation of a cellular protein kinase. It is known that it phosphorylates serine residues within the carboxy-terminal part of the core protein (Gerlich et al. 1982). Reports on the trapped protein kinase are divergent (Barrasa et al. 2001; Daub et al. 2002, Duclos Vallee et al. 1998; Kau and Ting 1998; Kann and Gerlich 1994; Kann et al. 1993). Possibly, different kinases can replace each other regarding their function. In infected human liver, or artificial genome-expressing cell cultures, core particles encapsidate a complex of the pregenomic RNA and the viral DNA polymerase. The polymerase transcribes the pregenomic RNA into a negative DNA strand, which is used as the template for second strand DNA synthesis. The viral polymerase consists of four domains: (1) the priming

domain; (2) a so-called spacer or tether; (3) the reverse transcriptase domain, which catalyses RNA-dependent DNA synthesis; and (4) the RNase H domain, which degrades the RNA from the resulting DNA–RNA hybrid (for review, see Nassal and Schaller 1996). Because HBV DNA in infected hepatocytes remains unintegrated as an episomal minichromosome (Bock et al. 2001), the HBV polymerase is, in contrast to retroviral polymerases, devoid of an integrase domain. Furthermore, no protease domain has been identified such as is found in retroviruses.

Genome structure and function

The HBV genome consists of a circular, partially double-stranded DNA in which the longer strand of negative polarity is ca. 3 200 nt long (Figure 3A). The 5′ end of this strand has a terminal redundancy of 8–10 nt. It is covalently bound to the primer domain of the viral polymerase. The polymerase presents the hydroxyl residue of tyrosine 96 (DHBV) or tyrosine 63 (HBV) as the acceptor for phosphodiester linkage to the first nucleotide of the negative DNA strand. The 5′ and 3′ end of this DNA strand are not covalently linked. The circular structure is caused by base pairing of the negative with the positive DNA strand at the discontinuity around the two ends of the negative DNA strand. The positive DNA strand has a defined 5′ end ca. 230 nt (HBV) upstream of the 3′ end of the negative DNA strand. The 5′ end is linked to a capped RNA oligonucleotide, 18 nt long that acts as a primer for second strand DNA synthesis and represents the undegraded 5′ end of the pregenomic RNA (see section entitled Replication, below, and Figure 3a). The length of the positive DNA strand varies between 1 100 and 2 600 nt,

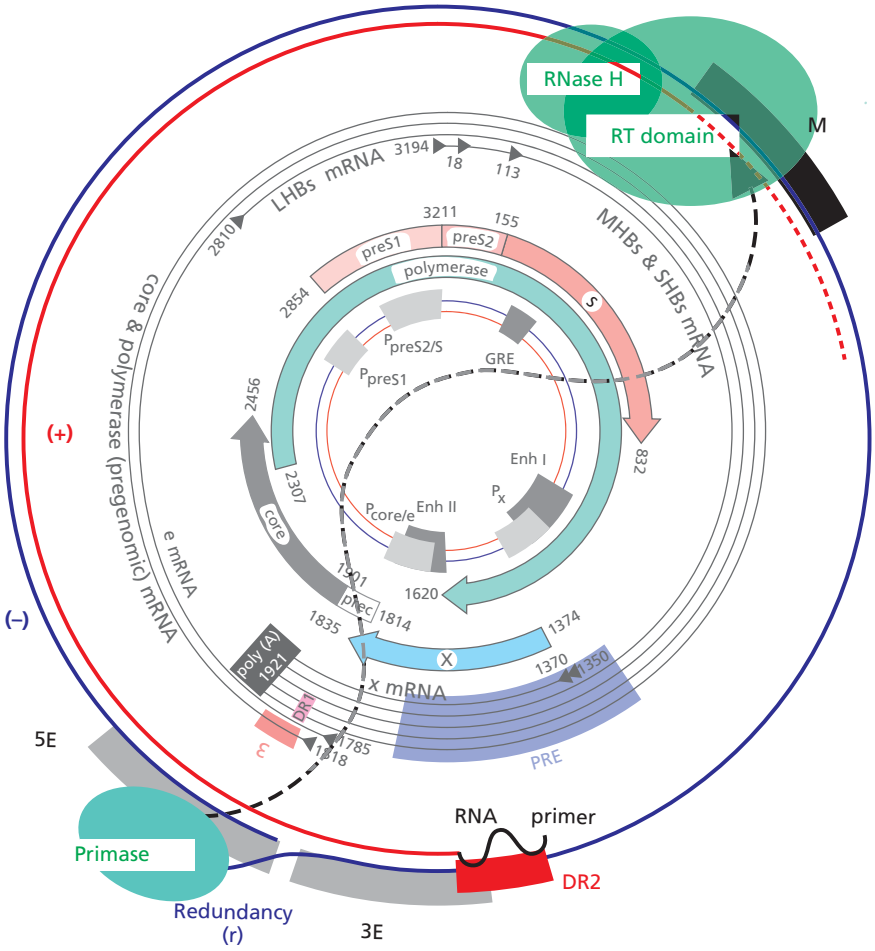

Figure 3 *Genome organization of HBV. Numbering follows the system of Galibert et al. (1979) and is shown for genotype A2 isolate 991 (GenBank association no. X51970.* **(a)** *Structure of virion DNA shown as the outer circle. The minus strand has a redundancy of 8–10 nt at the ends and is covalently linked to the primer (pr) domain of the polymerase. The active center of the reverse transcriptase domain (RT) is probably associated with the variable 3′ end of the incomplete plus strand, the RT domain is covalently linked with the primer domain via the tether domain. The plus strand starts at the 5′ end with a mRNA-derived cap and the 18 5′ terminal remaining bases of the RNA pregenome which are base-paired with the direct repeat DR2 to the minus strand. The circularization elements 5E, 3E, and M are also shown.* *(continued over)*

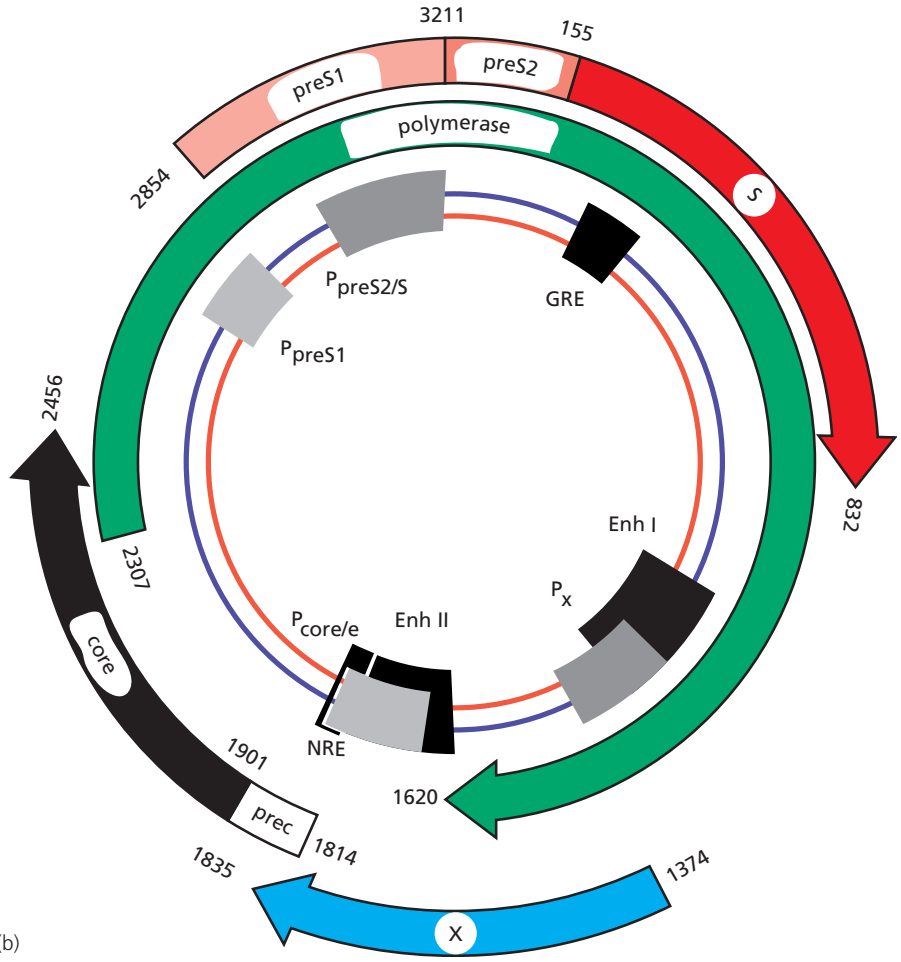

Figure 3 *Genome organization of HBV. Numbering follows the system of Galibert et al. (1979) and is shown for genotype A2 isolate 991 (GenBank association no. X51970. depending on how far the viral polymerase has proceeded. Therefore a single-stranded region of 600–2 100 nt is left and this gap can be partially filled in vitro by the viral polymerase after the addition of deoxynucleotides.

Cloning and sequencing of HBV DNA by many groups of workers confirmed the physical structure of the DNA. The genome of wild-type hepadnaviruses contains four conserved, partially overlapping, open reading frames (ORF) (Figure 3b), all on the negative DNA strand (Schlicht and Schaller 1989). Thus, the coding capacity of the 3 200 nt corresponds to 5 500 nt (had the ORFs been arranged in a linear manner). The ORFs encode:

- The core protein and an additional precore region which includes a signal peptide sequence; this additional precore peptide results in a secreted, proteolytically modified form of the core protein, called HBe (see section entitled Nonstructural proteins, below)
- The DNA polymerase
- The nested set of surface proteins
- A protein of unknown function, X protein (HBx), which was believed to be absent in the avian hepadnaviruses. Recent studies, however, describe the expression of an X-like protein from the DHBV genome via an unusual initiation site and the existence of an X-related gene in other avihepadnaviruses (Schuster et al. 2002).

The expression of the ORFs is controlled by at least four promoters, enhancers I and II (for review, see Tang and McLachlan 2001), glucocorticoid-responsive elements (GRE) increasing transcription, and a negative regulating element (NRE) that selectively inhibits the transcription from the core/precore promoter. Termination of transcription is encoded by a single polyadenylation signal so that all viral mRNAs share a common 3′ end.

On the level of the transcribed mRNAs, additional regulatory elements are found. Present on all mRNAs is the so-called post-transcriptional regulatory element (PRE), which suppresses splicing of the transcribed

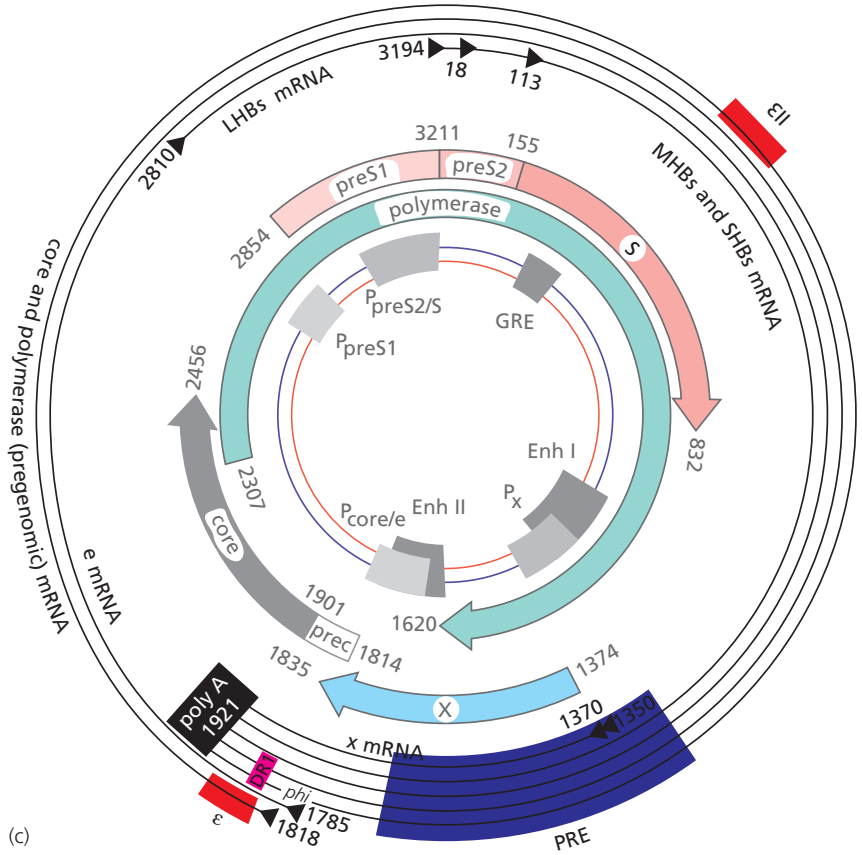

Figure 3 *Genome organization of HBV. Numbering follows the system of Galibert et al. (1979) and is shown for genotype A2 isolate 991 (GenBank association no. X51970. RNAs (Huang and Liang 1993). The pregenome contains signals to support reverse transcription and the formation of circularized DNA. This includes the ϵ signal, required for binding of the viral polymerase and subsequent initiation of reverse transcription, two direct repeats (DR) of 11 nt (orthohepadnavirus), which are termed DR1 and DR2. The minus-strand DNA, which is the product of reverse transcription of the RNA pregenome, comprises the M region, which supports the correct translocation of the polymerase to the site where subsequent plus-strand DNA synthesis is initiated. Circularization of the minus strand requires additional elements (Liu et al. 2004) as the terminal redundancy of the minus strand (r) and two flanking domains called 5E and 3E (Figure 3a) (see section entitled Replication, below).

Replication

OVERVIEW OF THE VIRAL LIFE CYCLE

Figure 4 outlines the essential steps in the viral life cycle. The mode of attachment and entry is not unequivocally identified. The uptake by clathrin-mediated endocytosis has been suggested for DHBV (Köck et al. 1996) (Figure 4). Recent data suggest actin-independence and microtubule-dependence of viral entry (Funk et al. 2004). These findings support the idea of endocytosis since endosomes are transported via microtubules towards the perinuclear region. Because hepadnaviruses multiply via RNA generated by the cellular RNA polymerase II, the DNA genome must be transported into the nucleus. Consequently, the DNA genome must escape from the endosome in a complex with viral proteins, which facilitate the transport towards the nuclear envelope. To pass the nuclear envelope, the genome must be transported through the nuclear pore complexes (NPC), which are the only sites for macromolecule exchange between the cytoplasm and the nucleus. At least inside the karyoplasm, the genome must be accessible to transcription factors and the polymerase II, which transcribes different sets of mRNAs.

For genome replication, one mRNA species of supergenomic length is used. This mRNA is translated into core protein and, in an overlapping reading frame, into the viral polymerase. This RNA can then specifically interact with the viral polymerase and cellular chaper-

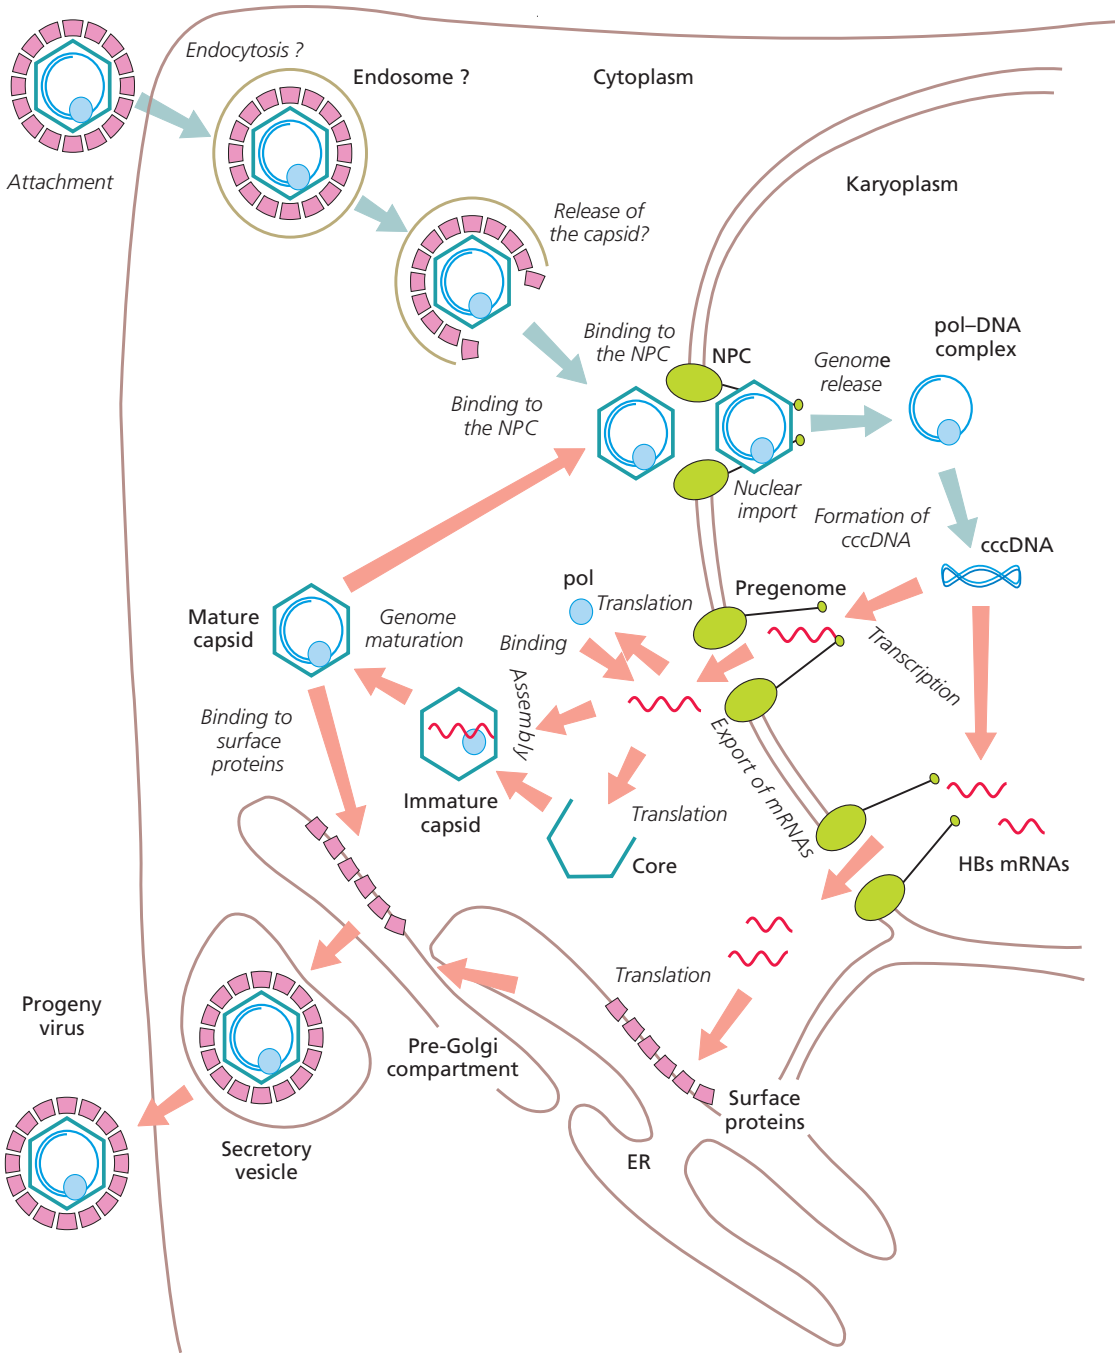

Figure 4 *Schematic presentation of the HBV replication cycle. Details of the figure are given in the text.*

ones. This complex is specifically encapsidated by the core protein into particles (Hu et al. 2002). Phosphorylation of at least some core protein subunits is required for the encapsidation (Gazina et al. 2000). Within the core particle, the encapsidated RNA serves as the template for reverse transcription and is therefore also called pregenomic RNA. The core particle containing the mature DNA genome can be either enveloped into the surface proteins and secreted as mature virus into the bloodstream or it can release the encapsidated DNA into the nucleus of the infected cell, leading to an amplification of the episomal viral DNA.

ATTACHMENT AND ENTRY

HBV infects naturally only humans and hominoidae, and is highly adapted to fully differentiated hepatocytes. Hepatocyte cultures are only susceptible for a very short time window, 1–3 days after explantation from the organ. Susceptibility can be prolonged and enhanced by addition of dimethyl sulfoxide and special hepatocyte media.

Primary duck hepatocytes are highly susceptible for DHBV and produce progeny virus after 2 days. Mammalian hepatocyte cultures are more difficult to obtain and less susceptible. Usually they require high virus input and produce little progeny virus with no spread from cell to cell. Permanent cell lines from hepatomas are usually not susceptible, but if transfected with double-stranded HBV DNA covering all genes, they express infectious HBV. Thus, the block in the susceptibility of permanent cell cultures comes at an early step in the viral life cycle before formation of covalently closed circular DNA (cccDNA). True infection requires species-, organ-, and differentiation-specific factors acting on attachment and uptake of the virus. Recently, a redifferentiated hepatoma cell line, Hepa RG, has been established which is after redifferentiation as susceptible as primary human hepatocytes (Gripon et al. 2002).

The scarcity of surgically obtained human liver and the low efficiency of the cell cultures have severely hampered studies on these early steps, but some limited data have been obtained for HBV. Additionally, studies with animal hepadnaviruses have been helpful. The preS1 protein sequence 10–36 (21–47 in HBV genotype A) is essential for binding of HBV to human hepatocyte membranes, and binding can be blocked by competing peptides or by antibodies against that sequence (Neurath et al. 1986; Pontisso et al. 1989). Such antibodies also block infection of primary human hepatocyte cultures (Maeng et al. 2000). Antibodies against SHBs in natural conformation also block infectivity, but a generally accepted role of SHBs in attachment has not been identified. Emergence of escape HBV mutants in infected anti-SHBs positive patients (Carman et al. 1997; Nainan et al. 2002) confirms the essential role of the SHBs antigen loop from amino acids 100–160 in vivo for viral spread. The woolly monkey hepadnavirus (Lanford et al. 1998) can infect human hepatocyte cultures, but much less efficiently than HBV. The determinant of the host range of this virus has been mapped to the region preS1 (1–40) that is also essential for attachment, with amino acids 5, 27, and 30 being most divergent (Chouteau et al. 2001).

In spite of their narrow host specificity, the human and the woolly monkey HBV, but not woodchuck HBV, quite efficiently infect primary hepatocyte cultures from the livers of *Tupaia belangeri* (Köck et al. 2001). These are small animals living in the tropical forests of South East Asia forming their own order (*Scandentia*) among the mammalians, unrelated to primates. They can be bred in large numbers in captivity and provide a more available source of fresh liver tissue than humans or primates. Using *Tupaia* hepatocytes for measuring infectivity of HBV, monoclonal antibodies against preS1 20–23 and against native SHBs have been found to be completely neutralizing while preS2 antibodies and a sequential SHBs antibody neutralized only partially (Glebe et al. 2003). With DHBV, both preS and S antibodies have also been found to be neutralizing (Sunyach et al. 1999). As with human HBV, the preS sequence of DHBV is essential for binding and uptake and determines the host range (Ishikawa and Ganem 1995). Infectivity of HBV and DHBV for hepatocytes requires the myristoylation of the conserved glycin 2 of the preS domains (Bruss et al. 1996). Competing preS peptides are also more potent inhibitors if myristoylated (Urban and Gripon 2002). The preS sequence of DHBV binds to duck carboxypeptidase D that is an essential, but not sufficient, receptor for infection (Kuroki et al. 1995; Urban et al. 2000). For human HBV, numerous candidate receptors have been described, binding either to preS1, preS2, or SHBs but a connection to the infection process could up to now not be demonstrated.

The preS2 domain of HBV binds a modified form of natural human or primate serum albumin (Krone et al. 1990). The nature of the modification is unknown but it can be mimicked by treatment with glutaraldehyde. Such a modified human serum albumin mediates binding of preS2-containing HBsAg particles including HBV to human hepatocyte membranes (Pontisso et al. 1989), but it is not known whether this phenomenon contributes to infection. LHBs and SHBs are essential for both morphogenesis and infectivity of HBV or hepatitis delta virus (HDV), the envelope of which is derived from HBV. MHBs is nonessential for infectivity of HBV or HDV. Natural or artificial deletion mutants without the MHBs start codon are viable in patients and in cell cultures.

Recent work suggests a slow, actin-independent entry of DHBV, the details of which are not understood (Funk et al. 2004). The receptor for DHBV, carboxypeptidase D, shuttles between plasma membranes and the Golgi apparatus and may mediate uptake of DHBV into the cells (Breiner et al. 1998). The postulated second receptor mediating entry to the cytosol is still unknown. All hepadnaviruses at the amino end of the S domain or SHBs protein contain a short hydrophobic sequence that is similar to fusion peptides of many enveloped viruses. This sequence can indeed replace the fusion peptide in influenza virus hemagglutinin in the step of membrane fusion (Berting et al. 2000) and may play a similar role during entry of hepadnaviruses. In HBV-infected *Tupaia* hepatocyte cultures, HBV binding is very efficient, but the later steps seems to occur at low efficiency (Glebe et al. 2003).

At least in DHBV, the entire capsid is transported towards the nuclear envelope (Köck et al. 2003). Unpublished data after lipofection of HBV capsids reveal that this transport is indeed facilitated by using the cellular microtubule transport machinery (Rabe and Kann 2005) as was shown for other viruses (Whittaker et al. 2000).

NUCLEAR ENTRY AND FORMATION OF EPISOMAL VIRAL DNA

Liver cells are differentiated cells of which the vast majority are nondividing. As with other viruses replicating in the nuclei of arrested cells, the hepadnaviral

genome has to travel through the cytoplasm towards the nuclear pores followed by passage through the pore. Furthermore, the conversion of the relaxed circular (rc) viral DNA to the cccDNA by cellular enzymes (Köck et al. 2003) requires its release from the capsid.

Most knowledge on the subsequent passage through the nuclear pores has been obtained by in vitro systems established for studying the nuclear import of cellular proteins. It has been shown that nucleocapsids bind to the NPC, following the 'classical' pathway of karyophilic proteins, which is mediated by the cellular proteins importin α and β (karyopherin α (and β). The exposure of a corresponding nuclear localization signal (NLS) on the surface of the nucleocapsids, which is bound by importin α, is dependent upon genome maturation and/or phosphorylation of the core subunits (Kann et al. 1999). In contrast to herpes virus capsids and adenoviruses, which also migrate to the NPC, HBV capsids are small enough to pass the nuclear pore as entire particles (Panté and Kann 2002), as demonstrated after microinjection into *Xenopus* oocytes.

After release from the capsid within the nuclear basket (Rabe et al. 2003), the partially double-stranded DNA genome with its protein primer at the 5′ end of the negative DNA strand and its RNA primer at the 5′ end of the viral positive strand, must be converted by cellular DNA modifying enzymes to a cccDNA. In fact, formation of cccDNA is the first marker of successful infection, followed by replicative intermediates after 24 h. The central role of cccDNA for transcription of viral RNAs was confirmed by infecting chimpanzees with cloned, circular HBV DNA via intrahepatic injection (Will et al. 1985). The following steps for the generation of cccDNA are implied: (1) removal of the 5′ terminal redundancies from the negative strand and removal of the covalently bound polymerase; (2) removal of the RNA primer; (3) completion of the positive DNA strand; and (4) linkage of the 5′ and 3′ ends of each strand by DNA ligase. The positive DNA strand may be filled up by the viral polymerase (Köck et al. 2003), but cellular polymerases may be also required, because treatment of primary hepatocytes with ddG, an inhibitor of cellular DNA polymerases, resulted in suppression of cccDNA formation (Köck and Schlicht 1993).

TRANSCRIPTION AND TRANSLATION

The four promoters and two enhancers of HBV control expression of at least five overlapping RNAs of different sizes (see Figure 3c) by the cellular RNA polymerase II (for a review: Moolla et al. 2002). Like most eukaryotic mRNAs, the viral transcripts include a CAP structure at their 5′ terminus and are polyadenylated at their 3′ end. The genome contains only one polyadenylation signal TATAAA, which is conserved in all mammalian hepadnaviruses. The transcripts contain many potential splice donor and acceptor sites, but they also contain a splice-suppressing sequence, homologous to the rev-responsive element (RRE) of human immunodeficiency virus (HIV). The corresponding sequence in hepatitis B viruses was termed PRE (Huang and Liang 1993). PRE acts context-dependently consistent with the observation that it has a secondary structure (Loeb et al. 2002). In contrast to the HIV-RRE however, the HBV RNA export is not sensitive to leptomycin B (Zang and Yen 1999), indicating that the nuclear export factor chromosome region maintenance (CRM)-1 is not involved whereas the corresponding WHV element is CRM-1 dependent (Popa et al. 2002). Probably, HBV-PRE acts like the constitutive transport element (CTE) found in the export of unspliced Mason–Pfizer monkey virus (MPMV) RNAs. CTE override the retention of intron-containing RNAs by a direct interaction with the export factor TAP, which is leptomycin insensitive. Polypyrimidine tract binding (PTB) protein has been reported to bind to PRE and to contribute to the nuclear export of HBV RNAs (Zang et al. 2001). HBV RNAs are post-transcriptionally down-regulated upon cytokine induction. The decrease of HBV mRNAs however is counteracted by a stabilization of the HBV transcripts mediated by the association to the autoantigen La (Heise et al. 1999). La was shown to bind to a stem–loop structure located between nts 1275 and 1291 of HBV. It was reported that the turnover of HBV RNAs depends on structural features and less on the primary nucleotide sequence (Ehlers et al. 2004).

As in most eukaryotic mRNAs, the first reading frame is most efficiently translated. Thus, the different mRNAs are named after the first encoded ORF HBe-, HBc/pol-, preS1-, preS2/S-, and X-RNA. Among these RNAs, two sets can be discriminated: RNAs of subgenomic length, encoding X and the surface proteins; and RNAs longer than the genome (supergenomic RNAs), encoding HBe, core, and polymerase. Regulation of transcription from the HBV genome has been studied in great detail.

The HBx RNA of mammalian hepadnaviruses is ca. 700 nt long, and starts at two closely situated initiation sites (Schaller and Fischer 1991). The presence of multiple binding sites for liver-specific transcription factors (hepatonuclear factors (HNF) 3 and 4; C/EBP) in its promoter, which overlaps the enhancer I, makes it likely that the transcription of this RNA is regulated in a tissue-specific manner, but it can also be expressed in a large variety of nonhepatic cell lines.

The major transcript of the HBV genome of ca. 2.1 kb does not contain a clearly defined 5′ end, and is well transcribed in a large variety of hepatic and nonhepatic cell lines (Cattaneo and Will 1983). This subspecies of mRNA contains the preS2 and S regions with their start codons, resulting in the expression of MHBs when the first AUG is used. In most translation events, the second AUG is used, leading to the expression of the small surface protein, SHBs (Gallina et al. 1992). Its promoter

is called preS2/S promoter and consists mainly of ubiquitously active SP1 binding sites (Raney et al. 1992), which explains the wide variety of cell lines and tissues in which the SHBs can be expressed.

In contrast to the above-mentioned transcripts, the LHBs-encoding mRNA of ca. 2.4 kb is transcribed in a liver-specific manner (Antonucci and Rutter 1989), requiring the presence of the liver-specific transcription factors HNF1 and 3 (Raney and McLachlan 1995). Because the expression of the encoded LHBs protein is essential for virus envelopment and secretion (Bruss and Ganem 1991), activation of the LHBs promoter seems to be an essential element in HBV–host cell restriction. In DHBV-transfected cells and DHBV-infected ducks, a common additional spliced mRNA is found with the start site of the pregenomic transcript, which seems to be essential for virus production (Obert et al. 1996). Because the resulting mRNA has the same length as the major LHBs mRNA, splicing of a 1.1 kb intron seems to be most probable. While splicing does not seem to be essential for HBV, various splice products have been identified in hepatocellular carcinoma cell lines (Rosmorduc et al. 1995) and in patients (Günther et al. 1996). A hepatitis B spliced protein (HBSP) composed of a fragment of pol and a new ORF seems to be often expressed and antibody against it may be associated with the generation of fibrosis (Soussan et al. 2003).

Two sets of supergenomic mRNAs exist, both of ca. 3.3 kb in length, being terminally redundant in ca. 150 nt. Owing to the redundancy of the RNAs, the polyadenylation signal, localized downstream of the AUG of the core ORF, must be ignored on the first passage of the transcription machinery. Apparently, this phenomenon is caused by the surrounding nucleotide sequences and by the length of the upstream region (Cherrington et al. 1992).

The transcription of these supergenomic RNAs is controlled by the core promoter and enhancer II which are liver specific owing to binding sites for nuclear hormone receptors, such as HNF4, retinoid X receptor, and peroxisome proliferator-activated receptor alpha (Tang and McLachlan 2001). The core/HBe promoter initiates the transcription of a subset of two classes of RNAs, which differ by ca. 30 nt at their 5′ end but have completely different biological functions. Only the longer mRNAs contain the AUG start codon of the preC region at their 5′ end, which is in frame with the AUG of the core reading frame. Therefore, these RNAs encode a primary translation product that differs from the core protein by 29 additional amino acids at the amino-terminal end. This additional domain, called preC, contains a hydrophobic sequence that serves as a signal sequence for secretion into the ER (see section entitled Nonstructural proteins, below). The resulting product is HBe antigen.

The genome replication is only supported by the other supergenomic transcript, which does not contain the preC AUG, but includes the initiation AUG at nt 1 900 for core protein (Ou et al. 1990). From this RNA, the overlapping *pol* ORF, beginning 407 nts downstream of the core AUG, is also translated, probably less efficiently. In contrast to retroviruses, which also have overlapping polymerase and nucleocapsid ORFs, expression of hepadnaviral polymerase occurs by de novo translational initiation and not by ribosomal frame shifting (Chang et al. 1990). The exact mechanism of pol translation remains unsolved because conflicting evidence has been reported for both an internal entry of the ribosomes at or near the pol AUG and for leaky scanning from the 5′ end of core/pol mRNA.

The ratio between pregenomic and 'preCore' HBe mRNA is variable and depends on the nucleotide sequence in the core promoter/enhancer. Particularly, mutations from A1762 to T and G1764 to A reduce HBeAg expression and enhance pregenome expression and thus replication (Buckwold et al. 1996). HNF 3β favors expression of HBe mRNA and inhibits pregenome transcription and replication (Banks et al. 2002).

In addition to cellular transcription factors, two virus encoded transcription factors regulate the gene expression of HBV. HBx protein is a promiscuous transactivator of many cellular genes and of the HBV genes (see below). The other transcription-activating element is located within the preS2 domain and acts only if located at the cytosolic side of the ER. This topology exists in LHBs protein and in carboxyterminally truncated forms of MHBs (Hildt et al. 1995). PreS2 activates the raf/MEK signal cascade that is essential for HBV replication (Stockl et al. 2003). HBx activates tyrosine kinases and calcium signaling which also activates HBV replication (Bouchard et al. 2003).

ASSEMBLY OF THE VIRAL NUCLEOCAPSID AND GENOME MATURATION

Expression of the viral nucleocapsid in *Escherichia coli* leads to core particles that, by electron microscopy, are indistinguishable from natural nucleocapsids found in infected liver (Kenney et al. 1995). (However, it should be considered that only the structure built by the first ca. 140 amino acids is depictable.) In these expression systems, devoid of any other viral protein, assembly is combined with nonspecific encapsidation of RNA. Specific encapsidation of the pregenomic RNA, as it occurs in vivo, is mediated by the epsilon (ϵ) signal and the viral polymerase (Bartenschlager et al. 1990; Hirsch et al. 1990). Mutations throughout the whole polymerase gene affect the ability for specific RNA encapsidation, suggesting a complex interaction between viral polymerase with pregenomic RNA and the core particle in which other proteins such as the cellular chaperone Hsp90 and co-chaperones may be involved (Hu and Seeger 1996; Beck and Nassal 2003).

The encapsidation signal ϵ of the pregenomic RNA was mapped within the preC region of DHBV and HBV

RNA (Nassal and Schaller 1996). Although ϵ is present in all HBV RNAs at the 3′ end and is redundant at the 5′ and 3′ ends of the supergenomic transcripts, only the 5′ terminal ϵ supports encapsidation (Junker-Niepmann et al. 1990). ϵ forms a base-paired stem–loop (see Figure 6a), conserved in its structure throughout all hepadnaviruses. Although ϵ seems to be sufficient for pregenome encapsidation by viral polymerase, additional sequence elements downstream increase the encapsidation efficiency (Hirsch et al. 1991; Calvert and Summers 1994). These elements may explain how the viral polymerase discriminates the 5′ terminal ϵ from the 3′ terminal ϵ in the super- and subgenomic RNAs. The nonreactivity of the HBe mRNA despite the 5′ terminal ϵ in encapsidation is caused by the translating ribosomes on the HBe RNA, which prevent the folding of ϵ or its interaction with the polymerase (Nassal et al. 1990). This indicates that only complete, translating 80S ribosomes are able to displace the ϵ-bound polymerase, because the pregenomic RNA must be scanned by the 40S ribosomal initiation complex for the initiation of core protein synthesis.

In addition to the polymerase and the pregenomic RNA, a protein kinase is encapsidated within core particles (Gerlich et al. 1982). This activity is associated with nucleocapsids, even when expressing the core gene alone in insect cells (Lanford and Notvall 1990). As mentioned above, the kinase is not unequivocally identified yet but it is known that it phosphorylates serine residues between the arginine clusters in the carboxy-terminal portion of the core protein (Lan et al. 1999).

Studies on the function of the protein kinase are difficult to perform since the carboxy-terminal part of the core protein is multifunctional. It comprises domains essential for RNA packaging and genome maturation (Nassal 1992). Hence, it is not surprising that point mutations of the protein kinase target sequences always resulted in a more or less complete inhibition of genome maturation. Using this approach, it has been shown that phosphorylation at serine 162 is required for specific encapsidation of the RNA pregenome (Gazina et al. 2000), mediated by the polymerase. However, phosphorylation in vitro inhibits interaction of nucleic acids and the core protein, implying that the majority of phosphorylation probably occurs after encapsidation of pregenomic RNA (Kann and Gerlich 1994).

The complex events that convert the linear RNA pregenome to the circular double-stranded DNA in the virion are outlined in Figure 5 (for review, see Ganem et al. 1994). Previous observations on the endogenous polymerase activity suggested that this enzyme is active only within nucleocapsids. However, DHBV RNA, which contains the ϵ signal, and the polymerase ORF, can be used in a cell-free translation system to express an active DHBV polymerase that can prime and elongate the first nucleotides of the negative-strand DNA (Wang and Seeger 1993). These data have been confirmed by expression of the DHBV polymerase in *Escherichia coli*, which was able to initiate reverse transcription at a synthetic template after complementation with eukaryotic chaperones Hsc70 and Hsp40 (Beck and Nassal 2003). Noteworthy, these cell-free systems could only be established for the polymerase of DHBV and allow only the addition of some nucleotides; attempts to express the HBV polymerase in a similar manner failed.

The progress on DHBV research allowed the understanding of the initial events in hepadnaviral replication. The polymerase starts at the bulge of the ϵ signal (Figure 5a) and not, as originally concluded from primer extension experiments, within the 3′ terminal DR1. For the priming of the negative-strand DNA, the hydroxyl group of tyrosine 96 of the DHBV polymerase serves as the acceptor for the synthesis of a phosphodiester bridge with the first nucleotide. After the addition of the first 4 nt (DHBV, 3 nt in HBV) encoded by the bulge, the oligonucleotide polymerase complex dissociates from the bulge, and reanneals with a sequence complementary to the 3′ terminal DR1 (Figure 5b). These findings were confirmed for the HBV polymerase by expression in yeast. However, because there are many complementary sequences to the three or four initial bases of the negative DNA strand within the hepadnavirus genomes, additional factors must be involved. These include the primary and secondary structure of the surrounding RNA sequences of the DR1 as well as the distance between initiation site and DR1 that regulate the transfer of the polymerase nucleotide complex from ϵ to a sequence element ϕ at the 3′ terminal DR1 (Tang and McLachlan 2001). At DR1, reverse transcription, that means negative-strand DNA elongation, proceeds towards the 5′ end of the pregenome. The catalytic center for the polymerization reaction contains the typical YMDD motif as has been described for retroviruses. A further similarity is that the elongation of the negative DNA strand is combined with degradation of the RNA strand in the resulting DNA–RNA hybrid. Mapping of the 3′ end of the negative DNA strand showed that it nearly coincides with the 5′ end of the pregenomic RNA. Thus, the 3′ end of the negative DNA strand is obviously specified by ‘run off’, when the polymerase reaches the end of its RNA template, resulting in the terminal redundancy of the negative DNA strand of 8–10 nt (Figure 5c). Since the RNase H domain is separated from the polymerizing catalytic center in the polymerase, an RNA oligonucleotide of 17–18 bases does not become degraded. This oligonucleotide represents the 5′ end of the pregenome including the 5′ CAP. Together or concomitantly with the polymerase, the oligonucleotide translocates to the complementary region of DR2 on the minus-strand DNA. The translocation requires a folding of the minus strand mediated by a structural element within the S ORF termed the M region (Liu et al. 2003).

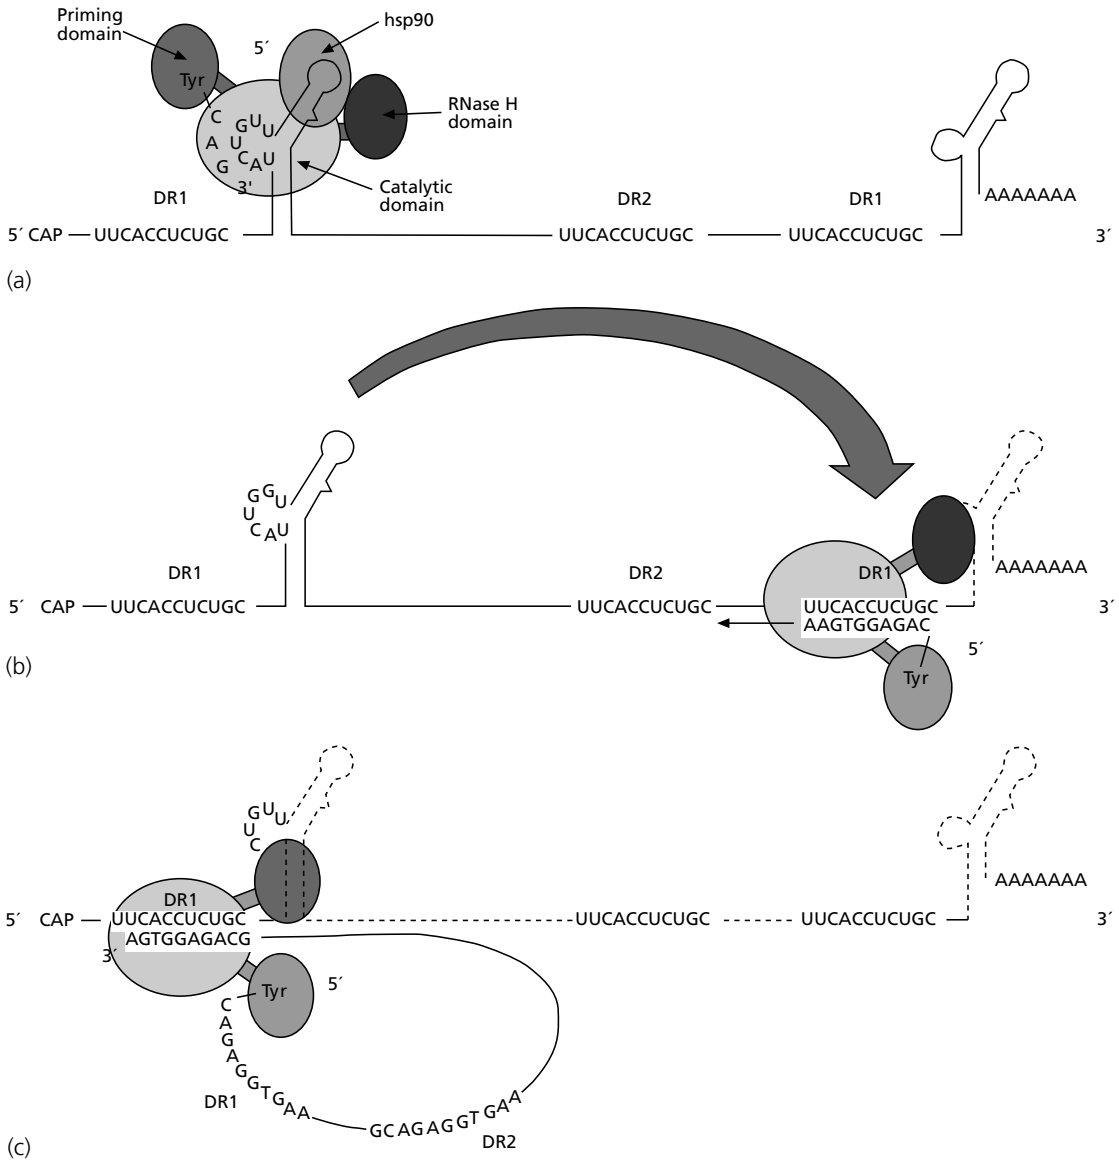

Figure 5 *Generation of the viral genome from the pregenomic RNA.* **(a)** *Binding of the viral polymerase and the cellular factor hsp90 to the encapsidation signal on the pregenomic RNA. Reverse transcription for the first 3 DNA nucleotides starts at the bulge of the stem–loop structure. The first nucleotide (C) is covalently linked to a hydroxyl group of a tyrosine within the priming domain of the polymerase.* **(b)** *Translocation (large arrow) of the polymerase–nucleotide complex to a complementary sequence on the DR1. Further negative DNA strand synthesis.* **(c)** *Completion of negative DNA strand synthesis. The degraded RNA template is depicted as a dotted line. The remaining undegraded RNA oligomer is shown in black. (continued over)*

At DR2, the polymerase uses the 3′ end of the RNA oligonucleotide as the primer for DNA synthesis, now accepting the single-stranded DNA of the minus strand as template. Since the polymerase is covalently bound to the 5′ end of the minus strand, this single strand must form a loop which narrows when the polymerase proceeds towards the 5′ end. Apparently, the distance between phosphodiester linked Tyr in the priming domain and the catalytic center of the polymerase allows that plus strand DNA synthesis reaches the 5′ end of the minus DNA strand template (Figure 5d, e). Because the negative DNA strand is linear, second-strand synthesis could run off at the 5′ end of the template, but mature HBV genome in core particles is predominantly circular. Thus, the polymerase is able to bridge the gap between the 3′ and the 5′ end of the negative DNA strand. On the basis of mutational analysis, a melting of the 3′ end of the positive DNA strand and the 5′ end of the negative DNA strand (Figure 5f) was suggested. Due to the terminal redundancy r, the 3′ end of the positive DNA strand can anneal with the complementary 3′ end of the negative DNA strand (Figure 5g). Besides

r, however, there are additional requirements for circularization. This includes the adjacent regions termed 5E and 3E (Liu et al. 2003, 2004).

Annealing of the plus strand 3′ end and 5′ end of the minus strand reconstitute a continuous single-stranded DNA template for the polymerase. Thus, the polymerase should be able to synthesize a double-stranded circular DNA with two nicks between the 5′ and 3′ end of both minus- and plus-strand DNA. The virion, however, contains a partially double-stranded DNA with the heterogeneous 3′ ends of the plus DNA strand leaving a single-stranded gap of ca. 800 nt. The reason for this phenomenon is unknown but one may hypothesize that the limited space within the capsid does not

allow an ongoing synthesis since double-stranded DNA is less flexible than single-stranded DNA. A minority of virions contain a linear double-stranded DNA genome instead of the partially double-stranded circular DNA molecule. As shown for DHBV these virions are infectious. Within the nucleus the cccDNA is formed by circularisation of the linear DNA using nonhomologous recombination between the two ends (Yang and Summers, 1998).

TRAFFICKING OF PROGENY HEPADNAVIRAL CAPSIDS

Transport to the nucleus

Mature core particles may enter two different pathways, which are important for the viral life cycle. Because the HBV cccDNA in the nucleus is subject to slow degradation, the pool of intranuclear HBV genomes must be restored permanently to ensure viral persistence. The restoration of the pool is usually possible either by new infection of the hepatocyte with HBV, or by re-entry of viral DNA after release from the viral nucleocapsid. Amplification of cccDNA between 10 and 50 copies per cell occurs even in cultured hepatocytes that are not susceptible to DHBV and HBV infection, so it obviously does not require reinfection but nuclear entry of viral genomes from newly synthesized core particles in the cytoplasm. This 'short cut,' without secretion and reinfection, occurs predominantly at the beginning of infection. It leads to the establishment of chronic infection on the cellular level. In addition, this unusual strategy, which has only been described for pararetroviruses, avoids the appearance of the virus in the serum, and minimizes the risk of being neutralized by circulating antibodies. However, DHBV cores cannot spread from cell to cell but must be enveloped, secreted, and enter new cells (Funk et al. 2004).

The mechanism of how the viral genome is delivered to the nucleus has been studied in in vitro systems and seems to follow the same strategy as during initial infection. Apparently, the genome is transported within the core particles, which use the cellular microtubule transport system for reaching the perinuclear region, followed by an active nuclear import mediated by cellular nuclear import factors. For interaction with the import factors, the core proteins expose a 'classical' localization signal (NLS) on the capsid surface. The NLS is localized within the carboxy-terminal domain of the core proteins and within the lumen of the capsid after assembly. The exposure of the NLS on the capsid surface thus requires a structural change, which is caused by phosphorylation of the carboxy terminus (Rabe et al. 2003). The NLS is bound by the adapter protein importin α and subsequently by the cellular transport receptor importin β. Following the established pathway of nuclear import, importin β mediates the binding to the cytoplasmic fibers of the NPC and the transport through the pore into the nuclear basket (Panté and Kann 2002). Exclusively at this site, the core particles disintegrate and release the viral DNA into the karyoplasm (Rabe et al. 2003).

Envelopment and secretion

The second pathway for core particles is the envelopment into the surface proteins, followed by virus secretion. DHBV mutants defective for envelope proteins but competent for replication lead to intranuclear cccDNA accumulation up to 50 times the natural copy number. The expression of surface proteins results in envelopment of core particles and secretion of virus, and regulates amplification of cccDNA (Summers et al. 1990). After de novo infection of hepatocytes, transcription of HBs mRNA is a late event (Tuttleman et al. 1986). Thus, the regulation of DHBV cccDNA amplification via surface protein synthesis guarantees that a large pool of cccDNA has been generated in the infected cell before virus is exported.

In contrast to HDV, where only SHBs is required for assembly and secretion, assembly of HBV requires LHBs and SHBs (Bruss and Ganem 1991). Stepwise truncation of LHBs showed that only sequences proximal to amino acid 108 of preS are required for HBV assembly. A series of mutations determined that the highly conserved preS1 region between Arg103 and Ser124 at the transition to preS2 is essential (Bruss 1997). Using the same technique, envelopment-negative core mutants were identified. Although being spread throughout the primary amino acid sequence, these mutants clustered at two sites on the capsid surface. One cluster is localized in a ringlike groove around the tip of the spikes and the second cluster at the amino-terminal end of the flexible carboxy terminus of the core protein (Ponsel and Bruss 2003).

In the current model of HBV (Figure 6c,d; and see Figure 2), the preS domains in LHBs have a dual topology. The preS domain in part of the LHBs molecules is cytosolically retained by Hsc70 (Lambert and Prange 2003); the other part is exposed at the surface of HBV, allowing multiple functions of LHBs:

- Like matrix proteins of many other enveloped proteins, it mediates the budding of core particles together with their envelope proteins. For this task, a matrix protein must be fixed at the membrane, but its binding site for the viral capsid should be located on the cytosolic side.
- The preS1 domain is also the attachment site to the cell surface during infection. For this purpose the preS domain has to be accessible on the surface of the particle.

The mechanism by which the preS domain post-translationally passes through the ER or post-ER membrane is unclear. Direct passage through the lipid bilayer without the involvement of signal recognition

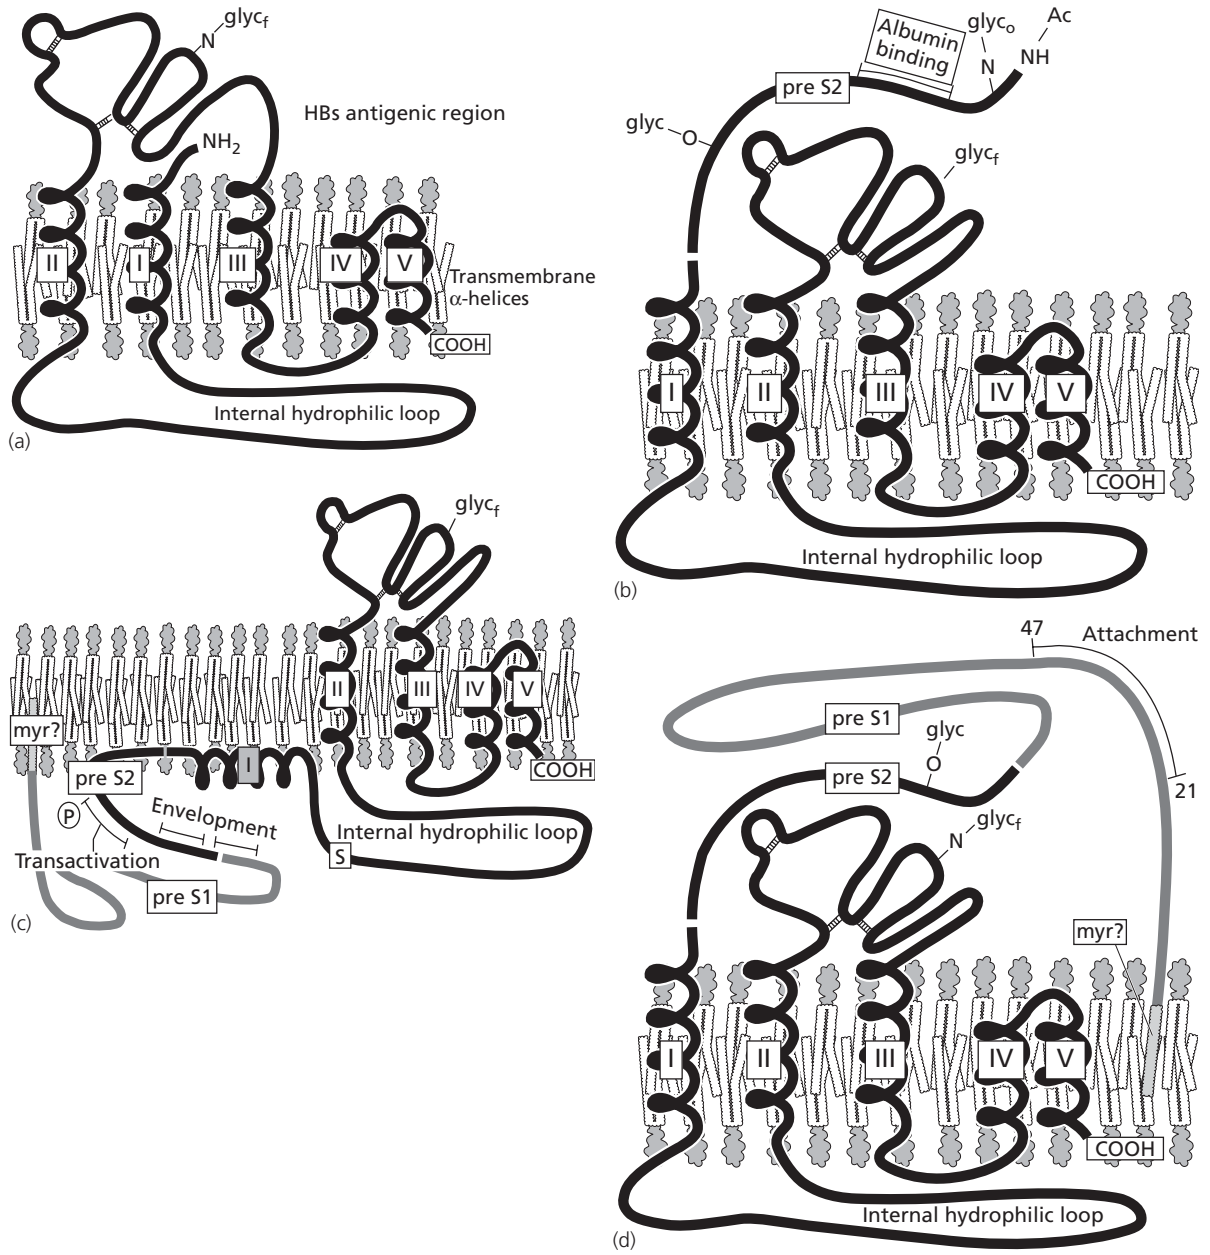

Figure 6 *Postulated topology of hepatitis B virus surface proteins.* **(a)** *SHBs;* **(b)** *MHBs;* **(c)** *LHBs with preS in the cytosol;* **(d)** *LHBs with the preS at the virus surface. In the nonassembled state, the bottom reflects the cytosolic side which represents, after encapsidation, the core particle of the inner part of the virus. The top of the figure represents nonassembled surface proteins in the lumen of the endoplasmic reticulum, after assembly and secretion the outside of the particle. particles (SRP) and secretion factors (sec) has been described for small amphipathic proteins, but the preS domain does not have this type of structure (Bruss et al. 1994). Incubation at low pH and at 37°C favors translocation of interior preS domains to the surface of virions (Bruss et al. 1994; Guo and Pugh 1997). The preS2 portion of preS carries a translocation motif that allows for energy-independent membrane passage (Oess and Hildt 2000) and may carry proteins into cells (Hafner et al. 2003). However, there are no data that this motif is involved in the translocation of the preS domain itself.

The forces that drive the budding and assembly of HBV and HBs particles are not yet well understood. The carboxy-terminal part and parts of the two hydrophilic loops in the S domain can be deleted or substituted, but most of the cysteine residues in the internal loop are essential. The high sequence conservation in the four α-helices suggests a coil-to-coil interaction,

which may contribute to the morphogenesis of virions and HBs particles (Berting et al. 1995).

The HBs particles mature in a pre-Golgi compartment. The *N*-linked glycosides of the HBs proteins at N146 of the S domain and N4 of preS2 are trimmed and modified to a complex biantennary oligosaccharide. *O*-linked glycan is linked to T37 of preS2, and an acetyl residue to the N-terminal methionine (Schmitt et al. 1999, 2004). Cultivation of HBV-expressing cells with inhibitors of glucosidase I (for example, *N*-butyldeoxynojirimycin) blocks the trimming and prevents the secretion of HBV (Block et al. 1994). MHBs is a specific target for this block of secretion (Lu et al. 1995).

HBsAg 20 nm spheres are constitutively secreted. However, HBs-filaments may be retained in the ER if they contain more LHBs than SHBs. The retention signal resides in the preS1 region (Gallina et al. 1995). MHBs does not significantly alter the secretion behavior if properly glycosylated.

Certain hepatocytes in HBsAg carriers seem to overexpress LHBs, relative to SHBs, and contain a dilated ER, which gives them a ground glass appearance in light microscopy. Such cells probably do not contribute to HBV production and are often found in so-called healthy HBsAg carriers with low viremia (Dienes et al. 1990). Only cells that express core protein, polymerase, SHBs, and LHBs protein in a well-balanced mixture are able to assemble and secrete HBV.

Nonstructural proteins

In contrast to the positive-strand RNA viruses that do not use reverse transcription, retroviruses and the hepadnaviruses do not use a major part of their coding capacity for nonstructural proteins. However, LHBs and SHBs are not only essential structural components of the virion; they occur also as secreted antigens. Furthermore, MHBs is a nonessential structural protein of mammalian hepadnaviruses.

Two proteins that are not essential for replication in cell cultures are HBe protein and HBx protein. Neither HBe protein nor HBx protein have yet been identified as a structural component of the virion. They are therefore considered here as nonstructural proteins, although their presence in low amounts in virions cannot be excluded.

HBs PROTEINS

A peculiarity of all wild type hepadnaviruses is expression of the HBs proteins in large excess. Even in HBV carriers producing many virions, empty HBs particles are present in ca. 1 000-fold greater number than virions and may reach concentrations of up to 1 g/l, as major serum proteins such as IgM. In low viremic HBsAg carriers, HBsAg may be present in particle numbers up to 10^{12}/ml even though HBV DNA is barely detectable by polymerase chain reaction (PCR). Thus, in a way, HBs proteins are nonstructural as well as structural proteins. HBsAg particles have a much longer half-life (>8 days) than virions, which disappear with a half-life of 1–3 days from the serum if replication is blocked (Chulanov et al. 2003). However, HBV-transfected hepatoma cells also produce an excess of HBs proteins. Thus, the excess of nonstructural HBs protein over virion-bound HBs protein is not only due to more rapid removal of virions from the circulation. The significance of this overexpression is not clear. It may contribute to an immune tolerance that is a precondition for highly productive persistent infection in an immunocompetent host. Furthermore the excess HBs proteins may block the HBV receptors of the host during late or persistent stages of infection and thereby allow the circulation of virions, which is a precondition for efficient transmissibility. The long delay of several weeks or even months between infection and the first appearance of virions and HBs protein is probably due to the slow replication of HBV, but may also be due in part to immediate readsorption to receptors not yet blocked. However, for DHBV intracellular down-regulation of the gp180 receptor by L-DHBs protein has been observed (Breiner et al. 2001).

The proportion of HBs proteins differs in the three morphological forms of HBs particles. Virions contain a high proportion of LHBs, HBs filaments intermediate amounts, but small amounts are present in 20 nm particles. The proportion of MHBs may be variable and is usually higher in HBs particles from high viremic carriers.

HBe PROTEIN

HBe protein was discovered by the analysis of HBsAg-positive sera from different donors by double diffusion in agar gels (Magnius and Espmark 1972). Some HBsAg carriers contained a precipitating antibody against a novel HBV antigen called e antigen (HBeAg). HBeAg was found predominantly in highly productive HBV carriers with a detectable endogenous HBV DNA polymerase, whereas anti-HBe was usually found in 'healthy' low viremic carriers. Sera from HBeAg-positive carriers typically have infectivity titers for chimpanzees of 10^8/ml or more and genome numbers of 10^9–10^{10}/ml, whereas anti-HBe- and HBsAg-positive sera have typically only ten infectious doses/ml (Shikata et al. 1977). The biochemical nature of HBe protein remained unclear until 1982, when recombinant HBc particles, devoid of any other viral component, were converted into HBeAg by treatment with protease and ionic detergents. Characterization of isolated HBe protein from the serum of HBV carriers revealed that it had an amino acid composition similar to that of HBc protein, but it had only ca. 15 kDa owing to a carboxy-terminal truncation at Val 149 of HBc.

It cannot be ruled out that a minor part of HBe protein in serum may be derived from degraded nucleocapsids or nonassembled HBc protein, but at least the major part of HBeAg, if not all, is generated by a biosynthetic pathway different from that of HBc protein. As mentioned in the section entitled Genome structure and function, above, HBV-containing cells express, besides the pregenomic RNA, a slightly longer RNA that contains not only the AUG for the HBc protein but also the AUG for the preC region 29 codons upstream. The preC sequence has the property of a signal peptide, which directs the nascent polypeptide to the membrane of the ER and causes its translocation to the ER lumen. The translocation is, however, incomplete, thus allowing the re-entry of part of the full-length HBe protein molecules with 25 kDa to the cytosol. This form of HBe protein may be transported to the nucleus because of its carboxy-terminal nuclear localization signal.

The major part of ER-associated HBe protein is cleaved at Ala19, thus generating a 22-kDa protein. During passage through the Golgi apparatus, a further protease cleaves HBe at Val149 or alternative sites downstream, generating proteins of 16–18 kDa. This cleavage is a precondition for release from the cell. HBe protein may oligomerize, but, in contrast to HBc, does not assemble to a closed particle. The tryptophan and cysteine residues in the remaining part of the preC peptide prevent assembly to corelike particles (Schlicht and Wasenauer 1991). The amount of HBeAg in the serum of HBV carriers by far exceeds the amount of HBc protein within circulating virions. Titers in enzyme immune assay (EIA) often reach 1:8 000, and detection by agar gel immune precipitation suggests amounts of several micrograms per milliliter. Thus, both major structural proteins HBs and HBc of the virion are accompanied by a large excess of slightly altered nonviral forms.

It is doubtful whether HBe protein has a direct function in the viral life cycle. The HBe mRNA does not support genome replication. HBe-negative mutated genomes of DHBV and WHV replicate in the natural hosts. Naturally occurring HBe-negative variants of HBV are present in many patients (see section Clinical and pathological aspects). It has even been found that preC-containing wild type genomes replicate less efficiently in transfected hepatoma cells than preC-negative genomes (Scaglioni et al. 1996).

The conservation of HBe protein in all known hepadnaviruses, in spite of its being nonessential, suggests that it provides an important advantage for the survival and spread of hepadnaviruses in their host population. A clue to the function of HBe protein may be the observation that newborn woodchucks infected with an HBe-negative mutant develop acute, but not chronic, infection as occurs with wild-type virus (Chen et al. 1992). It may be that HBe protein suppresses immune elimination of HBV, thus contributing to the development of a carrier state (Milich and Liang 2003). Furthermore, HBeAg is transferred in utero from a HBV carrier mother to the fetus (Wang and Zhang 2003).

HBx PROTEIN

HBV encodes a protein of 154 amino acids (141 in WHV and 138 in GSHV), the function of which is essentially unknown. The recent identification of a functional HBx protein in avian hepadnaviruses (Schuster et al. 2002) suggests that it is somehow essential during hepadnaviral replication in that it alters the host organism in a way that it is more permissive for viral replication. HBx is not essential for HBV production in transfected permanent cell lines (Yaginuma et al. 1987) or primary rat hepatocyte cultures (Blum et al. 1992). WHV genomes without a functional *HBx* gene do not replicate efficiently in woodchucks (Chen et al. 1993; Zoulim et al. 1994), but replicate sufficiently in vivo to induce immunity and may, thus, be considered as attenuated virus (Zhang et al. 2001). This observation suggests that HBx protein is not essential for low-level replication in vivo, but enhances infection (Xu et al. 2002). There may, however, also exist an effect of HBx on the immune system favoring tolerance against HBV, because HBV genomes with a truncated HBx variant have been observed preferably in immunodeficient patients (Repp et al. 1992). Evolution of such HBV genomes without a complete *HBx* gene in immunocompromised patients may indicate that HBx protein is not so necessary in patients without an efficient immune defense as in normal hosts. HBx protein may activate components of the specific and the innate immune system, for example, the nuclear factor of activated T cells NF-AT (Lara-Pezzi et al. 1998) or NF-κB (Su and Schneider 1997). HBV may enter lymphocytes and monocytes of HBV carriers and is weakly expressed. In these cells, HBx mRNA is expressed at highest levels compared to other HBV mRNAs (Stoll-Becker et al. 1997).

The genome position of the *HBx* gene and promoter next to HBV enhancer I is reminiscent of the genome position of the early 1A (*E1A*) gene of adenoviruses and of other immediate–early genes of DNA viruses. *E1A* is essential for adenovirus replication in most but not all cell types by *trans*-activating the early promoters of E2 and E4 in the adenovirus genomes. The *trans*-activating activity of HBx on HBV enhancer I and on various viral or cellular enhancers was first described in 1988 by Spandau and Lee and by Zahm et al. Numerous further studies (for example, Wu et al. 2002) confirmed the nonspecific promiscuous *trans*-activating activity of HBx (review by Murakami 2001), but usually the activation factor is low. HBx does not bind directly to DNA. If artificially expressed in the absence of other HBV genes, it is found most abundantly in the cytoplasm, but it is also present in the nucleus (Doria et al. 1995). Current evidence suggests that cytoplasmic HBx may act either

via a tyrosine kinase signaling cascade and/or mitochondrial calcium channels (Bouchard et al. 2003) but other pathways also seem to exist (Hafner et al. 2003). However, the *trans*-activating activity seems to be maintained in some systems if a nuclear localization signal is added. Many potential nuclear binding partners of HBx protein have been identified in vitro: transcription factors (TF), ATF II, and CREB, the TATA-binding protein TFIID, TFIIB, RNA polymerase subunit RPB5, a novel X-associated protein XAP-1 which may be involved in DNA repair, the ubiquitous transcription factor Oct 1, tumor suppressor protein p53, DNA repair-associated transcription factor ERCC3, and single-stranded RNA. Furthermore, binding of HBx to XAP-C7, an α-subunit of the proteasome, or to XAP-P13, a subunit of the regulatory 26S complex of the proteasome, or to a liver-specific HBx-interacting protein XIP were reported. The highly divergent results of the in vitro binding studies allow, for the moment, only one conclusion: that HBx is very sticky. The association with the proteasome appears to be significant, because proteasome inhibitors may restore HBV replication activity of HBx-deficient mutants to wild-type levels (Zhang et al. 2004). A problem with all the *trans*-activation studies is that they depend on heavy transient overexpression of both HBx proteins and the target sequence. Moreover, they were carried out in culture systems that produce HBV without the presence of HBx and may thus be irrelevant in respect to the viral life cycle.

Many viral immediate–early transcription-activating factors, such as E1A of certain adenoviruses, or P6 and P7 of certain papillomavirus types, are also tumor proteins. They bind and inactivate tumor suppressor proteins such as Rb or p53. HBx was reported to bind and inactivate essential functions of p53. An Rb-inactivating factor of HBV has not yet been reported. HBx transforms the SV40TAg-immortalized fetal mouse hepatocyte line FMH 202 to overt malignancy if expressed in large amounts (Höhne et al. 1990). Similar results were obtained in p53-negative mouse cells (Oguey et al. 1996). Of several strains of mice transgenic for HBx protein, only one strain developed liver tumors; high expression of HBx in these mice was necessary. In one transgenic mouse line, an enhanced susceptibility against chemical carcinogens was noted (reviewed by Schaefer and Gerlich 1995). In human hepatocellular carcinoma (HCC) and cirrhotic liver HBx protein may be detected with selected anti-HBx antibodies in the cytoplasm of some but not all cells (Su et al. 1998). More recently, a very clear association of anti-HBx antibodies in the plasma and HBx antigen in the liver with the presence of HCC was found in contrast to findings in chronic hepatitis B patients (Hwang et al. 2003).

While immortalized cells may become malignant under high expression of HBx, primary cells seem to go into apoptosis (Terradillos et al. 1998; Schuster et al. 2000). HBx also enhances the apoptotic effect of tumor necrosis factor (TNF) alpha (Su and Schneider 1997). It appears that overexpressed HBx interacts with a variety of apoptosis-inducing or inhibiting factors, for example, c-FLIP (Kim and Seong 2003), mitochondrial membranes (Shirakata and Koike 2003), Bcl-2 (Terradillos et al. 2002), or the Fas-ligand (Yoo and Lee 2004). The oncogenic effect of HBx seems to reside in the amino terminal portion (Gottlob et al. 1998), whereas the proapoptotic and transcription-activating effect is in the carboxy-terminal portion (Schuster et al. 2000). HBx mutants present in HCCs abrogate the antiproliferative and transactivating effects of wt HBx and may, thus, maintain oncogenicity (Sirma et al. 1999). The proapoptotic function is conserved in the avihepadnaviruses (Schuster et al. 2002).

In natural infection, HBx mRNA is usually expressed in low levels. Furthermore, the half-life of HBx seems to be very low. Even if one postulates an oncogenic potential of HBx, this may explain why acutely infected patients and chronically infected HBV patients with high replication do not develop HCC. In WHV-infected woodchucks, WHxAg is localized in the cytoplasm of infected cells, but is rarely found in HCC (Jacob et al. 1997).

It is open to question whether HBx is not oncogenic at all in natural settings, or its expression is too low, or viral factors suppress the activity of HBx. With regard to the latter possibility, it has been observed that the core gene of HBV, if co-expressed, suppresses the *trans*-activating activities of the *HBx* gene on a variety of promoters. As with oncogenes from other viruses, *HBx* may be negatively controlled by viral genes the expression of which is stimulated by *HBx*. In HCC, *HBx* may be expressed from HBV DNA integrates, which often do not encode other complete HBV ORFs.

In summary, HBx probably has a role in liver-specific expression of HBV and a weak oncogenic potential that, however, can be effective only in combination with other oncogenesis-favoring events. The significance of the proaptotic effect is not understood.

Integration of HBV DNA and liver cancer

Integration of the viral genome into the host genome is not part of the hepadnaviral life cycle, in contrast to the retroviruses. Nevertheless, integration of HBV DNA fragments into the hepatocyte genome is a frequent event during HBV infection. Even if a full-length genome would be integrated the circular HBV genome is thereby disrupted and no longer able to express a viable pregenomic RNA. (Viable HBV DNA can be integrated for experimental purposes in the form of artificial linear constructs covering the sequence of the pregenome plus homologous or heterologous upstream transcription signals.) However, subgenomic mRNAs

and viral proteins may be expressed from integrated HBV DNA fragments. Integration sites in the viral genome are very often around DR1 at one end and at variable sites at the other end. These integrates may express a carboxy-terminally truncated HBx protein fused to cellular sequences which still has *trans*-activating activity in experimental systems (Wollersheim et al. 1988). Furthermore, a cryptic polyadenylation site may be used that generates a polylysine tail at the carboxy-terminal end of a truncated HBx protein (Rakotomahanina et al. 1994).

The integrated HBV DNA is quite often composed of two, or even more, fragments that are linked together in a head-to-tail arrangement or in other complex rearrangements. Occasionally, such a rearranged DNA fragment may express truncated forms of preS/S proteins, in particular truncated MHBs and HBx. Such truncated LHBs or MHBs proteins have been found to *trans*-activate transcription factor AP1 and others, suggesting an additional growth-stimulating effect of these defective HBV proteins (Hildt et al. 1997). Such HBV DNA fragments induce malignant growth in cell cultures and nude mice (Luber et al. 1996).

With human HBV DNA, no clear preference for a defined integration site has been identified and it was noted that the integration site might be rearranged. It seems that integration of HBV DNA destabilizes the host genome. In two independent studies from Japan (Kawai et al. 2000; Okabe et al. 2000), a loss of heterozygosity was more often found in HBV-associated HCC than in nonviral or HCV-associated HCC. It has been suggested that oxidative stress – as may occur in inflammation – induces not only DNA-damage but also enhances HBV DNA integration (Dandri et al. 2002). A model has been proposed that topoisomerase I mediates the integration of HBV DNA around the DR1 site. A role of the integrated HBV DNA in the development of HCC is suggested by the fact that virtually all HCC-derived cell lines from HBV carriers contain one, or usually more, HBV DNA fragments and that the HCCs are usually of monoclonal origin. The model of insertional mutagenesis leading to deregulation of growth control genes has been verified for several human HCCs. One example is the fusion of a retinoic acid receptor β chain with 29 amino-terminal residues from preS1, which may lead to uncontrolled expression of this differentiation factor (Dejean et al. 1986). Another example is the insertion of preS2/S sequences of HBV into an intron of cyclin A, generating a preS2/2 fusion with cyclin A devoid of its amino-terminal degradation signals (Wang et al. 1990). This altered cyclin A has transforming properties in cell cultures. A third example is the activation of mevalonate kinase (Graef et al. 1994). More recently, a systematic search for HBV DNA integration sites revealed, in six of 21 isolates, insertion into cellular genes which are key regulators of cell proliferation and viability, among them the human telomerase reverse transcriptase gene (Gozuacik et al. 2001), which has also been found by others (Ferber et al. 2003). Further integration sites were reported next to the RNA-binding motif of Y chromosome gene which was found to be ectopically expressed in three of 10 HCCs from children (Tsuei et al. 2002). More typical are, however, integrations into Alu-type repeats, mini-satellite-like, satellite III or a variable number of tandem repeat sequences, suggesting a preference of HBV DNA integration into sites where other multiple insertions have already occurred during evolution (Rogler and Chisari 1992).

Development of HCC is a regular event in woodchucks chronically infected with WHV. In HCCs of this animal, insertion of WHV DNA very often occurs upstream of a functional retrotransposon encoding cellular N-*myc*2. The viral enhancers activate the cellular N-myc2, which finally leads to the development of HCC (Flajolet et al. 1998). Insertion of hepadnaviral DNA into c-*myc* sequences was observed both in woodchucks and in ground squirrels. However, in human HCC c-*myc* or N-*myc* activation was found only occasionally (Buendia et al. 1993). Hepadnaviral DNA integration has also been found in HCC from ducks, but development of HCC in ducks seems to be exclusively correlated to exposure to aflatoxin B.

HBV genotypes, HBsAg subtypes, and HBV variants

The sequencing of numerous HBV isolates in the late 1970s and early 1980s has revealed a surprisingly high degree of conservation; even rodent hepadnaviruses are ca. 60 percent homologous to human HBV. Human HBV splits into eight identified genotypes, A to H, which diverge by 8–15 percent in the DNA sequence (Norder et al. 2004). Furthermore, genosubtypes with a typical predominant ethnical distribution have been defined: A1 in Africa, Brazil, and India, A2 in Europe and USA, B1 and B2 in Japan and China, B3 in Indonesia, B4 in Vietnam, C1 and C2 in Japan, Korea, and China, C3 in Oceania, C4 in Australian aborigines), D1–D3 in Europe, the Mediterranean, Middle East, and Central Asia, D4 in East Asia, E in West Africa and Madagascar, F1 and H in Central America, F2 in South America and Polynesia. The latter observation supports the debated theory of Thor Heyerdahl that a part of the Pacific Islands was settled from South America (Norder et al. 2004). Genotype G is rare and has no clear geographical pattern. HBV has also been found in apes, every species having its own genotype(s). Due to vertical and intrafamiliar transmission, the genotype usually reflects the ethnic origin even after several generations and not the actual geographical location. Americans or Canadians of East Asian origin usually have genotype B or C, Brazilians often genotype A1 originating from Africa.

Human and ape genotypes are phylogenetically equally distant (reviewed by Bartholomeusz and Schaefer 2004), but genotypes F and H branch off and are more distant. This suggests that there may have been a common ancestor to old world primates' hepadnaviruses and most human HBV genotypes whereas genotypes F and H may have been acquired in the new world. The next relative to human and ape hepadnaviruses has been isolated from woolly monkeys (a new world monkey) (Lanford et al. 1997). Since this virus is not viable in chimpanzees, it is considered an own species as is WHV (Mason et al. 2005). Avian hepadnaviruses are only distantly related to mammalian hepadnaviruses, despite their similar genomic organization and replication strategy.

The multiple functions of the viral nucleic acid sequences for the coding of overlapping genes, regulation of replication, transcription, and assembly of the virions prevent excessive variability. A hot spot of variability between virus species is the preS1 region, probably because of its role in host specificity and because the overlapping polymerase sequence functions in this region only as spacer.

Variability in the hydrophilic loop of the SHBs protein on the virion surface or on HBs particles, respectively, determines the serological HBsAg subtype. Besides the common antigenic determinant *a*, subtype-specific alleles *d* or *y*, and *w1*, *w2*, *w3*, *w4*, or *r* were described. Combinations of these alleles define nine HBsAg subtypes according to a workshop held in 1975 in Paris. Position 122 of SHBs is lysine for determinant *d* and arginine for determinant *y*. Position 160 is lysine for the four *w* alleles and arginine for *r*. Differentiation into *w1* to *w4* is mainly based on exchanges at position 127 (Norder et al. 1994). There is no clear correlation between genotype and HBsAg reactivity. Thus, HBV genomes should preferably be characterized by their genotype. Antigenic differences, defined by reactivity with monoclonal antibodies, also exist in the preS2 and preS1 regions. The predominant sequences of an HBV isolate are usually conserved within an infection chain from person to person, suggesting low variability. Obviously the existing genotypes of HBV are optimally adapted to replication in their host population. However, HBV turns out to be a quasi species at all stages of infection if a large number of cloned genomes is analyzed.

HBV variants can be generated by point mutations, small deletions or insertions, and by splicing events. The reverse transcription of HBV is very inaccurate and whereby all possible mutations may be created in a very short time. One can estimate that a highly viremic chronic carrier generates ca. 10^{13} new viral genomes per day. At an assumed error rate of 10^{-5}, 10^{8} mutants per day are generated. While in the quasi-immunotolerant state one genome species is strongly favored, any kind of selection leads to a great variety of variants. Breakdown of immunotolerance is indicated by disappearance of HBeAg and leads to a rapid accumulation of viable and nonviable mutants (Bozkaya et al. 1996). The main targets are

- the preS1/S2 junction leading to a loss of MHBs (Blackberg and Kidd-Ljunggren 2003)
- alterations in the binding sites for transcription factors in the core promoter and enhancer region (Erhardt et al. 2000) leading to less HBeAg production and stronger replication
- inactivation of the precore region, i.e. the HBeAg leader sequence (Chu et al. 2003)
- or deletions in the core protein (Günther et al. 1996).

The type of mutations leading to a HBeAg loss of production differs with the genotype (Chan et al. 1999; Tanaka et al. 2004). X-protein deletions are often found in immunosuppressed patients (Schlager et al. 2000). All these mutations supposedly develop under the host's own immune system as the only selective pressure. Active immunization with SHBs vaccine (Lu and Lorentz 2003) or passive immunization with anti-HBs (Carman et al. 1999) may select for escape mutations in the HBsAg antigen loop. Treatment with nucleoside or nucleotide analogues selects for mutations in the reverse transcriptase domain of the HBV DNA polymerase, which also become evident in the S domain (Locarnini 2003). Often, several types of selection come together leading to complex combinations of mutations. Typically, heavily mutated variants are more often found in late stage infection or HCC.

CLINICAL AND PATHOLOGICAL ASPECTS

Normal ('wild') types of *Hepadnavirus* species are not overtly cytopathogenic. Inflammatory liver disease is caused by the host immune response against viral antigens whereby cellular cytotoxic lymphocytes exert the strongest effect (Chisari and Ferrari 1995). Consequently, symptomatic liver disease is absent in persistently infected individuals whose immune system is either immature at birth or severely impaired. Some healthy adults may also develop persistent oligosymptomatic infection without an efficient immune response; possibly immunogenetic factors predispose for persistent infection.

Another type of oligosymptomatic infection occurs when the infectious dose is very low or the immune response is rapid and efficient, or both. In such cases, silent immunization results. Acute hepatitis occurs in most immunocompetent adults who are infected by the percutaneous route with highly infectious serum or blood. A variable, but usually small, proportion of such patients develops chronic disease after acute hepatitis B. Depending on the balance between viral replication and host defense, chronic disease may cease spontaneously or proceed over years or decades to liver cirrhosis or HCC,

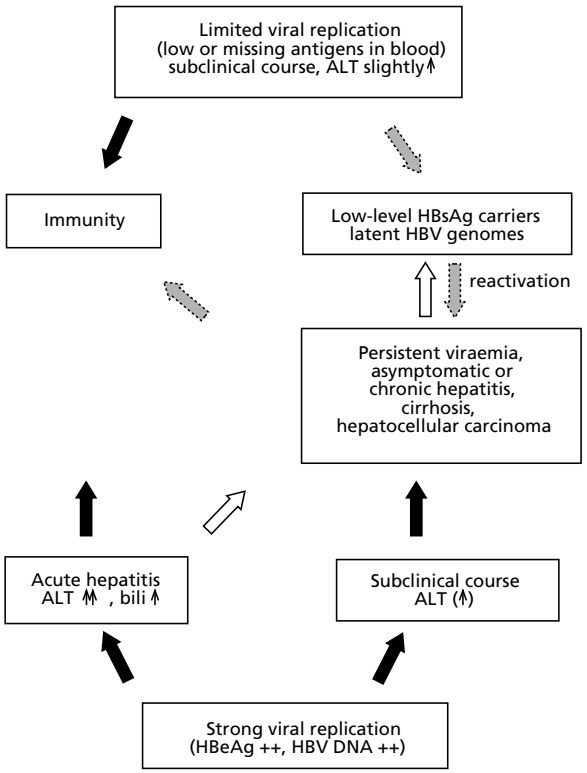

Figure 7 *Possible courses of hepatitis B virus infection. Black arrows show frequent courses, white arrows possible courses, and gray arrows rare or hypothetical events.*

or both. HCC usually develops in cirrhotic liver but may also appear independently of cirrhosis. In infections with high virus replication, extrahepatic manifestations (e.g. glomerulonephritis or periarteritis nodosa) due to circulating immune complexes may occur. Figure 7 illustrates the possible courses of HBV infection.

Clinical course of HBV infection

For more detailed descriptions and original literature, see textbooks on hepatology (e.g. Bircher et al. 1999) or on hepatitis viruses (e.g. Thomas 2000 or Lai and Locarnini 2002).

ACUTE HEPATITIS B

Diagnosis of acute hepatitis based merely on clinical symptoms is unreliable. Early nonspecific symptoms are malaise, poor appetite, nausea, and right upper quadrant abdominal pain which lasts for several days. In ca. 10 percent of patients with acute hepatitis B, a prolonged prodromal phase of up to 4 weeks occurs with serumlike sickness, including arthralgia or even frank arthritis, fever, and skin rash. In the more severe cases, after 3–6 days, fatigue and anorexia worsen and jaundice develops. Essential for the diagnosis is the determination of the alanine amino transferase (ALT) in the serum. In Germany, the upper limit of the normal range is 50 IU/l for men and 35 IU/l for women (measured at 37°C). Clinical hepatitis is associated with values higher than 500 IU/l, reaching several thousand IU/l in severe cases (Thomas 2000). The level of ALT indicates the degree of hepatocyte damage. It increases sharply at the end of the prodromal phase and usually reaches peak values shortly before the appearance of jaundice caused by levels of high bilirubin in the serum. In less severe cases, bilirubin concentrations are below 50 μmol/l; in severe cases >340 μmol/l. In contrast to cholestatic jaundice, alkaline phosphatase is only moderately increased in the serum.

The time course of a typical acute hepatitis B is shown in Figure 8a. Clinical and biochemical data do not allow distinction between infections by the various hepatitis viruses. The most reliable serological marker for acute hepatitis B is IgM antibody against HBcAg (IgM anti-HBc). With the onset of symptoms, IgM anti-HBc appears and reaches peak values within a few days.

Many clinicians rely more on the detection of HBsAg in the serum. HBsAg appears during the incubation phase (Figure 8a), depending on the infective dose and the mode of exposure, several weeks or months after the infective event. It increases over several weeks, typically to peak levels of 10 000–100 000 PEI units/ml of HBsAg (PEI = Paul Ehrlich Institute, Germany). Decrease of HBsAg concentration starts with the onset of the prodromal phase and continues until complete recovery. Most patients remain HBsAg positive for several months.

In 2–10 percent of acute cases, HBsAg may have been eliminated so rapidly that it is already undetectable in the first available serum sample. To identify HBV as the etiological agent in these cases, it is essential to obtain a quantitative IgM anti-HBc result if no other cause for the hepatitis has been identified. Some EIAs for HBsAg may detect less well variants of HBsAg with altered *a* determinant, but these variants are rare in acute hepatitis B.

Persistence

Persistence of HBsAg for more than 6 months after onset in high concentrations (>100 PEI units/ml) means that (1) the acute hepatitis B evolved to chronicity (Figure 8b); or (2) a pre-existing chronic HBV infection was superimposed by an acute hepatitis of another etiology; or (3) the acute disease may actually be an exacerbation of chronic hepatitis B. Again, a high IgM anti-HBc during the early acute phase confirms recent acute HBV infection, whereas moderate amounts or absence indicate previous HBV infection.

Full recovery

Full recovery is assumed if the ALT reaches normal or close to normal levels and if HBsAg becomes negative

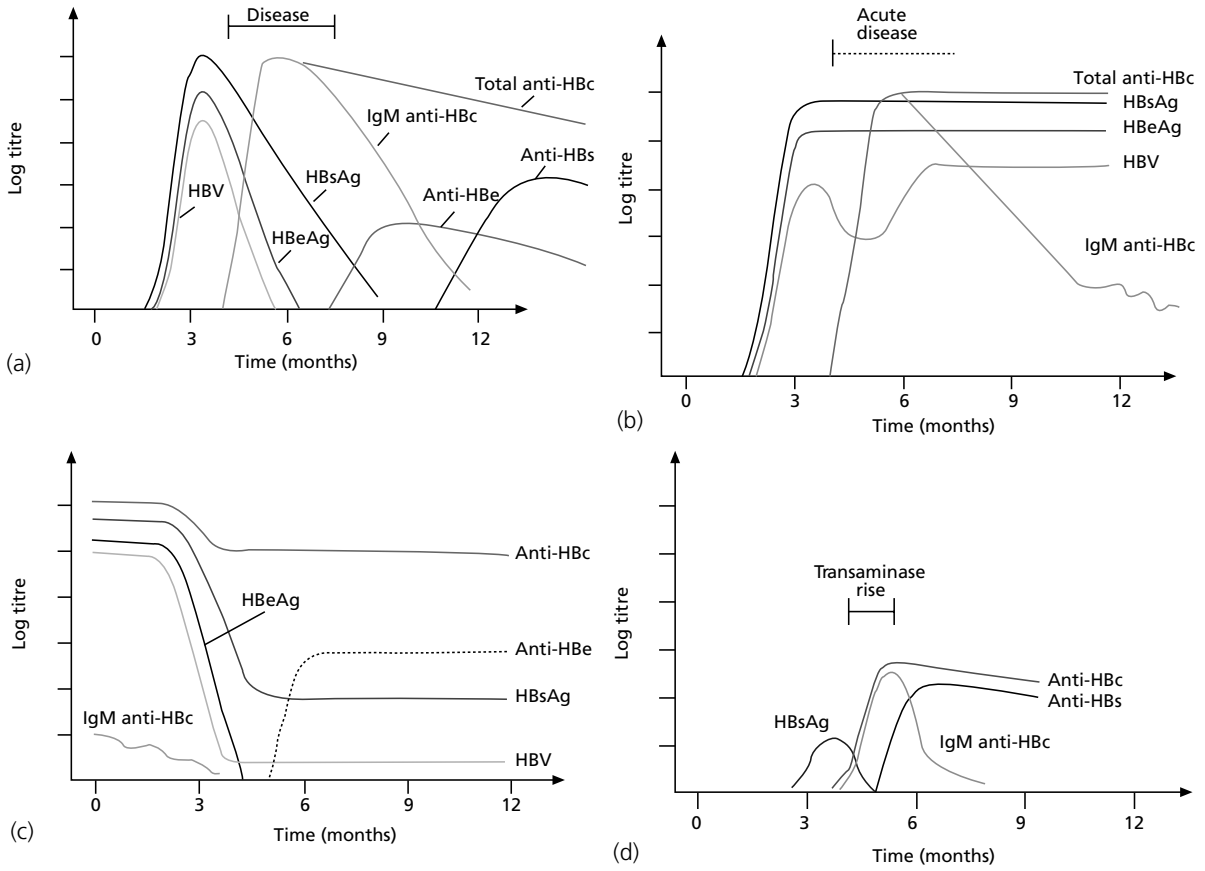

Figure 8 *Serological markers during the different courses of hepatitis B in arbitrary units:* **(a)** *acute hepatitis B, resolving;* **(b)** *acute hepatitis B, chronic evolution;* **(c)** *HBe seroconversion in chronic hepatitis B;* **(d)** *subclinical course of transient HBV infection.*

in EIA. This takes more than 6 months in some cases of protracted disease. Anti-HBs appears several weeks or even months after the disappearance of HBsAg. IgM anti-HBc falls to levels <100 PEI units, but may occasionally remain positive at low levels for several years. Anti-HBc of the IgG class may either persist lifelong or disappear after several years or decades.

HBV itself appears in the serum during the incubation period several weeks before HBsAg in amounts that allow its DNA to be detected by sensitive PCR techniques. Hybridization assays are not usually sensitive enough to detect HBV before HBsAg. Maximum concentration of 10^6–10^9 genomes/ml is reached before the onset of symptoms. About 40 percent of patients are already negative in hybridization assays (<10^6 genomes/ml) when the first serum sample is available.

Low-level persistence after recovery and reactivation

Cumulative evidence suggests that a major proportion of recovered patients retain intrahepatic HBV genomes. These continue to stimulate a cytotoxic T-cell response, which controls viral expression and replication (Rehermann et al. 1996). Occasionally, the cellular immune response is the only marker of the previous hepatitis B. Low level persistence may allow reactivation of HBV replication if the T-cell immunity breaks down, for example, after organ transplantation or during cancer therapy. Even a high anti-HBs level cannot reliably protect against reactivation because escape mutants may grow up. Cessation of immune suppression is extremely dangerous in that situation because memory T cells will proliferate and severely attack the infected liver (Westhoff et al. 2003). Thus, it is highly advisable to screen all patients before immunosuppression not only for overt (i.e. HBsAg positive), but also for occult HBV infection and to monitor for reactivation in positive patients.

Subclinical course and occult infections

The mild courses of transient HBV infection (Figure 8d) will usually go unnoticed unless sought after known exposure. For a few days, serology will show low amounts of HBV DNA, HBsAg, IgM anti-HBc, and a moderate transient rise of ALT to levels <500 IU/l for less than 4 weeks. Anti-HBc may appear at the peak of ALT, anti-HBs somewhat later. This inapparent course will often develop in healthy people

who were exposed to low doses or mucocutaneously. In completely inapparent HBV infections without ALT elevation, markers of HBV may be difficult to detect and occasionally follow unexpected patterns. Anti-HBs may occur before anti-HBc or remain the only serological marker. In some transient infections, HBV DNA may be the only marker of infection. While these 'occult' HBV infections are irrelevant for the patient and his contact persons, HBV may be transmitted if such HBV infected persons donate blood or organs, particularly liver (Allain 2004).

Fulminant course

About 0.2 percent of clinically apparent cases of acute hepatitis B are so severe that the patients develop symptoms of hepatic failure within a few days and ensuing hepatic coma. This course is often fatal. Survivors recover completely and develop immunity to HBV characterized by anti-HBs and anti-HBc. Fulminant cases are often associated with coinfection by hepatitis delta virus (see Hepatitis Delta virus) or possibly other hepatitis viruses. The significance of HBe-negative HBV variants for the development of fulminant hepatitis B is discussed controversially but they are found in ca. 50 percent of the cases.

Coinfection

Acute HBV-infection may occur together with hepatitis A virus (HAV), hepatitis C virus (HCV), HDV or HIV. None of the other hepatitis viruses aggravates the course of acute hepatitis, but HDV suppresses HBV viremia and enhances HBs antigenemia. HIV favors persistence of HBV. Pre-existent HCV may be transiently suppressed by HBV (Chulanov et al. 2003).

CHRONIC HEPATITIS B

Clinical signs of chronic hepatitis are usually mild and nonspecific. They include lack of energy, easy fatigability, and malaise. Myalgias, arthralgias, and skin rash may be present in cases with high virus replication due to circulating immune complexes. HBV-associated immune complex disease is an important cause of glomerulonephritis in tropical countries. The course of the disease is usually intermittent with acute exacerbations during which abdominal discomfort, nausea, weight loss, dark urine, jaundice, and mild fever may occur.

However, chronic HBV infection may go unnoticed until compensated or even decompensated cirrhosis of the liver is present. In this late phase of the disease the above-mentioned symptoms are enhanced and signs of hepatic encephalopathy may be present. Blood coagulation is decreased due to reduced synthesis of coagulation factors in the liver. Serum albumin is also decreased whereas IgG is increased, probably due to impaired degradation in the liver. The ALT levels are usually only moderately enhanced to, at the most, several hundred IU/l and often fluctuate. A major complication is the collateral blood circulation due to impaired blood flow through the cirrhotic liver. Breakages of the esophageal varices are life-threatening, and are a result of portal hypertension. A further consequence of portal hypertension is the development of ascites in some cases.

It is important to distinguish between disease activity reflected by markers of viral replication, antiviral immune response, and hepatocyte damage, on the one hand, and symptoms caused by the lack of functional hepatocytes and the replacement of normal liver tissue by connective tissue on the other. Whereas the viral disease activity may come to an end either spontaneously or as a result of treatment, the conversion of normal liver tissue to cirrhotic tissue is irreversible. The liver status can be assessed only by histology, liver function tests, and determination of serum proteins synthesized or metabolized by the liver. Sonography describes the shape and density of the liver and may detect an increased diameter of the portal vein due to portal hypertension.

Most patients with persistent HBV infection are not aware of a previous acute hepatitis B episode. As pointed out above, HBV persistence very often develops in individuals who are immunologically immature or somehow impaired. Perinatal HBV infection virtually always results in persistence, unless HBe-negative variants are predominant. In the early years of life, symptoms are usually absent in HBV carriers despite high virus replication. The same is true for patients who acquired infection during significant immune deficiency. However, in otherwise healthy HBV carriers, a cytotoxic immune response will eventually develop and cause chronic disease. This cytotoxic immune response is directed primarily against the HBc protein, whereas the HBs protein seems to be a minor target in chronic hepatitis B. The HBc-specific T-cell response suppresses HBV replication and may even eliminate many HBV-expressing cells. As a result, an exacerbation of chronic hepatitis B may lead to a new form of persistent HBV infection, in which HBsAg is still present in the serum but the number of virions is much lower than in the previous phase of high viremia. HBeAg disappears and anti-HBe is often present in this phase. If HBV replication is constantly controlled by the immune system at low levels, the so-called healthy HBsAg carrier status is reached. Eventually, HBsAg may also disappear from the serum. In these cases, anti-HBc is often the only marker of HBV infection. This phase of low viral activity may be reached at all degrees of irreversible liver disease. Thus, a seemingly favorable serological constellation suggesting low viral replication does not necessarily mean insignificant liver disease.

During the high viremic HBeAg-positive phase, variability of the HBV epitope regions is low. In HBeAg-negative cases, however, considerable variability is

observed. This variability may be generated by the immune elimination of the original strains.

A dangerous clinical situation occurs if a low viremic HBV carrier (with or without HBsAg or symptoms) is therapeutically immunosuppressed because of autoimmune disease, organ transplantation or anti-cancer therapy. In such cases, high HBV replication may reappear, but, as soon as the immune suppression is terminated, the existing memory cells induce a vigorous cytotoxic immune response that often results in fatal fulminant hepatitis B. In such cases, early pre-emptive therapy with an antiviral substance is indicated.

Coinfection of chronic hepatitis B patients with other hepatitis viruses and/or HIV is frequent. Intravenous drug users are often coinfected with HCV and/or HDV, male homosexuals often with HIV. Both HCV and HDV suppress replication of HBV, HCV often to the point that it becomes occult (Pontisso et al. 1993). In HIV coinfected patients, HBV may become the dominant pathogen under successful HIV therapy and requires an antiviral therapy, which is also effective against HBV (Rockstroh 2003). Superinfection of chronic hepatitis B patients with HAV does not lead to an aggravated course (Vento et al. 1998).

HEPATOCELLULAR CARCINOMA

HBV is the major cause of HCC in regions with high HBV prevalence. HCC usually develops after cirrhosis, but may also occur without cirrhosis. The involvement of HBV may not be recognized by testing for HBsAg in the serum, requiring the search for HBV DNA. In some cases in which the HCC contains integrated HBV DNA fragments no classic serological HBV marker may be present. However, in highly endemic areas of the world, people positive for HBsAg are 100 times more likely to develop HCC as compared to those who have anti-HBc and/or anti-HBs but no HBsAg (Beasley et al. 1981). An important cofactor is exposure to aflatoxin B (Ming et al. 2002). In low endemic areas the relative risk of HBsAg carriers to develop HCC is also increased. A British study found a 26-fold increased incidence of HCC in male HBsAg-positive blood donors compared to the male general population. The incidence was 33.5 per 100 000 persons year for male, but only 4.4 for female HBsAg carriers (Crook et al. 2003).

In some countries with intermediate HBV prevalence, HCV may be the major cause of HCC, but coinfection with HBV, HCV, and even HDV is quite common in HCC patients. In Italy, 45 percent of HCC patients have heavy alcohol intake, 36 percent HCV infection, and 22 percent HBV infection as risk factor for HCC (Donato et al. 1997). In Germany HBV is the leading risk factor for HCC (45 percent) followed by HCV (37 percent) and alcohol (Kubicka et al. 2000). While HBsAg persistence is associated with a highly increased risk for HCC, absence of HBsAg does not exclude development of an HBV-associated HCC (Yu et al. 1997; Tamori et al. 2003; Pollicino et al. 2004). It is believed that in addition to HBsAg, the level of HBV replication is positively correlated to the risk for HCC (Tang et al. 2004). The strong preponderance of HCC in male HBV carriers is positively correlated to the testosterone levels and to the structure of the androgen-receptor gene (Yu and Mertz 2001).

The development of HCC may be diagnosed early by quantitative measurement of α-fetoprotein (AFP) in the serum, but levels may be normal (<20 ng) before the HCC reaches a size of 3 cm. Levels above 1 000 ng/ml, or a sharp rise of AFP, indicate HCC. Abdominal imaging by ultrasound of HBsAg-positive patients, particularly those with liver cirrhosis, is advisable at intervals of 3–4 months.

Pathogenesis and immune response

The pathogenesis of HBV is based on the immune reaction. Virus replication itself is not overly pathogenic but subtle effects on hepatocyte function cannot be excluded. Transgenic mice expressing HBV or single HBV proteins are normal or almost normal. However, selective expression of LHBs in transgenic mice leads to storage of LHBs-containing filaments in the ER and pre-Golgi compartments. The LHBs-storing hepatocyte acquires a ground glass-like appearance. In mouse strains with very high expression of LHBs, hepatocytes become very sensitive to interferon-γ. Inflammatory liver disease and eventually HCC develop whereby the tumors no longer express LHBs (Rogler and Chisari 1992). LHBs containing ground glass hepatocytes are often found in healthy HBsAg, carriers but their diagnostic or pathogenetic significance in humans is not clear.

A potential pathogenic role has been suggested for HBx protein due to its apoptosis inducing properties, which may even protect against malignant transformation (Schuster et al. 2000). On the other hand, HBx has been reported to counteract p53-induced apoptosis (Wang et al. 2002) and to enhance malignancy of immortalized cells (Höhne et al. 1990; Oguey et al. 1996). HCCs usually contain variants of the *HBx* gene, which are less frequent in chronic hepatitis B patients (Yeh et al. 2000). Selective overexpression of HBx protein in a certain mouse strain has generated HCC late in life, but other mouse strains did not develop HCC. However, HBx-expressing mouse lineages were more susceptible to chemical carcinogens. Thus, HBx may be one oncogenic factor of HBV infection acting together with chronic inflammation (Nakamoto et al. 1998), insertional mutagenesis (Gozuacik et al. 2001), testosterone levels (Yu and Mertz 2001), or aflatoxin (Ming et al. 2002). Basal core promoter mutations 1762T and 1764A have been reported to be associated with HCC (Kuang et al. 2004; Kao et al. 2003), but this may be an indirect association because these mutations

appear late in infection and lead to enhanced HBV replication (Blackberg and Kidd-Ljunggren 2003).

SHBs, HBc, and HBe proteins are not pathogenic when expressed in transgenic mice. SHBs and HBe protein are secreted whereas HBc protein is stored as HBc particles in the nucleus. Cytoplasmic HBc particles are rapidly degraded whereas nuclear HBc protein has a longer half-life. All these findings are in accordance with observations on human HBV infections. HBsAg, secreted HBeAg and nuclear HBcAg are not associated with disease per se.

There may be differences in pathogenicity and virulence between the various HBV genotypes. In Africa, Europe, and the USA genotypes A, D, and E predominate which lead less frequently to perinatal transmission, probably due to a shorter period of high level viremia in females. However, their horizontal transmission is frequent in early childhood (Dusheiko et al. 1985). In Asia, with genotypes B and C, perinatal transmission is frequent and seroconversion from anti-HBeAg to anti-HBe with a concomitant decrease in viremia occurs later. With genotype C, seroconversion to HBeAg occurs still later than in genotype B resulting in an even more progressive liver disease (Kao et al. 2004) and worse response to therapy.

HBeAg-negative variants are presumed to cause a more severe acute infection but less persistence. However, after persistence has been established by the HBeAg-positive virus, HBeAg negative variants can evolve and persist further.

Virtually all infected individuals develop anti-HBc antibodies. Development of IgM anti-HBc indicates significant ongoing HBV replication and is a serological marker of inflammatory disease. The appearance of anti-HBs usually shows that HBsAg production is low or absent. However, HBsAg and anti-HBs may co-exist and, rarely, HBs escape mutants are present. Anti-preS1 and anti-preS2 appear during recovery from acute hepatitis B earlier than anti-SHBs, and disappear earlier. In some cases, however, these antibodies may also contribute to the formation of circulating HBs immune complexes in chronic HBV carriers. Anti-HBx and anti-HBpol antibodies are detected in many but not all patients with acute or chronic hepatitis B, and are neither diagnostically nor pathogenetically important. HBs and HBe immune complexes contribute to extrahepatic manifestations of HBV, but are probably not a major pathogenic factor in viral hepatitis.

Administration of anti-SHBs in high doses protects against de novo infection with HBV. The administration of anti-SHBs to individuals already infected (for example, liver transplant recipients or some HBV-infected patients) favors outgrowth of HBs escape mutants. In vitro experiments with infection of cell cultures show that anti-preS2, and in particular anti-preS1, are also neutralizing antibodies, but their protective function in vivo is not well established.

The elimination of HBV-producing cells during acute hepatitis B is mediated mainly by a strong T-cell response to HBc/e and HBs proteins (Chisari and Ferrari 1995). Passive transfer of HBs-specific T-cell clones from immunized mice to HBs-transgenic mice induces acute hepatitis. The severity of the disease correlated directly with the dose of cytotoxic $CD8^+$ cells against HBs and the amount of HBs protein in the liver. It may result in fulminant hepatitis, as shown in animals with LHBs storage. The cytotoxic $CD8^+$ cells stimulate nonspecific inflammatory cells which form necroinflammatory foci, inducing necrosis of hepatocytes. However, these nonspecific cells are not necessary for HBV elimination (Sitia et al. 2002). The histological picture of this CD8+ cell-induced disease in transgenic mice is similar to that in acute or fulminant hepatitis B of humans. HBc/e- and HBs-specific $CD8^+$ cells have been isolated readily from the blood of patients with acute hepatitis B. In contrast, chronic hepatitis B patients have only low numbers of circulating or intrahepatic $CD8^+$ cells specific for HBs or HBc. This low number may explain the persistence of HBV and the continuous inflammation at moderate levels. Control of HBV replication in liver cells does not necessarily require the elimination of all HBV-expressing cells. Activated $CD8^+$ cells secrete interferon-γ and interleukin-2 which induce secretion of TNF-α. TNF-α reduces the stability of HBV mRNAs (Heise et al. 2001) and suppresses expression of HBV or its proteins, or both, without necessarily inducing cytolysis or apoptosis. In experimentally infected chimpanzees, $CD8^+$ cells induce the elimination of cccDNA even before cytotoxicity occurs, but final elimination of cccDNA is associated with hepatic turnover (Wieland et al. 2004a). A complete elimination of all cccDNA-containing cells is, however, not always achieved. $CD4^+$ lymphocytes against HBc/e are numerous in most patients with acute resolving hepatitis, but few are found during chronic hepatitis B. $CD4^+$ cells against HBs proteins are less abundant than those against HBc/e.

The mechanisms of how HBV escapes the immune system are not understood. Even in those individuals who resolve acute hepatitis B, HBV is able to replicate for weeks or even months without inducing an immune response. Evaluation of the gene expression pattern in acutely HBV-infected chimpanzees characterized HBV as a 'stealth virus' not visible to the innate immune system and with little influence on the host cells (Wieland et al. 2004b). Only after a period of several weeks of logarithmic expansion of HBV was the immune system activated, most likely via $CD4^+$ cells and interferon-γ. It is not known which factors finally activate the immune system after a long period of inertia.

HBV persistence seems to be caused by immune evasion and nonpathogenicity of the wild-type virus. It has been suggested that intrauterine transfer of maternal HBV antigens, particularly HBeAg, generates immune

tolerance to HBV in the newborn, but most newborns of HBeAg-positive mothers respond very well to HBsAg vaccine. HBeAg in the serum may be involved in the suppression of a vigorous cytotoxic immune response against HBc protein, because newborns (both human and woodchuck) develop persistent infection only if the infecting HBV-positive serum is also HBeAg positive. However, HBeAg in cells also becomes a target for the inflammatory immune response (Milich and Liang 2003). Other potential factors supporting immune evasion are the high excess of secreted HBs proteins and the high resistance of SHBs protein to proteolytic degradation, which may impair antigen presentation.

Diagnosis

A survey of the significance of HBV parameters for different diagnostic problems is given in Table 1.

ACUTE HEPATITIS

According to the description in 'Acute hepatitis B', virtually all cases of acute hepatitis B show at the onset of symptoms easily detectable levels of anti-HBc. Thus, a test for anti-HBc clarifies whether a patient with hepatitis is infected with HBV. Lack of anti-HBc excludes HBV as the causative agent of a present acute hepatitis or of a subclinical transaminase rise (Table 1).

If anti-HBc is positive, a test for HBsAg and IgM anti-HBc should follow (Table 1). A negative or low IgM anti-HBc (<600 PEI units) excludes HBV as the cause of a clinically apparent acute hepatitis, but points to previous HBV infection, which may have resolved or be persistent. (Persistent infection is recognized by a positive HBsAg test, immunity by a positive anti-HBs.) During early or very late phases of the acute disease, IgM anti-HBc may have concentrations lower than 600 PEI units/ml. In mild HBV infections, IgM anti-HBc may also be lower (Gerlich et al. 1986).

HBsAg is at least positive in most hepatitis B-infected individuals transiently. It may be eliminated very rapidly in fulminant hepatitis with extremely strong immune elimination or in very mild infections with very low viral expression. Alternatively, HBsAg may be present, but undetectable, by the usual immune assays because of mutations in the major epitopes. Such cases can be diagnosed by the quantitative assay of IgM anti-HBc and by the test for HBV DNA using PCR. HBV infection of a patient may suggest, in addition, a risk of HDV, HCV, and HIV infection, and appropriate tests for these infections may be advisable.

Table 1 *Serological parameters of HBV infection*

Serological parameters	
Ongoing or previous infection (prevalence)	Anti-HBc
Ongoing infection	HBsAg
Time of infection	IgM anti-HBc (quantitative)
Infectivity	HBV DNA (quantitative)
Natural immunity	Anti-HBc and anti-HBs
Immunity after vaccination	Anti-HBs (quantitative)

The patient's disease status should be followed by determination of the ALT level until it is close to normal. An early favorable prognosis is possible if the HBeAg patient is negative already in the first serum sample, or HBV DNA negative in hybridization assays. These two parameters become negative in resolving cases within 4–6 weeks. Thus, a second assay of HBeAg or HBV DNA after 6 weeks, when they were initially positive, is advisable. Alternatively, the HBsAg quantity may be measured accurately by electroimmunodiffusion or a quantitative EIA. In resolving cases, HBsAg drops within 6 weeks by more than 60 percent. A definitive resolution may be assumed if HBsAg is negative and anti-HBs is positive but this may take up to one year. However, even in this condition, low-level viremia and intrahepatic persistence of HBV DNA has to be assumed in a major proportion of the convalescents.

CHRONIC HEPATITIS

Patients with symptoms of chronic hepatitis need a thorough examination of the liver, including liver function tests and, if possible, liver biopsy. The viral activity is not clearly correlated to disease activity or to the histological appearance of the liver, but HBsAg is virtually always detectable. In early phases of chronic infection, HBeAg is often present and HBV DNA detectable even by the insensitive hybridization assays. Quantities of ALT, HBV DNA, HBeAg, and IgM anti-HBc are often unstable, fluctuate or are occasionally even negative. HBeAg is sometimes absent, but HBV DNA is usually detectable however PCR may be required as a more sensitive technique for detection. The diagnostical parameters associated with persistent HBV infection are shown in Table 2.

A typical feature of late phase chronic HBV infection is the selection of variants with deletions or mutations leading to an altered expression of HBV or to altered gene products. Most frequent are mutations (stop codons, promoter inactivation, frame shifts) that abolish expression of HBeAg. Deletions also occur quite often in the B-cell epitope regions of HBcAg and preS. Deletions within the *HBx* gene are common in patients with impaired immune reactions and are often the only mutation in these people, but they are rare in HCC patients (Blackberg and Kidd-Ljunggren 2003).

INAPPARENT PERSISTENT HBV INFECTION

Infrequently, HBV infection is not recognized subjectively. Thus, HBV carriers are often detected accidentally – during blood donation, because of an occupational risk, before operations or during search for a

Table 2 *Three states of HBsAg carriership – typical parameters*

Parameters	Immune tolerance	Chronic disease	'Healthy' HBsAg carrier
Serum			
HBsAg μg/ml[a]	30–150	<30	<30
HBeAg PEI[b] – U/ml	2 000–10 000	<2 000 or absent	Negative, anti HBe^+
HBV-g.e./ml[c]	10^9–10^{10}	10^6–10^9	$<10^6$
Anti-HBc	+ to ++	+++	+ to ++
IgM-antiHBc PEI units	<50	10–500	<10
ALT IU/ml 37°C	<120	>120, variable	<50
Liver			
$HBcAg^+$ cells	90–100%	Variable, low	Negative
$HBsAg^+$ cells	90–100%	Variable, low	Variable, frequent ground glass cells, $LHBs^+$
Dynamics	Stable	Unstable	Stable
Interferon response	Transient or none	Often sustained	No treatment required

One IU HBV DNA in the WHO standard corresponds to ca. 5 g.e./ml.
a) 1 μg HBsAg = 1 000 PEI units or 2 000 WHO units. So-called ng units are often inaccurate.
b) PEI: Paul Ehrlich Institute for Sera and Vaccines, Langen, Germany.
c) g.e.: genome equivalents.

possible source of HBV infection. The most universal test to detect an ongoing or previous HBV infection is anti-HBc. However, anti-HBc may remain negative for up to 6 months post-infection, whereas HBsAg is positive much earlier. In some chronic HBV carriers who were infected perinatally, anti-HBc may remain negative lifelong although HBV replication is very strong. Anti-HBc may also be absent in reactivated HBV infections due to immune suppression or in conditions where antibody synthesis is generally suppressed. The earliest marker of HBV infection is HBV DNA in the serum if detected by a highly sensitive nucleic acid amplification technique (NAT) such as PCR.

If a person is identified as being positive for HBsAg, he or she should be tested for anti-HBc. Negative anti-HBc suggests an early phase of infection with a possible acute hepatitis B still to come, or a severe state of immune deficiency which, however, usually would have been known for other reasons. Absent IgM anti-HBc in the presence of IgG anti-HBc suggests low disease activity and a stable carrier state (Table 2). HBsAg carriers stay, by definition, HBsAg positive for more than 6 months. Positive HBeAg suggests high viremia and high infectivity, but some HBeAg-positive carriers have only moderate viremia ($<10^8$ genomes/ml) and are less infectious. Absence of HBeAg suggests low viremia ($<10^6$ HBV particles /ml) but does not exclude higher levels. A quantitative HBV DNA assay is therefore recommended. Most HBeAg-positive carriers and some HBeAg-negative carriers reach very high viremia levels of 10^9–10^{10} genome-containing HBV particles.

Chronically infected individuals may be divided into three groups, as shown in Table 2. The immunotolerant type is highly infectious but oligosymptomatic. The HBsAg carrier is also healthy but noninfectious (except for blood donation). A status between these two extremes is usually associated with liver disease that, however, may be unrecognized. In this phase, disease activity is often fluctuating. Silent HBsAg carrierlike phases may change with flareups. Viremic HBV carriers often spontaneously reach the HBsAg carrier state after one or more episodes of recurrent liver disease. Unfortunately, this disease phase may be longlasting and result in liver cirrhosis or HCC. Thus, regular monitoring of ALT levels in persistently HBsAg-positive people is advisable until it is known whether a stable state is present. HBeAg and HBV DNA should also be regularly checked if positive.

NATURAL IMMUNITY

People who have been at risk for HBV may have acquired immunity by silent HBV infection. In order to detect natural immunity the person's blood should be tested for anti-HBc, and then, if positive, for anti-HBs. Naturally immune people should be anti-HBc and anti-HBs positive (see Table 1). It has, however, been noted that anti-HBs may occasionally disappear several years after an acute hepatitis B infection. Isolated anti-HBs without previous vaccination may be nonspecific and nonprotective, but asymptomatic transient HBV infection may also lead to low levels of anti-HBs without anti-HBc. Isolated anti-HBc may have different meanings:

- The person may be in the phase after disappearance of HBsAg but before the appearance of anti-HBs (so-called window period). In this case the titer should be high.
- It may be present long after previous HBV infection in which anti-HBs has already disappeared. In this case, the titer should be low.
- It may be a response to an HBV infection, in which HBsAg is mutated, bound in immune complexes or below the detection limit. Anti-HBe may be present.

- The anti-HBc test may react nonspecifically. Usually, the signal strength is low.

If distinction between the four situations is required, an HBV DNA assay by NAT may be helpful. If it is necessary to decide whether a person is immune, vaccination against HBV with one dose of vaccine is recommended and a quantitative test for anti-HBs should be done 1–2 weeks later. Situation (2) will lead to a rapid anamnestic response with a reappearance of anti-HBs at high titers. If this does not occur, vaccination should be continued by the regular schedule with two or three further doses. In situation (3), no anti-HBs may develop. For the discussion of vaccine-induced immunity see 'Active immunization'.

DETECTION OF HBV IN TISSUE SPECIMENS

Because of its ability to generate high viremia and antigenemia, HBV infection is usually easy to diagnose with the aid of serum samples. Liver biopsies are necessary to examine the degree of inflammation, necrosis, and fibrosis, and repeated biopsies give information on the progression of the disease. Because of the risk associated with biopsy, it should be done only if the clinical, biochemical, and virological data suggest severe, progressive disease. Once the biopsy is available, it may be stained for HBsAg, preS1 antigen, HBcAg, or HBV DNA. In HBsAg-positive patients, usually no more information can be derived from these stainings than from a complete quantitative HBV serology. The situation is different in HBsAg-negative patients with liver cirrhosis or HCC. Here, a liver biopsy or tumor tissue may allow detection of extracted HBV DNA by NAT and, if highly positive, by Southern blot. Distinct bands in a Southern blot prove mono- or oligoclonal outgrowth of hepatocytes with integrated HBV DNA and, thus, HBV-associated liver disease.

DIAGNOSTIC TESTS FOR HBV

HBsAg

HBsAg is detected qualitatively by solid-phase immune assays with unlabeled anti-HBs as the carrier and labeled anti-HBs for detection in the liquid phase. Originally, radioactive iodine 125 was used as label (radioimmune assay) but today enzymes (EIA) are preferred which generate a colored or fluorescent product. Chemoluminescence labeling is also used. The specificity and sensitivity is mostly determined by the quality of the anti-HBs reagent. Most commercially available assays use either as the solid phase or as label or for both just one monoclonal antibody against SHBs. While this is sufficient for most genotypes of wild-type HBV, mutants of the *SHBs* gene may escape detection in reactivated hepatitis B (Westhoff et al. 2003), in blood donors (Jongerius et al. 1998) or in the general population (Carman et al. 1997). Use of affinity-purified polyvalent antibodies or several non-overlapping monoclonal antibodies, possibly also against preS epitopes, help to overcome this problem. Analytical sensitivity is also very important. An international standard is available for its validation which contains 33 IU/ml heat-inactivated SHBsAg of subtype adw2 and genotype A2. The detection limit should be below 0.1 IU/ml, but not all tests are so sensitive. Nonspecific reactions are usually rare (<0.1 percent) and may be verified by inhibition tests using polyvalent anti-HBs. Quantification may be achieved by using reference samples and appropriate dilutions of the sample which give a result in the proportionality range (<100 PEI units/ml) of the EIA. Results may be expressed either in PEI or in International Units /ml. One IU is 0.55 PEI-Unit. One PEI-Unit corresponds to 1 ng of fully native HBsAg. Unfortunately, many test kit producers use 'ng' units, which are calibrated with partially denatured HBsAg. Furthermore, test kits may react differently with various subtypes of HBsAg or with variants of HBsAg. A useful technique for quantifying HBsAg in the range of 1 000–100 000 PEI-units/ml is Laurell electrophoresis (Glebe and Gerlich 2004). This is the relevant range for quantitative assessment of acute and chronic hepatitis B.

Anti-HBc

Anti-HBc is usually determined by inhibition EIAs with recombinant HBcAg (expressed e.g. in *E. coli*) at the solid phase and labeled anti-HBc, the binding of which is inhibited by the anti-HBc within the samples. Sandwich assays with HBcAg at the solid phase and labeled HBcAg or labeled anti-IgG are also available. There are nonspecific inhibitors of HBcAg in human sera; nonspecific reactions may therefore be as frequent as 1 percent in the normal population. Repetition of the test using a test kit from a second producer usually yields a positive result if the reaction is specific, but a false-negative result in this second assay cannot be excluded. Divergent anti-HBc results in different tests are particularly frequent in individuals with a high risk of HBV exposure. Western blotting is not helpful and quantification of anti-HBc is not usually done. Chronic HBV carriers and acute hepatitis B patients may have end point titers up to 1:1 000 000 whereas immune people usually have titers below 1:1 000.

IgM anti-HBc

IgM anti-HBc is usually detected by the anti-μ capture EIA. This type of EIA binds via anti-μ antibodies IgM from the sample to the solid phase; thereafter labeled HBcAg is added. If the sample contains IgM anti-HBc, labeled HBcAg will be bound. Quantification is highly advisable. Results may be expressed in PEI units/ml or as an EIA index. Some commercial test kits employ very high cut-off values to give a positive result only with sera

from acute hepatitis B, but all test kits react significantly stronger with sera from patients with active chronic hepatitis than the negative control giving values up to 600 PEI units/ml. Testing for IgM anti-HBc is advisable only if the screening for total anti-HBc was positive.

Anti-HBs

Anti-HBs is usually detected by a sandwich EIA with HBsAg at the solid phase and labeled HBsAg in the liquid phase. Some producers use natural purified HBsAg from HBV carrier plasma; others use recombinant HBsAg particles from yeast or from mammalian cells devoid of preS antigen. Thus, quantitative results obtained for one serum using various test kits may differ significantly. The detection limit is usually between 1 and 10 mIU/ml and saturation of the assay is reached at 100–1 000 mIU/ml. Sera may contain more than 100 000 mIU/ml after vaccination with HBsAg. Nonspecific results are possible, but they are rare. Coincident positivity of HBsAg and anti-HBs may occur in patients with chronic hepatitis B. The anti-HBs in these patients usually reacts with HBsAg subtypes not present in the HBV carrier. Normally, anti-HBs should be assayed only in anti-HBc-positive people or after vaccination.

HBeAg

HBeAg should be determined only in people with HBsAg. It is tested by EIA and may be quantified using PEI units. Detection limits of commercial assays are between 1 and 10 PEI units/ml and high viremia is usually associated with high HBeAg titers (>2 000 PEI units/ml). Anti-HBe is a less important marker of HBV infection. However, monitoring of chronic hepatitis B patients for seroconversion (Figure 8c) from HBeAg to anti-HBe is clinically relevant. Furthermore, assay of anti-HBe may help to interpret the significance of anti-HBc without HBsAg or anti-HBs.

HBV DNA

HBV DNA has become very important in the diagnosis of HBV infections and may be helpful for answering many questions:

- HBsAg positive anti-HBc negative samples need confirmation of specificity. A highly sensitive HBV DNA assay, preferable NAT, will react positively in almost all specifically positive samples.
- In anti-HBc positive but HBsAg and anti-HBs negative samples, HBV DNA can help to identify low level HBV carriers, or carriers with a mutated HBsAg which escaped detection.
- In very early phases of infection, inapparent transient or occult persistent HBV infection, HBV DNA may be the only detectable viral marker. Persistent low level HBV infections are particularly frequent in HCV, HBV-coinfected persons.

For these applications an assay of the highest possible sensitivity is required. With todays techniques, usually few or even one DNA molecule in the tested sample volume are detectable. Thus, the sample volume is often the limiting factor. Unfortunately, some inapparent HBV infections show extremely low levels of viremia around 1 genome/ml (Kuhns et al. 2004). Nevertheless, HBV DNA assays should be employed whenever a serological pattern is inconsistent or of uncertain specificity. In-house NAT assays (if adequately validated) may be superior to commercially available assays because several target regions may be used. This can prevent false-negative results due to mutations in the primer or probe target regions.

In the 1990s, NAT was plagued by false-positive results due to cross contaminations between the amplificate and samples. The use of closed systems and/or degradation or amplificates has helped to avoid this problem during handling and extraction. However, cross contamination between samples is still a problem because sera may contain up to 10^{11} genome equivalents/ml. False-negative results due to polymerase inhibitors, false reagents, or wrong performance should be excluded by inclusion of an internal control or by spiking of a suspected false-negative sample with a known positive sample. False-negative results due to mutations in the target sequence of probes and primers remain a problem of unknown magnitude, but the existence of HBsAg true-positive, HBV DNA-negative samples give a hint to its existence. For diagnostic purposes only, NAT systems with detection of the amplificate by labeled probes should be used, because they are less prone to contamination by the amplificate. Techniques with in situ generation and measurement of the signal after each amplification step (real-time PCR) are preferable. The great advantage of these systems, besides their high contamination resistance and analytical sensitivity, is the ability to quantitate the complete range of concentrations from <100 to $>10^{10}$ g.e./ml. The TaqMan system uses a fluorescent probe, which is degraded when being annealed to the amplificate and is thereby released from a fluorescence quencher. The fluorescence resonance energy transfer (FRET) technique uses two probes with two different fluorescence dyes. FRET can only occur and generate the signal when the probes bind next to each other to the amplificate. Due to the existence of a World Health Organization (WHO) approved International standard, both assays can be standardized. The WHO has preferred not to define the HBV DNA in g.e./ml or 'copies/ml' but in International Units, because different results were obtained with different methods of detection (Saldanha et al. 2001). These differences are most likely caused by variable losses during extraction, because the HBV

DNA carries the covalently bound HBV polymerase with it. This protein alters the extraction properties of the DNA, and it is the reason why for the standardization of HBV DNA assays HB-virion-derived DNA and not cloned DNA should be used. With adequate extraction and calibration one IU corresponds to ca. 5 g.e./ml of HBV genotype A2 (Heermann et al. 1999). One picogram HBV DNA is 280 000 g.e./ml.

Real-time PCR is superior to competitive PCR because it is more sensitive and does not reach an upper limit of quantification. Hybridization assays have been used for a long time to quantitate HBV DNA, but they are too insensitive (detection limit $>10^6$ g.e./ml) for therapy monitoring or assessment of infectivity. These are the main applications of HBV DNA quantitation.

HBV DNA genotyping or resistance testing can be done via hybridization of a NAT product with commercially available sets of probes, but sequencing of a NAT product covering the SHBs/RT region is a cost-effective and more informative in-house alternative.

Epidemiology

PREVALENCE

It is estimated that 50 percent of the world's population have had contact with HBV and about 10 percent of these (ca. 350 million) have developed persistent infection. HBV carriers have a high risk of developing liver cirrhosis and a 20 to 100-fold greater risk of developing HCC. Mortality from acute hepatitis B is low (<1 percent), but much higher from chronic hepatitis B. It is estimated that 1 million people per year die from the sequelae of chronic hepatitis B. Prevalence of anti-HBc, the best marker for current or previous infection, is highly variable in different geographic regions, ethnic or behavioral groups. Areas of low prevalence of anti-HBc positivity (<5 percent) are Northern Europe, North America, and parts of South America; areas with a particularly high prevalence (>50 percent) are sub-Saharan Africa, most parts of Asia and Oceania except India, where more than 10 percent of the adult population are HBsAg carriers. In Australia, New Zealand, and Alaska the native population is much more affected than the Caucasian immigrants. There are no hints that certain races are more susceptible to persistent infection. There may also be very large differences within a country; for example, southern Italy has a much higher prevalence than most northern areas. Lower socioeconomic status is often (but not always) connected with higher prevalence. In areas of low or moderate endemicity, prevalence increases gradually with age, being very low during childhood. In areas of high prevalence most individuals have acquired the infection before school age.

The prevalence pattern is changing due to lower incidence in young people. Vaccination has an efficacy of ca. 90 percent if performed optimally. Indeed in highly endemic countries like Taiwan or Oceania, which have implemented general vaccination in childhood, the prevalence of HBsAg has decreased by a factor of five from 14–20 percent to 3–5 percent (Lin et al. 2003; Wilson et al. 2000).

INCIDENCE

In many countries, hepatitis B is a notifiable disease and, thus, numbers on the annual incidence are available. In Germany, incidence of acute hepatitis B has continuously decreased from a high level in the seventies (>10 per 100 000 person years) to 1.7 per 100 000 person years, in 2002. Similar decreases are observed in other developed countries. Thus, acute hepatitis A and C are now more frequent than hepatitis B. In Germany, the peak incidence is found in males aged between 20–29 years pointing to i.v. drug use and male homosexuality as major risk factors. It is almost certain that acute hepatitis is under-reported. The true number of cases is probably two or three times higher. The true number of new HBV infections is even more difficult to determine, because most infections are subclinical, even those that finally lead to chronic hepatitis. On the basis of 6 percent prevalence of anti-HBc in the general population of Germany, even the general population must have had an incidence of 100–500 inapparent HBV infections per 100 000 person years before the 1980s. However, today's incidence is probably much lower.

MODES OF TRANSMISSION

Because of the extremely high infectivity titer of $>10^8$/ml serum, even the slightest trace of serum is dangerous, but other bodily secretions such as saliva, ejaculate, vaginal secretions or menstrual blood may also cause transmission, and titers of 10^6/ml may be present in these materials. HBsAg and HBV DNA have been detected in urine (Knutsson and Kidd-Ljunggren 2000), but there is no epidemiological evidence that the infection is transmitted by exposure to urine. Transmission is most efficient by intravenous injection, 100 times less efficient by the intramuscular or percutaneous route and least efficient by mucosal contact. Intact skin is impermeable to HBV but open wounds allow efficient entrance. Assuming an infectivity titer of 10^8/ml serum in an unrecognized HBV carrier, 1 nl of this serum (an invisible amount) would still contain 100 infectious doses, which would almost certainly cause infection if administered by a contaminated syringe or other medical device. Even dilution of this serum by $1{:}10^5$ (e.g. a blood spill of 0.1 ml has been washed away with 10 liters of water) would leave 1 ml of this liquid still infectious when administered percutaneously. Swallowing highly infectious blood or serum, blood splashes into the eyes, and contact with open wounds almost invariably lead to infection of susceptible individuals. Heterosexual contacts are a less effective but still relatively efficient

way of transmission. Transmission has been very frequent between male homosexuals, depending on their sexual practices. The danger of transmission by intense kissing is unknown whereas bites transmit very efficiently. Experience suggests that the rate of transmission from HBV carriers to contacts is proportional to the genome titer, frequency and intensity of exposure. Genome titers $<10^6$/ml have been empirically found not to pose a risk to even the closest contact person unless contaminated syringes or similar devices are involved. HBsAg-positive mothers with a negative HBV DNA hybridization test ($<10^6$/ml) do not usually transmit HBV to their newborn babies (Ip et al. 1989). Thus, sources of infection are almost invariably (except for blood products) highly viremic HBV carriers. Even with very high titers, transmission to household contacts usually requires time and special situations; normal school or professional contact is not a risk. Transmissions occur more easily in nursery school or in injury-prone sports or jobs; for example, a young HBV carrier infected his co-pathfinders by hiking along the same thorny trail, and an HBV-positive butcher infected all his colleagues within a short time because of the many skin injuries they received during the course of their work. Nosocomial infections have been frequent in previous decades but today they occur only in rare cases of accidents or failures to follow hygiene. Transmission of HBV from patients to medical staff is a well-known risk, but the reverse is also well documented (Gunson et al. 2003). In recreational activities, devices for ear or nose piercing or tattooing have been sources of transmission, but the most significant are shared syringe and needles for intravenous drug use.

Control

Control of HBV includes counseling of HBV carriers, general hygiene, disinfection, blood screening, active and passive immunization, and treatment of persistent infection.

COUNSELING OF HBV CARRIERS

As pointed out under Modes of transmission above, even the slightest trace of highly infectious blood on a sharp item will transmit HBV if it penetrates the skin of a susceptible person. The job and the life style of a highly viremic HBV carrier must be analyzed as to whether their blood might contaminate sharp items that may percutaneously infect other people. The carrier should be informed that simple cleaning by wiping the blood away or washing with water will be insufficient to remove infectivity reliably. All highly viremic HBV carriers should be instructed to avoid injuries, to keep lost blood under control, and to disinfect items that are contaminated by their blood if they cannot be cleaned by regular washing.

Surgeons who have their hands and sharp instruments within the body of their patients cannot completely avoid small, often unnoticed, injuries. Thus, highly viremic carriers (HBeAg positive or HBV DNA hybridization positive ($>10^5$/ml)) should not operate or work as dentists. HBV transmission by HBeAg-negative and low-viremic ($<10^5$/ml) carriers has not yet been reported, except for one case (Corden et al. 2003). Operations performed by them should be safe if combined with wearing two pairs of gloves and an injury-avoiding technique. European recommendations added to this limit a safety margin and suggest that HBV carriers should have <1 000 g.e./ml when performing exposure prone procedures (Gunson et al. 2003). The main point is that all medical staff should be vaccinated and be tested at least once for HBsAg and for anti-HBs. No restrictions are necessary for noninvasive medical procedures.

Household contacts, close friends, and sexual partners should be vaccinated or (if appropriate) tested for anti-HBc and HBsAg, or both. Physicians should be informed before they do invasive procedures with the HBV carrier. To take appropriate precautions, it would be desirable that sexual partners and close social contacts should know that a person is a carrier of HBV; they may, however, fail to understand the nature of the risk and discriminate against the carrier. The HBeAg and HBV DNA status should be checked at least twice a year. The usefulness of antiviral therapy should be considered carefully, because an unsuccessful treatment might cause more harm than good.

HYGIENE

Human blood is almost ubiquitous in medical practice and laboratories, and HBV infections were once very frequent in the medical profession. Protection against the contamination with blood is now observed more strictly since the occurrence of HIV; this includes wearing gloves and facemasks and using safer equipment (for example, for blood taking) that causes fewer injuries.

Patients are now better protected by the use of disposable items, in particular syringes and needles, and by a generally higher awareness of hygiene. Breaking of hygiene rules during blood taking or injections still causes small outbreaks of HBV infection even in developed countries, and originates usually from an unrecognized highly viremic carrier. Nondisposable devices that cannot be autoclaved (e.g. endoscopes) can still pose a problem, if the available disinfection devices are not adequately used.

In dialysis centers, HBV carriers must have their own room with their own dialysis machine. Furthermore, dialysis patients should be vaccinated or – if nonresponders – monitored for HBsAg. Outbreaks of HBV have been observed in pediatric oncology wards despite good hygiene. Here patient-to-patient contact is

common but HBV infections usually go unnoticed if the patients are not screened for HBsAg. Transmission from an operated highly viremic carrier to the next operated patient occurs occasionally even in these days and points to lack of hygiene. However, general screening of all patients, or at least of all those who undergo surgery, is considered to be cost-inefficient.

Isolation of patients with acute or chronic HBV infection is not essential if they are instructed as described above, behave responsibly, and do not lose blood in an uncontrolled fashion. However, HBV-carrying children should be supervised carefully.

DISINFECTION

Modern disinfectants should be validated with test organisms. In the European Community, a standard test is required in which a working dilution of a disinfectant must reduce the infectivity titer of poliovirus by a factor of $>10^4$ within 1 hour at room temperature. Because there is no feasible infectivity test for HBV, no disinfectant is formally validated for HBV even though it is one of the most important disinfection problems in medicine. The use of duck HBV as a model that can be titrated has been generally accepted, but its structural proteins (which are the targets) and its mode of transmission (almost exclusively vertical) are very different. A better model would be woodchuck HBV but the test system is not readily available. Inactivation of HBsAg or of the viral endogenous DNA polymerase is an inadequate substitute because their connection with infectivity is not established and a reduction by a factor of $>10^4$ has not been measured. The morphological alteration and disintegration test (MADT) using purified HBV particles and electron microscopy has been of some value. Disinfectants that inactivate simian virus 40 would also be expected to inactivate HBV, whereas adenovirus may be a more sensitive virus than HBV. Recently, agents that target viral DNA can be validated by PCR. Furthermore, neutralizing epitopes may be used as targets (Jursch et al. 2002) and finally cell cultures for infectivity testing of HBV have become available (Gripon et al. 2002; Gerlich et al. 2004).

SAFETY OF BLOOD PRODUCTS AND ORGAN DONATIONS

All blood or plasma donations must be tested as a minimum requirement by licensed highly sensitive tests for HBsAg; HBsAg-positive blood or plasma must not be used. However, in developing countries with very high HBV prevalence and very limited financial resources, HBsAg testing is often not done or is suboptimal. It has been estimated that in a highly endemic country like Ghana, the risk of children <10 years for acquiring HBV is 1:11 for unscreened and 1:360 for HBsAg screened blood (Allain et al. 2003). In Germany, the residual risk of HBV in a blood donation despite HBsAg screening is 1:100 000 to 1:500 000. While this risk is very low it is still 10 times higher than for HCV or HIV transmission. A similar situation exists in most developed countries. Additional measures like screening for HBV DNA and/or anti-HBc to reduce the small residual risk of HBV transmission are in most countries optional.

Donor blood may contain HBV despite HBsAg screening, because of:

- a mix-up in the blood bank
- a very early phase of HBV infection
- a late phase of HBV infection
- an escape mutant or a variant of HBV or
- immune complexing of HBsAg.

In cases (2) to (5) above, NAT may detect HBV DNA; in cases (3) to (5), anti-HBc should be also positive. Screening of every blood donation for HBV DNA by NAT has been introduced in sample pools by blood donation services of the German Red Cross (Roth et al. 2002) and in Japan (Minegishi et al. 2003). Screening for anti-HBc by EIA in low prevalence areas has also prevented a few cases of HBV infection in the recipients, but it caused a large loss of donors. In high prevalence areas, exclusion of anti-HBc positive persons is not feasible because most donors would be positive. To avoid loss of donors, anti-HBc-positive donors should be tested for anti-HBs and only anti-HBs-negative donors excluded. Anti-HBs-positive blood is thought to transfer protective antibody. HBV DNA-positive, HBsAg-negative blood with anti-HBs did not transmit HBV (Prince et al. 2001). Besides screening for HBV DNA, vaccination of non-yet immune donors against HBV would prevent transmission of fresh HBV-infections to recipients.

Anti-HBs in large plasma pools cannot exclude infectious HBV. In 1994, a clotting factor IX preparation transmitted HBV to at least 30 people, although the donors were screened for HBsAg the pool was anti-HBs positive and the transmitted HBV was not an escape mutant. The pool was, however, HBV DNA positive when tested by a highly sensitive NAT (detection limit 10 genomes/ml) and the product was suboptimally inactivated.

Since 1995, virtually all plasma protein products have been required to be treated with one or more validated virus inactivation steps, i.e. by heat at 60–70°C for 10–30 hours in the presence of protective factors. Experience suggests that low contamination by HBV ($<10^4$ infectious doses/ml) can be completely inactivated by such a heat treatment. High contamination can be prevented by donor screening for HBsAg and NAT testing of plasma pools. Treatment of plasma with solvent/detergent is probably effective against HBV as against other enveloped viruses. Recently, methods for chemical inactivation of cellular blood products have been developed and validated with DHBV infectivity and HBV DNA reaction in PCR (Aytay et al. 2004). HBV transmission by blood or blood products should be

extremely rare exceptions today. However, if a new HBV infection occurs in a recipient, the producer of the product and the responsible public health institution should be notified and the source of infection identified.

For screening of organ and tissue donors, principally the same rules should be followed as for blood donors. However, livers from anti-HBc-positive donors will often reactivate HBV in the recipient and should be used only for HBV positive recipients or under protection with an antiviral substance and/or passive immunization.

Active immunization

All aspects of active and passive immunization have been described in detail by Ellis (1993). The first attempt to vaccinate against HBV used boiled HBsAg-containing serum as inactivated vaccine. More convincing success was obtained with HBsAg 20-nm particles purified from the plasma of HBV carriers. Residual infectivity of HBV and of other viruses potentially present in plasma was minimized by various inactivation procedures. The most frequently applied plasma-derived vaccine was treated with pepsin at pH 2, urea, and formalin. Other products were inactivated with higher doses of formalin or heating to 100°C. Plasma-derived HBsAg has been used in millions of recipients without any known transmission of viruses. Meanwhile, most countries use 'recombinant' HBsAg that has been expressed in transformed yeast cells. HBsAg expressed in mammalian cells is also used as a vaccine, but is more expensive and not generally available. Today, vaccines typically contain 10–20 μg purified 20-nm HBsAg particles as a standard dose, adsorbed to aluminium hydroxide as an adjuvant, and an antibacterial substance; some products are treated with formalin. Usually, three doses, the second 1 month after the first and the third at 6 months, are recommended for adults. For infants of HBsAg-negative mothers, combination with other vaccinations is recommended. The exact observance of the intervals is not essential, but long intervals between the second and the third dose favor development of high titers of anti-HBs. When rapid protection is required, or after exposure, a shortened schedule of 0, 1, and 2 months and a fourth dose after 6 or 12 months should be used. For infants, smaller doses (2.5–10 μg) are advisable, and for immunodeficient recipients, larger doses of 40 μg HBsAg. Vaccines with stronger adjuvants or HBs-encoding DNA are in clinical evaluation.

Indications for vaccination

The WHO has recommended the vaccination of all children worldwide during the first year of life. In areas where perinatal transmission is frequent, vaccination should start as soon as possible after birth. The same is true for children whose mothers are known to be HBsAg positive or who have not been tested for HBsAg. Post-exposure vaccination with four doses of 10 μg recombinant yeast-derived HBsAg (at 0, 1, 2, and 12 months) was reported to protect 95 percent of the babies born to HBsAg- and HBeAg-positive mothers. Most other studies on the prevention of perinatal HBV infection combined HBsAg vaccine with passive immunization (see 'Passive vaccination', below), but it is not clear whether immunoglobulins against HBV (HBIG) really improve the protection rate if highly efficacious active vaccines are used (for review, see West 1993). Studies without HBIG in South Africa (Hino et al. 2001) and in Oceania (Basuni et al. 2004) revealed a relatively low rate of vaccine failures and no selection of escape mutants whereas after passive/active immunizations escape mutants emerged (Nainan et al. 2002). Vaccination failure occurs more often in mothers with very high viremia ($>10^8$ g.e./ml). Thus, reduction of viremia to lower levels has been attempted with lamivudine therapy before delivery (Van Zonneveld et al. 2003).

In 2004, the majority of countries are following the WHO programme, but many countries with high prevalence have financial limitations and are not able to take part. Some countries with low prevalence do not consider early childhood vaccination to be necessary. In 2002, Germany had a vaccination coverage of 80 percent in early childhood and 60 percent in adolescents.

Among adults, vaccination is strongly recommended for people at risk. Everyone who is or will be in professional contact with blood from other persons, whether directly or indirectly, should be offered free vaccination against HBV by their employer or teaching institution. This includes not only medical and paramedical professions, but also people in the armed forces, the police, staff and inmates of prisons or other closed institutions, and social workers. Patients who need continuous invasive or infusion therapy should be vaccinated, as should relatives and close contacts of HBV carriers. Intravenous drug users should be offered free vaccination and also free access to syringes and needles. Travel to high-prevalence countries does not require hepatitis B vaccination unless close contact or a long stay is expected. Male homosexuals have a high risk of HBV infection and heterosexual promiscuity poses a greater risk than nonpromiscuous heterosexual activity. For many of these risk groups the combined vaccine containing HAV and HBs antigens is advisable.

Side-effects

The vaccine causes no local side effects except moderate pain at the injection site. Generalized nonspecific side effects are rare or mild. Recipients should be questioned about hypersensitivity to yeast components, formalin or the antibacterial substance, but such reactions are very rare. Induction of neurological autoimmune disorder has been suspected in some cases of

being associated with hepatitis B vaccine, but several studies did not confirm this. It should be noted that HBsAg may be detected in the serum for a few days after vaccination, and thus for one week after vaccination no blood should be donated.

Pre- and post-testing

People to be vaccinated because of already existing high risk should be tested for anti-HBc before vaccination. Ethnic origin from a high prevalence area is also a risk. If anti-HBc is positive the serum sample should be tested further and the person vaccinated as described in 'Natural immunity,' above. If anti-HBc is negative, vaccination should be started following the schedule of the vaccine producers. If there is a high probability that HBV infection is already present, the person should be tested for HBsAg, even if negative for anti-HBc. An HBsAg-positive person should not be vaccinated, although accidental vaccination is not known to be harmful.

The immune response should be controlled by a quantitative anti-HBs test 4 weeks after the third dose in anyone who is at greater than average risk. Although T-cell responses and immunological memory may be more important than the anti-HBs itself, an easily detectable anti-HBs level is a marker of protection. The detection limit is 1–5 IU/l; 10 IU/l is considered to be a marker of protection. People with less or no anti-HBs should be revaccinated immediately with a further dose. Low responders with <100 IU/l should be revaccinated after one year, all others after 10 years if the special risk is still present, but the necessity of boosters is debated.

Children who have been vaccinated during the first year of life should be revaccinated at the onset of adolescence because then they are again at increased risk. Nonresponders after four doses may receive further doses if protection is urgently requested. Response rates are >90 percent in the healthy general population, but decrease strongly with age. Further risk factors for nonresponse are male gender, obesity, and smoking. Vaccines with preS antigen or other adjuvants may induce a better response but are not yet generally available at the time of writing.

Escape mutants

Post-exposure prophylaxis by active and passive vaccination is usually successful if given soon after injury (e.g. needle-sticks) with HBV-contaminated items. Active vaccination of newborns from HBeAg-positive mothers is also successful in up to 95 percent of cases. In ca. 5 percent of the children, HBsAg may appear in spite of vaccination or never be negative from the first day. Such infants may have already been infected in utero. In some children, HBsAg appears despite seemingly protective levels of anti-HBs. These children have escape variants, detectable by sequencing of the *SHBs* gene, with mutations in the major HBs epitopes between amino acids 120 and 150. Escape variants have been described with various genotypes except for genotype A. A frequent escape mutation is glycine 145 of the S protein to arginine (Nainan et al. 2002).

Although early experiments in chimpanzees suggested that immunization with one HBsAg subtype protected against all HBV genotypes, it should be noted that most recombinant vaccines have genotype A2 or HBsAg *adw2* respectively. It is possible that genotype-specific antibodies may contribute to protection.

Experiments in chimpanzees and in cell culture suggest that anti-preS1 and partially also anti-preS2 contribute to protection. Experiments with transgenic mice suggest that helper cell epitopes of the preS region may induce a better B-cell response against SHBs. The potentially better protection of humans by preS-containing vaccines has not yet been confirmed by field studies. However, induction of anti-HBs in many non-responders to the normal recombinant SHBs vaccine has been found with a vaccine containing preS1 and preS2 (Zuckerman et al. 2001). A similar vaccine induced a stronger and more rapid anti-HBs response than the conventional vaccine (Shapira et al. 2001).

PASSIVE VACCINATION

Normal immunoglobulin does not contain enough anti-HBs to be used for passive vaccination. A special immunoglobulin is produced from donors who are naturally immune and boosted with plasma-derived vaccine or from anti-HBc-negative donors who have particularly high titers after vaccination. 15 percent HBIG for intramuscular administration must contain 200 IU/ml; 5 percent HBIG for intravenous application must contain at least 50 IU/ml. Studies in the 1970s and 1980s showed that HBV infection was prevented in newborns from HBsAg- and HBeAg-positive mothers if HBIG was given within 24 h after birth. Active vaccination seems to be more effective and does not require complementation by passive immunization, but in many countries both active and passive vaccination are still required.

Passive immunization of HBeAg-positive liver transplant recipients usually fails unless combined with antiviral therapy, but in HBeAg-negative patients continuous levels of 100 IU/l of passively administered anti-HBs are able to prevent recurrence of liver disease. Passive immunization of the recipient prevents also viral reactivation in a transplanted anti-HBc positive donor liver (Roque-Afonso et al. 2002).

Passive immunization is recommended together with active immunization after proven accidental exposure of a nonimmune person. In these situations, the blood of the 'donor' should be rapidly tested for HBsAg and, if positive, the 'recipient' should be vaccinated passively

and actively, after a blood sample has been taken for anti-HBc and anti-HBs testing.

TREATMENT

The treatment of acute hepatitis B can be directed against symptoms, but this is usually not necessary. Antiviral therapy of fulminant cases can be attempted but usually comes too late. The aim of antiviral or immunotherapy is to reduce persistent viral replication.

Immune modulators

Interferon-α and interferon-β have been used for the treatment of chronic hepatitis B. Success of interferon therapy depends very much on the status of the patient:. Patients with the so-called immunotolerant state (see Table 2) cannot usually be cured and should be monitored until they reach the state of chronic active disease, when the success rate of interferon therapy is much higher. Patients with a high probability of sustained response have typically $<10^9$ genomes/ml, low or absent HBeAg (<2 000 PEI units), low HBsAg (<30 000 PEI units/ml) and high ALT levels (>120 IU/l) (Burczynska et al. 1994; Erhardt et al. 2000). The higher the initial ALT levels are, the higher is the response rate in terms of low replication and HBeAg-negativity (Lok et al. 1998). Treatment is undertaken with quite high doses (2.5–10 MU/m^2 three times a week) if the patient tolerates the severe side effects such as flulike symptoms, depression, hair loss, leukopenia, and thrombopenia. Autoimmune antibodies should be monitored. Usually the HBV DNA concentration will fall within few weeks to levels $<10^6$ genomes/ml. Some patients do not respond at all, some may redevelop high levels of viremia even during therapy and others may become positive again soon after withdrawal of interferon. Six months of therapy are considered the minimum in responders before withdrawal is attempted. A relapse is not rare and a second course of interferon may be tried. Interferon may be harmful to patients with cirrhosis and is therefore not recommended in the terminal phases of chronic liver disease. In spite of its many disadvantages and relatively low efficacy, interferon has the advantage that in many cases it is able to induce seroconversion from HBeAg to anti-HBe and sustained cessation of viral replication, which is correlated with a very good clinical prognosis (Niederau et al. 1996).

Conjugation of interferon with polyethylene glycol (PEG) improves its pharmacological properties and has been used for therapy of chronic hepatitis B with at least as good success as standard interferon (Janssen et al. 2005). In this recent study, it was noted that genotypes A (47 percent) and B (44 percent) respond almost twice as well as genotypes C (28 percent) and D (25 percent). Combination with lamivudine did not improve the long-term response.

Immune therapy

Vaccination of chronic HBV carriers with licensed SHBs vaccines together with the application of interferon (Heintges et al. 2001) or with a MHBs-containing vaccine without interferon (Pol et al. 2001) increased the rate of HBV DNA negativation above rates in untreated controls but the effect was barely significant. Vaccination of chronic HBV patients with a preS1-, preS2-, and S-containing vaccine induced a Th2 response against these antigens but could not reduce the viremia (Jung et al. 2002). Hepadnaviral DNA vaccines or conventional protein vaccines alone or together with antivirals have been partially successful in the woodchuck (Menne et al. 2002) or duck model (Le Guerhier 2003), which warrants further studies. The successful use of a DNA vaccine in healthy humans to induce a protective Th1 and anti-HBs response is a further stimulus to follow this line (Roy et al. 2000). The optimal adjuvant and combination with antivirals has still to be found.

Antiviral substances

In the 1980s and early 1990s, only highly toxic nucleoside analogues were available. As a side-effect of HIV therapy, several nucleosidic inhibitors of reverse transcriptase were found to be active against HBV as well. Oral Lamivudine (3TC), at 100 mg per day, has been found to be very effective in reducing the viremia by several logs and to improve the HBV-associated liver disease. However, this drug and the other inhibitors of reverse transcription cannot block expression of the viral genes including the pregenome RNA and they cannot eliminate the pre-existing cccDNA of HBV. Lamivudine is able to suppress the release of mature HBV particles and infection of new target cells. Lamivudine induces an enhanced T-cell response against HBV antigen but this stimulation is transient and normally not sufficient to overcome persistent productive infection (Boni et al. 2003). Long-term therapy is necessary and well tolerated due to low toxicity. After 1 year of treatment most patients experience a clear improvement of ALT levels but more than half of them experience a relapse within 12 months after therapy. High pre-treatment levels of HBV DNA were predictive for a relapse after stop of therapy (Huang et al. 2003). Loss of HBeAg is a favorable prognostic marker for a sustained response to lamivudine. In one study (Dienstag et al. 1999), 32 percent of the patients seroconverted after 1 year on lamivudine, but usually the seroconversion rate is lower than with interferon and only twice above the control group, for example, in a study (Jonas et al. 2002) in HBeAg positive children. If HBeAg seroconversion has been reached and HBV DNA was undetectable by PCR, the favorable result is maintained in the majority (64 percent) of patients (Dienstag et al. 2003). The relapse rate can be further reduced by continuation of lamivu-

dine therapy for 6 months (Ryu et al. 2003). Further extension was useful in one study (Chien et al. 2003) but not in another (Lee et al. 2003). One predictor of HBeAg seroconversion under therapy is a high pretreatment ALT level >5-fold the upper limit of normal (Perrillo et al. 2002), furthermore a rapid decrease of HBV DNA to levels $<10^4$/ml (Gauthier and Bourne 1999).

The limiting factor for a permanent therapy with lamivudine is the development of resistance. After 1 year of lamivudine, 23 percent of patients were resistant, after 5 years 65 percent. Resistance development was associated with hepatitis flares in most cases and in 5 percent with serious liver disease-related adverse events (Lok et al. 2003). Whether lamivudine should be stopped or continued once resistance has emerged is debated. The resistance occurs with mutations in the YMDD amino acid motif of the HBV reverse transcriptase domain of M204 to I or V or S (Stuyver et al. 2001). The mutant replicates less efficiently than the wild type, but compensatory additional mutations restore viability (Bock et al. 2002). The appearance of resistance severely impairs the long-term efficacy of lamivudine in cases of chronic hepatitis B, but this does not preclude its short-term usefulness. It is useful to suppress viremia in HBV patients before liver transplantation where reinfection is usually highly detrimental. However, lamivudine alone protects only a part of the patients and needs to be complemented at least for a short period of time with HBIG (Buti et al. 2003). Lamivudine is sufficient to suppress reactivation of HBV infection by an HBsAg-negative anti-HBc-positive donor liver or in anti-HBc-positive, HBsAg-negative recipients (Nery et al. 2003). Lamivudine also supports the establishment of adoptive immunity originating from an anti-HBs-positive liver donor in a HBV-positive recipient (Lo et al. 2003). Furthermore, it is useful to prevent reactivation of hepatitis in HBsAg-positive patients receiving various forms of immunosuppression or cancer therapy (Shibolet et al. 2002; Lau et al. 2003). In highly viremic pregnant women, lamivudine may suppress HBV to levels insufficient to infect the baby (Su et al. 2004). Lamivudine is also supportive in treatment of the HBV-induced immune complex disease polyarteritis nodosa (Guillevin et al. 2004).

If lamivudine resistance has developed, Adefovir – a nucleotide analogue and licensed drug – is in most cases effective (Perillo et al. 2004). Continuation of lamivudine together with Adefovir is not superior to Adefovir alone (Peters et al. 2004). Adefovir is active in HBeAg-positive (Marcellin et al. 2003) and HBeAg-negative chronic hepatitis B (Hadziyannis et al. 2003). The response rate is similar to that of lamivudine but resistance development is rare. Since Adefovir is nephrotoxic at higher doses than 10 mg/day, and expensive, therapy can start with lamivudine under close monitoring of viremia and continued with Adefovir if resistance arises. Before licensing of Adefovir, Tenofovir, another inhibitor of reverse transcription, licensed for HIV, has been found even more effective (Dore et al. 2004) and should be considered in certain cases where both lamivudine and Adefovir have failed. Entecavir is also efficient against lamivudine-resistant HBV but further resistance can develop (Tenney and Levine 2004). Combination therapy, which is extremely valuable in HIV, has not yet been established for HBV. Combinations of Adefovir and lamivudine are not useful (Peters et al. 2004) combinations of lamivudine (Cooksley 2004; Janssen et al. 2005) or Adefovir (Marcellin and Lau 2004) with interferon were not superior to the single drugs.

Experimental drugs

Immunotherapy with various approaches has not reached advanced clinical studies. Even less developed are the various gene therapy approaches (Farrell 2000) including the most recent discovery of small interfering RNAs, which induce degradation of their target RNAs (McCaffrey et al. 2003). Inhibitory peptides which block viral attachment may also have potential (Glebe et al. 2005). In spite of modern drug design, high-throughput screening may still discover new drugs like the heteroaryl-pyrimidines, which inhibit maturation of HBV cores (Deres et al. 2003).

Hepatitis delta virus

JOHN M. TAYLOR

Properties of the virus	1	References	5
Clinical and pathological aspects	3		

In 1977, the first clue to the existence of this virus came from a study of patients chronically infected with hepatitis B virus (HBV). A novel antigen, termed the delta antigen, was found in the hepatocyte nuclei of patient biopsies (Rizzetto et al. 1977). An initial interpretation was that the delta antigen might be a new variant of HBV. However, a more surprising explanation was subsequently obtained. By 1980, it was shown that this antigen was part of an infectious agent that could be transmitted to chimpanzees (Rizzetto et al. 1980). It is sometimes called the hepatitis delta agent, but more frequently hepatitis delta virus (HDV) or hepatitis D virus (HDV). Strictly speaking it is a subviral agent that is dependent upon HBV to provide the envelope proteins needed for the assembly of new virions. On one hand, this dependence of HDV replication on HBV means that many aspects of HDV and HBV biology overlap. On the other hand, the RNA genome of HDV and its strategy of replication have proven to have features unlike those of the helper HBV or any other infectious agent of animals.

PROPERTIES OF THE VIRUS

Classification

Currently, HDV is classified as the sole member of the genus *Deltavirus*. As mentioned above, it is a **satellite** of HBV, since its genome shows no obvious sequence relationship to that of HBV. The RNA genome of HDV and its mechanism of replication are unique relative to RNA viruses of animals, but, as discussed in the section on Plant viroid analogy below, they show important similarities to certain infectious agents of plants.

Virion structure

In the serum of an HDV-infected individual, there are not only HDV particles but also the non-infectious, empty, surface antigen particles that are characteristic of HBV infection. The 42 nm diameter HBV may also be found, though surface antigen particles are always in at least 100-fold excess. The hepatitis B surface antigen particles, termed HBsAg, include both 22 nm diameter roughly spherical particles and elongated filaments. Several groups have tried to purify the HDV particles away from HBV and HBsAg particles. HDV was thus estimated to be around 38–43 nm in diameter (Bonino et al. 1984; He et al. 1989; Ryu et al. 1992). The envelope proteins of these particles include the same three found in HBV. Inside the HDV particle is the RNA genome and around 70 copies of the delta antigen (Ryu et al. 1993; Gudima et al. 2002). The size and shape of this HDV ribonucleoprotein structure may be more heterogeneous than initially claimed; it is certainly not like the more defined icosahedral core structures of HBV.

The single-stranded RNA genome of HDV is in several ways fundamentally different from other RNA viruses of animals (Lai 1995). At ca. 1 700 nt it is the smallest.

- The genome has a circular conformation whereas the other viral genomes are linear.
- The circle is able to fold on itself, with Watson and Crick base pairing of ca. 70 percent of the nucleotides, forming an unbranched rod-like structure.

- On the genome is a domain of about 85 nt, which acts as a self-cleaving ribozyme. When heated in vitro, in the presence of magnesium ions, this domain catalyzes a specific transesterification reaction. The reaction can also be reversed in vitro (Sharmeen et al. 1989), although there is evidence to suggest that in cultured cells, a host factor is needed to achieve ligation (Reid and Lazinski 2000). Recent studies have determined the structure of this ribozyme (Ferre-D'Amare et al. 1998) and the folding pathway followed to achieve this structure (Chadalavada et al. 2002).

Replication

As reviewed in Hepatitis B, HBV is a hepatotropic virus but we still do not know the receptor(s) by which it enters hepatocytes. We do know, however, that antibodies against epitopes within the pre-S1 and pre-S2 domains of the HBV envelope proteins neutralize the virus. The same is true for HDV (Sureau et al. 1992). The replication of HDV in an infected animal is limited to the liver (Netter et al. 1994).

Inside infected cells there are not only HDV genomes but also complementary copies, called antigenomes. These have the same four properties mentioned for the genomes in the section on Virion structure above. In addition, the antigenomic RNA encodes, down one side of the rod-like structure, the 195 aa delta antigen. However, the antigenomic RNA, like the genomic RNA, is not translated. Translation of the delta antigen is considered dependent upon a third HDV RNA. This RNA is 5′-capped, 3′-polyadenylated, and cytoplasmic. Its size and sequence include the appropriate side of the antigenome; it is thus considered the mRNA for the delta antigen (Hsieh et al. 1990; Gudima et al. 1999). There is disagreement as to whether or not the mRNA transcription precedes that of antigenomic RNA or whether the two are separate and concurrent (Modahl and Lai 1998; Macnaughton et al. 2002). It has been estimated that an infected liver cell contains 300 000, 50 000, and 600 copies of the genome, antigenome, and mRNA, respectively (Chen et al. 1986). More recent quantitative studies indicate that during replication there is typically around 200 copies of the delta protein per molecule of genomic RNA (Gudima et al. 2002).

It is still not clear which host polymerase(s) carry out the HDV RNA synthesis. There is currently agreement that the host RNA polymerase II produces the transcripts of genomic RNA and mRNA (Modahl et al. 2000; Moraleda and Taylor 2001; Macnaughton et al. 2002). However, it has also been claimed that a different polymerase is needed to produce transcripts of antigenomic RNA (Modahl et al. 2000; Macnaughton et al. 2002).

Initially it was believed that during replication the majority of both genomic and HDV genomic RNAs were restricted to the nucleus (Taylor et al. 1987). More recent studies indicate that a significant fraction of the genomic RNA might by cytoplasmic (Gudima et al. 2002; Macnaughton and Lai 2002). There is even evidence that ribonucleoprotein complexes of HDV RNA and delta protein might undergo nuclear shuttling between the nucleus and the cytoplasm (Tavanez et al. 2002). Such complexes might also involve host proteins such as the splicing factor SC35 (Bichko and Taylor 1996), nucleolar proteins B23 and nucleolin (Lee et al. 1998; Huang et al. 2001), and the protein known as delta interacting protein A (Brazas and Ganem 1997).

During genome replication an ever-increasing fraction of the antigenomes undergo one or more post-transcriptional RNA-editing events. One such event is specific and essential for the life cycle. The adenosine located in the middle of the amber termination codon for the 195 aa delta antigen is deaminated by a host enzyme (Polson et al. 1996). Apparently only a small element of the rod-like folding structure of the antigenomic RNA is needed to define the target for this editing (Reid and Lazinski 2000). Transcription after editing leads to molecules of mRNA with the amber termination codon replaced by one for tryptophan. This altered mRNA encodes a somewhat longer protein, the 214-aa delta antigen. Both the small and large forms of the delta antigen are essential for HDV replication.

The small form of the delta antigen is required for genome replication (Kuo et al. 1989). The large delta antigen, which appears later in infection, does not support genome replication and, instead, can be a dominant-negative inhibitor of such replication (Chao et al. 1990). A more important property is that the large delta antigen is essential for the assembly of HDV ribonucleoprotein particles into new virions containing envelope proteins of the helper HBV (Chang et al. 1991). The large form becomes farnesylated at a site 4 aa from the new C terminus (Otto and Casey 1996). This modification is essential for virion formation (Glenn 1995; Glenn et al. 1998), presumably because it facilitates interactions with membranes and/or HBV envelope proteins. A monophosphorylated form of the large delta antigen has been detected, but only inside infected cells and not in serum particles (Bichko et al. 1997). Phosphorylated forms of the small delta protein have also been detected and may be needed for the support of genome replication (Mu et al. 2001).

The two forms of the delta antigen thus have quite distinct biological functions. At the same time, since they share a common 195 aa, they have some common properties (Hwang et al. 1995). These include:

- a domain involved in protein–protein dimerization and multimerization
- a bipartite signal which acts as a signal for localization to the nucleus

- a bipartite signal for protein–RNA interactions; the delta antigens have some specificity for recognizing HDV rodlike RNAs relative to other RNAs.

Both proteins are highly basic.

Experimental systems

The HBV envelope proteins are essential for virion formation, but replication of the HDV genome can be achieved in cells independent of the helper virus. Genome replication can be studied in established cell lines and even with in vitro systems.

Other than man, the only hosts that are known to allow complete replication of HDV are the chimpanzee and the woodchuck. The woodchuck hepatitis B virus (WHV) is a near relative of HBV, and it was found that HDV could replicate in woodchucks with WHV replacing HBV as helper (Ponzetto et al. 1984). Other hepadnaviruses, like duck hepatitis B virus (DHBV), are not able to support HDV replication; this may reflect the minimal ability of HDV to replicate in avian cells (Chang et al. 2000; Liu et al. 2001).

The only cultured animal cells that can be infected with HDV are primary hepatocytes. This is considered to reflect the need for the same receptors as used by the helper HBV. Thus, HDV with an HBV coat will infect human or chimpanzee hepatocytes (Sureau et al. 1991), and HDV that has been passaged in woodchucks, will infect woodchuck hepatocytes (Taylor et al. 1987). It is possible to implant human hepatocytes within the mouse and use these for HDV infection (Ohashi et al. 2000). Alternatively, injection of HDV into the mouse tail vein or peritoneal cavity can lead to infection of some mouse hepatocytes (Netter et al. 1993).

If one obviates the need for a receptor interaction by using techniques that directly fuse viral and cell membranes, then HDV can be introduced into established cell lines that are not necessarily of liver origin (Bichko et al. 1994). Under such conditions, HDV genome replication will occur. This can also be achieved by transfection of cells with HDV RNA or cDNA constructs. For RNA transfections, it is necessary that the small form of the delta antigen either is already present in the transfected cells or enters with the RNA. One interpretation is that HDV RNA will only migrate to the nucleus as a ribonucleoprotein complex with the delta antigen. In agreement with this idea, the initial requirement for a source of delta antigen can be met by providing a mRNA for this protein (Modahl and Lai 1998). Transfection can also be used to initiate HDV genome replication in mouse skeletal muscle (Polo et al. 1995a) and in mouse liver (Chang et al. 2001). Finally, using mice, made transgenic for HDV cDNA sequences, HDV genome replication can be detected in multiple tissues (Polo et al. 1995b).

If transfected cultured cells are also expressing the envelope proteins of the helper virus, then HDV virus-like particles are released. These will be infectious if not only the small but also the large envelope proteins of HBV are present; the large envelope protein contains the pre-S1, domain that is essential for HBV receptor interactions (Sureau et al. 1992).

Plant viroid analogy

Even though HDV is in many respects unique among RNA viruses of animals, it does seem to have some relatives in the plant world. Viroids, of which more than 25 have been described, are subviral agents of plants. Like HDV, they have small single-stranded RNA genomes that are circular in conformation and able to replicate via redirection of the host RNA polymerase II. In some cases they are known to contain both self-cleavage domains and the ability to self-ligate. However, unlike HDV, they are much smaller (only 240–375 nt), encode no proteins, and are not dependent in any way on a helper virus (Taylor 1999). In addition to the viroids there are also plant agents sometimes referred to as virusoids, which share similarities to HDV. However, the virusoids, unlike the viroids and HDV, replicate via an RNA polymerase provided by a helper virus (Taylor 1999).

CLINICAL AND PATHOLOGICAL ASPECTS

Transmission

Like HBV, HDV is a blood-borne pathogen. Cycles of HDV replication are dependent upon the envelope proteins produced by HBV; nevertheless, the modes of successful HDV transmission can be somewhat different from those of HBV. (Expression of envelope proteins via integrated copies of HBV DNA, might be able to support HDV replication cycles.) HDV is transmitted via contaminated needles among drug abusers and via blood products and transfusions. Sexual transmission is rare and so is perinatal transmission.

In natural situations, cycles of HDV replication fall into two classes: superinfections, where the patient is already infected with HBV, or co-infections, where the patient receives both HDV and the helper HBV at the same time. Superinfections are more likely than co-infections to lead to fulminant hepatitis. It has been hypothesized that since HDV replication may be aided by a more aggressive HBV replication, it could be the response of the host to the HBV replication that is the principal cause of pathogenesis (Casey et al. 1996). Some HDV infections pass through the acute phase and survive as a chronic infection. Such chronicity is also dependent upon a chronic HBV infection; thus, it should not be a surprise that HDV superinfections of patients already chronically infected with HBV are more likely, after the acute phase, to proceed onto chronicity.

A third mechanism of HDV infection was considered to arise in some patients with terminal HDV-associated cirrhosis that are given a liver transplantation from a virus-free donor. The interpretation was that hepatocytes of the new liver can first become infected by HDV alone; these would be nonproductive or latent infections, in which genome replication occurs but no particles are produced. Later, superinfection of such hepatocytes with HBV could lead to rescue and spread of the HDV (Rizzetto and Ponzetto 1995). Analogous latent infections were considered to be produced in experimental animals (Netter et al. 1994). More recently, the concept of latent infections, especially in humans, has been called into question because of evidence that at no time was HBV actually totally absent (Smedile et al. 1998).

Detection and clinical manifestations

There are several serum-based, commercially available, assays for HDV infection. The most widely used test is for antibodies (IgM and/or IgG) directed against the delta antigen. Tests that are more expensive are available for detection in serum of the delta antigen or the genomic RNA. Hybridization assays typically need more than 105 viral genomes per sample. By the use of reverse transcriptase to produce cDNA copies and the subsequent amplification of this cDNA with the polymerase chain reaction, as little as 10 molecules of the genome can be detected; however, sequence heterogeneity between isolates can render difficult the choice of appropriate oligonucleotide primers (Niro et al. 1997).

At one time, liver biopsy, with direct detection of delta antigen by immunohistochemistry, was considered the gold standard for detection of HDV infections (Rizzetto and Ponzetto 1995). However, in chronic infections, the number of infected hepatocytes and the level of replication per infected hepatocyte can be too low for easy detection. Not surprisingly, with more sophisticated in situ hybridization procedures, the sensitivity of detection can be increased. The possibility of adverse consequences of liver biopsy recommends against the use of this approach for routine purposes.

HDV infections may not always have a pathogenic effect. For example, on one Greek island there was an endemic chronic infection with both HBV and HDV, and yet infected individuals had no detectable signs of liver damage (Hadziyannis et al. 1993). By contrast, there have been local epidemics of HDV in the Amazon Basin of South America associated with a high incidence of fulminant hepatitis and death. It is possible that in such individuals there is an excessive HBV replication with associated immune response and liver damage and that the HDV, which after all depends upon HBV, replicates more efficiently (Casey et al. 1996). Early studies ascribed for such patients specific histological lesions, such as cytoplasmic eosinophilia, and microvesicular steatosis without an inflammatory infiltrate. Later studies argue against any direct involvement of HDV markers in such lesions. The lesions may reflect derangement in the secretory pathway of certain hepatocytes (Rizzetto and Ponzetto 1995) or the consequences of exposure to interferon presumably induced in response to the viral infection (Shimizu and Purcell 1989).

As recently reviewed (Gerin et al. 2001), the incubation period prior to an acute HDV infection is about 3–7 weeks. This is followed by a preicteric phase of about 1 week during which there can be various nonspecific symptoms, such as fatigue, lethargy, anorexia, and nausea. During this time the levels of virus in serum rise to a peak, and then fall, usually within a period of a few days. Peak titers of 10^{10}–10^{12} HDV particles per ml can be detected in the serum. Such titers are much higher than for HBV, which usually do not exceed 10^{9}–10^{10} particles per ml, but are similar to the titer of HBsAg 22 nm particles. Also detected in serum is an increase in biochemical markers of liver damage, such as alanine and aspartate aminotransferases. The appearance of jaundice defines the next phase, the icteric phase. Fatigue and nausea may persist. Serum bilirubin levels may become abnormal. Although the markers of HDV replication are decreasing, this phase may be the most severe clinical stage. At this point, a fulminant hepatitis may occur, but this is rare, though about ten times more frequent than for hepatitis induced by HBV alone, or by other hepatitis viruses. For most coinfections, the patient recovers over a period of weeks to months, and HDV infection is cleared. By contrast, with superinfections, the acute phase is usually followed by a chronic HDV infection. Such chronicity has a high chance of proceeding to cirrhosis and even hepatic failure. It has been previously thought that chronic HDV infections can progress not only to cirrhosis but also to hepatocellular carcinoma (Fattovich et al. 2000). One evaluation suggests that while chronic HDV infections frequently increase the risk of cirrhosis, they may only indirectly via HBV, increase the risk of hepatocellular carcinoma (Kew 1996).

Epidemiology and phylogenetics

HDV has been detected in many parts of the world, including Europe (Italy, Spain), Asia (China, Taiwan, Japan), the former USSR, and South America (Amazon Basin, Peru). The incidence in the USA is relatively low.

Chronic HBV infections are currently estimated at around 400 million worldwide. In 1993 it was estimated that there were around 25 million chronic cases of (both HBV and HDV) (Alter and Hadler 1993). However, worldwide the HDV levels are decreasing with the impact of HBV vaccination (which also protects against HDV), testing of blood prior to transfusions, and in some cases, altered patterns of intravenous drug usage. New cases of HDV are becoming rare and chronic HDV is being referred to as a ‘vanishing disease’ (Gaeta et al. 2000).

Primary sequence differences between isolates can be as much as 40 percent. Such sequence differences have been used to divide isolates into genotypes I–III. Genotype I contains the majority of isolates and it has been divided further into subgroups (Niro et al. 1997). Genotype II consists of several isolates from East Asia. Newer data suggest it is almost as widespread as genotype I (Ivaniushina et al. 2001). Genotype III includes only a small number of isolates from life-threatening infections in the Amazon Basin of South America. It is difficult to determine to what extent this pathogenesis is specific for the genotype of HDV relative to that due to the replication of the associated HBV, of genotype F (Casey et al. 1996; Gerin et al. 2001). Studies with transfected cells have shown that there are limitations in the ability of genomes of one genotype to be assisted in replication by the small delta proteins of other genotypes (Casey and Gerin 1998).

Pathogenicity and interactions with the helper virus

It has been reported that when the small form of the delta antigen is expressed in cultured cells there can be an associated cytopathic effect (Cole et al. 1991). In contrast to this, mice made transgenic for the expression of either the small or large forms of the delta antigen fail to show any associated pathology (Guilhot et al. 1994). Overall, it is agreed that there are no striking direct cytopathic effects of HDV (or HBV) replication (Gowans and Bonino 1993).

Nevertheless, HDV replication does have consequences for the infected cell. For example, mice experimentally infected with HDV showed that a small fraction of the hepatocytes became infected and were, within several days, somehow replaced, even in mice with a severe combined immunodeficiency (Netter et al. 1993). Also, some studies in tissue culture do support the interpretation that in cells replicating the HDV genome the rate of cell division is decreased (Bichko and Taylor 1996; Wang et al. 2001).

It has been noted that at the peak of an acute HDV infection, replication of the helper virus may be transiently suppressed (Gerin et al. 2001). However, in some cases this suppression can be as little as several-fold (Netter et al. 1994). It must be realized that there can also be evidence for 'interference' in patients infected with hepatitis C virus (HCV) superimposed on HBV and HDV (Jardi et al. 2001).

Treatment

Treatments with interferon-alpha are known to suppress particle production. However, the doses have to be very high and associated side effects are substantial. Moreover, when the patient is withdrawn from therapy, HDV production usually promptly resumes. The cure rate ascribable to such treatment, after subtraction of spontaneous cures, is probably <20 percent (Rizzetto and Ponzetto 1995; Lau et al. 1999).

A reasonable expectation was that suppression of HBV replication and assembly would indirectly suppress HDV replication. It was expected that some of the inhibitors, such as lamivudine, that act so potently on HBV replication should therefore inhibit HDV. Even the effects of interferon-alpha on HDV in large part might be indirect, via suppression of the HBV. However, from a study of four patients given 1 year of lamivudine therapy, it was observed that HDV RNA levels in the serum did not significantly decrease and liver damage continued (Lau et al. 1999).

Vaccination

In most cases, an HDV-specific vaccine is not needed since that for HBV is effective, indirectly. However, for individuals already chronically infected with HBV, an HDV vaccine might be of use. Several preliminary studies have used the delta antigen for vaccination, with variable success (Rizzetto and Ponzetto 1995).

Natural history of infection	3	References	6

TT virus (TTV) is one of several human viruses discovered in recent years, following the development of sensitive techniques for showing foreign nucleic acids in tissues. Soon after the discovery, it became clear that this novel virus was just one of a vast group of related, previously unrecognized viral agents, all of which were characterized by small, circular single-stranded DNA genomes with negative polarity. Presently, all these viruses are classified within a new genus, *Anellovirus*, that includes two species clearly distinct for their different genome sizes, TTV and TT minivirus (TTMV) [previously referred to as TTV-like minivirus (TLMV)].

Knowledge on TTV and related viruses has accumulated rapidly, but many fundamental aspects remain unresolved, particularly their significance for human health. In fact, anelloviruses have been found to be amazingly widespread, with abundant viral DNA detectable in the plasma of 80 percent or more of the general population worldwide, but in spite of this and the publication of more than 500 papers, no associated clinical disease has yet been identified. This unprecedented situation has actually led to the proposal that anelloviruses should be considered completely nonpathogenic and be regarded as the first recognized viral member of the normal commensal microflora (Mushahwar 2000). This view appears, however, somewhat premature considering all the many issues that still wait to be addressed (Bendinelli et al. 2001; Simmonds 2002).

DISCOVERY

TTV was first described in 1997 by Japanese workers who detected part of its genome whilst, in an attempt to identify additional agents of human hepatitis, were comparing by representational difference analysis, the nucleic acids contained in sequential blood samples of a patient (TT) with cryptogenetic post-transfusion hepatitis (Nishizawa et al. 1997). TTV discovery was soon followed by the detection, in diseased and healthy individuals, of numerous other viruses with genome properties clearly akin to those of TTV although often very divergent from it and from each other in sequence. The latter received specific names – SANBAN, YONBAN (meaning the third and the fourth, respectively, in Japanese), PMV, SENV, KAV – or were indicated with numbers (Hijikata et al. 1999; Hallett et al. 2000; Primi et al. 2000; Takahashi et al. 2000a; Tanaka et al. 2001) but are now classified as distinct genotypes of TTV. Furthermore, polymerase chain reaction (PCR) testing of certain blood donors for TTV produced shorter amplicons than expected, and further characterization revealed the existence of additional viruses also clearly related to TTV but with smaller genomes, namely TTMV (Takahashi et al. 2000b).

VIRIONS AND GENOMES

Physicochemical and immunoelectron microscopy studies have shown that the TTV particle has a density of 1.31–1.35 g/ml and is approximately spherical, 30–32 nm in diameter, and devoid of external lipids (Okamoto et al. 1998; Mushahwar et al. 1999; Itoh et al. 2000). Although most information on virion structure has been obtained with genotype 1, there are no indications that significant genotype-related differences might exist within TTV. TTMV, however, has a smaller size, as determined by

filtration (Takahashi et al. 2000b). Like other non-enveloped viruses, both TTV and TTMV are unaffected by ether and chloroform and are believed to resist chemical and physical inactivating agents at least as effectively as parvoviruses and circoviruses (Todd et al. 2001).

Complete or near complete genome sequences, determined for a number of TTV and TTMV isolates, have revealed a high degree of divergence between the two viruses. The DNA of TTV is approximately 3 800 nt long (Erker et al. 1999; Kamahora et al. 2000; Muljono et al. 2001; Okamoto and Mayumi 2001; Hino 2002) whilst that of TTMV ranges around 2.8 kb. The general organization of the two genome types is, however, similar. Approximately one-third of their length has no coding functions (untranslated region (UTR)), but appears to control virus replication and expression through a number of regulatory sequences and secondary structures. Prominent among the latter is a stretch of approximately 100 nt with high guanine and cytosine content (GC region; Miyata et al. 1999). A number of such regulatory elements are highly conserved among TTV and TTMV isolates and are therefore exploited for designing universal primers (see below).

As deduced from the sequences, whilst no open reading frames (ORF) are present in the genomic DNA of either viruses, the antigenomes contain one large ORF (ORF1) and several partially or totally overlapping smaller ones (Kakkola et al. 2002; Yokoyama et al. 2002). ORF1 has a coding capacity of 770 and 675 amino acids in TTV and TTMV, respectively. The deduced encoded protein, which represents the putative capsid protein, contains an arginine-rich hydrophobic region at the N terminus, three hypervariable regions (HVR) (HVR-1, 2, and 3) located centrally, and variable numbers of potential glycosylation sites (Hijikata et al. 1999). The other ORFs are variously conserved amongst different genotypes. ORF2 encodes putative nonstructural proteins of approximately 120 and 100 amino acids in TTV and TTMV, respectively, which might have kinase activity in at least some genotypes. ORF3 seems to lead to two differently phosphorylated proteins, thus resembling gene *NS5A* of hepatitis C virus (HCV) (Asabe et al. 2001).

TAXONOMY AND NOMENCLATURE

At the time TTV was discovered, all known viruses of vertebrates with small circular, single-stranded DNA genomes were classified within the family *Circoviridae*, leading to the suggestion that the new virus should also be included in this family. Indeed, TTV has a high genome-relatedness to the *Chicken anemia virus* (CAV), a circovirus that causes damages to the poultry industry. However, the creation of a new virus family was also proposed (Mushahwar et al. 1999; Takahashi et al. 2000b; Okamoto and Mayumi 2001) to accommodate the considerable differences existing with other circoviruses [*Porcine circovirus* (PCV), *Beak and feather disease virus* (BFDV) of parrots], even though the latter have ambisense and not negative-strand genomes like CAV, TTV, and TTMV. More recently, following the advice of an appointed study group, the International Committee for the Taxonomy of Viruses (ICTV) has decided to classify TTV and TTMV as distinct species within a newly created, temporarily self-standing genus named *Anellovirus* (from *anellus*, Latin for ring). The ICTV has also decided to change the extended names of the two viruses in torque-teno-virus (TTV) (from the Latin words *torques* and *tenuis*, meaning necklace and thin, respectively) and torque-teno-minivirus (TTMV). This was suggested to conform to the rule that no official virus designation should be derived from people's names, without having to extensively modify the acronyms (Hino 2002).

Both TTV and TTMV show a remarkable degree of genetic heterogeneity. This diversity, which is especially high in the coding portion of the genomes (for example, amino acid divergence is as high as 68 percent in the ORF1 of isolates TA278 and SANBAN) has been exploited in order to group isolates. The criteria adopted for TTV are similar to the ones used for HCV: genotypes (identified by Arabic numbers) are defined by nucleotide divergences of 30 percent or greater, and subtypes (identified by small letters) by nucleotide divergences of between 15 percent and 29 percent. By such criteria, at least 40 genotypes of TTV, each (or most) subdivided in several subtypes, are presently known. In addition, genotypes have been clustered into five major TTV groups (designated 1–5), distinct from one another by nucleotide divergences of 50 percent or greater (Table 1). TTMV has been less investigated but existing data indicate that it may be even more diversified than TTV: comparison of full-length and ORF1 sequences has so far identified three clusters diverging by 40 percent or more at the nucleotide level (Table 1). Due to their considerable genetic distances, it is likely that in the future TTV genogroups will come to be regarded as distinct species. For both TTV and TTMV, the recognition of much greater diversity is expected with analysis of increasing numbers of sequences. It should also be noted that TTV-like viruses have been detected in several species of nonhuman primates, other mammals, and birds (Leary et al. 1999; Abe et al. 2000; Okamoto et al. 2002). From the limited amount of sequence data available, it would appear that primate viruses have undergone long-term co-evolution with their host species (Simmonds 2002).

INTERACTIONS WITH INFECTED CELLS

TTV and TTMV can been found in many tissues of the body and this, together with the demonstration of

Table 1 *Viruses recently classified in the genus* Anellovirus

Virus	Genogroup	No. of genotypes included	Representative isolates	Reference
TTV	1	6	TA278	Nishizawa et al. 1997
	2	6	PMV	Hallett et al. 2000
			KAV	Heller et al. 2001
	3	15	SANBAN	Hijikata et al. 1999
			SENV	Primi et al. 2000
	4	9	YONBAN	Takahashi et al. 2000a
			CT23	Peng et al. 2002
	5	4	JT33	Peng et al. 2002
TLMV	1	At least 4	CBD203	Takahashi et al. 2000b
			PB4TL	Biagini et al. 2001
	2	At least 2	CBD231	Takahashi et al. 2000b
	3	At least 2	NLC023	Biagini et al. 2001

replicative nucleic acid intermediates of TTV in several tissues, has suggested that both viruses might infect many different cell types (see below). However, the precise cell type(s) that support virus replication remain undetermined (Takahashi et al. 2002; Yu et al. 2002). In culture, only fresh human peripheral blood mononuclear cells have hitherto been found to permit TTV propagation (Maggi et al. 2001b; Mariscal et al. 2002).

Current understanding of TTV and TTMV replication mechanisms is scanty and mostly inferred from what is known about CAV. CAV grows in lymphoid cell lines and other cell types, is found in the nucleus, and appears to depend on cell proteins expressed during the S-phase for replication (Todd et al. 2001). TTV also appears to replicate in activated, but not resting, lymphoid cells (Maggi et al. 2001b; Mariscal et al. 2002). Viral DNA replication is believed to occur by the rolling circle mechanism. Such a mechanism, which is particularly well suited for replicating single-stranded DNA viruses, is indicated by the presence in the deduced ORF1 product of conserved Rep protein motifs typical of the many viruses that replicate in this manner (Hino 2002). It should be noted, however, that the great genetic diversity of TTV has also led to the theory that polymerases with low proofreading activity intervene (Umemura et al. 2001b). Indeed, the rates of nucleotide change reported for the HVR of TTV (up to 7.3×10^{-4} per site per year) are at least tenfold higher than in hepatitis B virus (HBV) and other DNA viruses and in a range similar to RNA viruses (Umemura et al. 2001b). Transcription profiles are poorly understood. Recently, TTV genome transcription and splicing has been found to produce three to four species of viral mRNA, transcribed from the negative strand and having different lengths but with common 5′ and 3′ terminals, in infected tissues (Okamoto et al. 2000a, 2001) and in experimental systems (Kamahora et al. 2000; Yokoyama et al. 2002).

Modes of virion assembly and release from producer cells are not known. In analogy with what is observed with other nonenveloped viruses, egress of progeny virions is likely to imply the destruction of infected cells. Genetic recombination between different genotypes appears to be a frequent event in TTV and TTMV (Worobey 2000; Biagini et al. 2001), indicating that the same cell can become infected with more than one genotype. Recombination is most often observed in the noncoding portion of the viral genome, most likely due to the high conservation of this region. As discussed below, individuals who harbor multiple genotypes are numerous, thus contributing to the explanation as to why recombination is a frequent occurrence. Available data exclude that TTV can persist as an episome or become integrated into cell DNA (Yu et al. 2002).

NATURAL HISTORY OF INFECTION

A well-documented property of both TTV and TTMV is that they readily establish chronic productive infections in many, if not all, exposed individuals. Apart from this, information about the infection course is still sketchy and almost exclusively limited to TTV. Whilst others appear likely (Okamoto and Mayumi 2001), three modes of TTV entry into the body have been clearly documented: inoculation of contaminated blood or blood-derived products (Simmonds et al. 1998; Bendinelli et al. 2001), transplacental infection (Morrica et al. 2000), and airborne infection (Maggi et al. 2003). In the latter study, 87 out of 100 young children hospitalized for acute respiratory infections were found to carry larger TTV loads in the nasal secretions than in blood and, in some, the same virus was demonstrable earlier in the nares than in the circulation, thus suggesting that the respiratory tract is a port of entry and also a site of primary virus amplification. This and other studies (Kobayashi et al. 1999; Matsumoto et al. 1999) have also shown that TTV becomes detectable in the blood within one or a few weeks after exposure, thus indicating that dissemination of infection throughout the body is rapid.

Self-limited TTV infections have been described (Lefrere et al. 1999; Matsumoto et al. 1999), and, according to a recent report (Ohto et al. 2002), their frequency depends on viral genotype; however, the possibility is not excluded that such findings reflect

post-acute reductions of viremia levels under the detection threshold rather than true virus eradications. Large fluctuations of TTV viremia levels have been observed in a number of subjects over time (Ball et al. 1999; Matsumoto et al. 1999). In any case, prolonged, possibly lifelong, TTV persistence is by far the most frequent outcome (Lefrere et al. 1999; Matsumoto et al. 1999; Takayama et al. 1999). Plasma TTV loads vary extensively in chronically infected persons, ranging between 10^2 and more than 10^8 DNA copies per ml (Pistello et al. 2001). Similarly to what has been observed with other chronic plasma viremia-inducing viruses, TTV viremia is the result of the continuous shedding into, and clearance from, the bloodstream of large numbers of virions (Table 2).

Cerebrospinal fluid is usually virus-negative in infected individuals with an intact blood–brain barrier (Maggi et al. 2001a). All other anatomic sites tested have been found to harbor variably abundant TTV. These include liver, lung, pancreas, spleen, kidney, lymph nodes, skeletal muscles, thyroid gland, bone marrow, and circulating leukocytes. For some such tissues, namely liver, bone marrow, and circulating peripheral blood mononuclear cells, there are also molecular indicators (double-stranded viral DNA and viral mRNA) that TTV replicates locally (Okamoto et al. 1998, 2000a, b, c, 2001; Kikuchi et al. 2000; Suzuki et al. 2001). However, the possibility that these findings reflect circulating virus or ubiquitous virus-infected cells, such as lymphocytes and/or macrophages, cannot be excluded at present. That proliferating hematopoietic cells might be a major source of TTV is suggested by observations that baseline viremia decreased to undetectable levels in virus carriers treated with myelosuppressive drugs (Kanda et al. 1999). The possibility has also been suggested that different TTV genotypes differ in tropism and replicate preferentially in selected body compartments (Okamoto et al. 2001).

It is probable that the extraordinary ability of anelloviruses to persist and continuously release copious progeny into the systemic circulation is due to a complex combination of virus and host factors. That primary infections generally occur early in prenatal or postnatal life (see below) may be important for persistence by inducing partial immunotolerance. Also, if productive viral replication is indeed possible only in cycling cells (Maggi et al. 2001b; Mariscal et al. 2002), then only a fraction of potentially susceptible cells might be permissive at any given time, thus allowing even supposedly cytocidal agents, such as anelloviruses, to persist. On the other hand, it might well be that immune responses elicited by anelloviruses are not particularly vigorous and/or the immune effectors produced are incapable of controlling the infection with sufficient efficacy.

Immune responses have not been properly investigated as yet, at least partly due to lack of suitable viral antigens. A few attempts to produce recombinant TTV antigens have yielded confusing or negative results. Recently, an enzyme-linked immunosorbent assay using antigen extracted from the feces of a carrier has permitted the following of the antibody responses developed by two patients with post-transfusion TTV infections. Specific IgM and IgG were detected after 10–21 and 12–17 weeks, respectively (Tsuda et al. 2001), possibly indicating that humoral responses to TTV mount slowly. Furthermore, immunoprecipitation studies have shown that a variably large proportion of total TTV found in chronically infected patients has IgG bound to its surface (Nishizawa et al. 1999; Ott et al. 2000). It would be of interest to ascertain whether such immunocomplexed virus is still infectious for cells. The fact that mixed infections by multiple TTV strains are numerous (see below) indicates that antiviral immunity does not efficiently protect against superinfection by heterologous genotypes.

Table 2 *Dynamics of chronic TTV viremia, relative to other viruses*

Virus	Mean virion half-life in plasma	New virions entering plasma per day	Reference
HBV	1.2 days	$>1.7\times10^{13}$	Whalley et al. 2001
HCV	2.7 hours	$>1.3\times10^{12}$	Neumann et al. 1998
HIV-1	< 1 hour	$>9.8\times10^{9}$	Ramratnam et al. 1999
TTV	6.5 hours	$>3.8\times10^{10}$	Maggi et al. 2001c

LABORATORY DIAGNOSIS

Reliable tissue culture and immunological methods for demonstrating TTV and TTMV or induced antibodies are lacking. Diagnosis of infection relies, therefore, solely on the detection of viral genomes in blood or other specimens. The PCR procedures most commonly used at present are listed in Table 3. Due to the great genetic diversity of both TTV and TTMV, the choice of the viral DNA segment targeted for amplification has an enormous impact on PCR assay sensitivity. For example, early tests for TTV, which targeted poorly conserved sequences in the ORF1 (Bendinelli et al. 2001), greatly underestimated the prevalence rates of infection since they almost exclusively detected genogroup 1 viruses. The UTR of both TTV and TTMV are now known to be most suitable for the design of primers capable of detecting all, or the majority of, the viral genotypes hitherto identified (Okamoto and Mayumi 2001). However, no method which has the potential to simultaneously detect all possible variants of both TTV and TTMV with a single test has yet been described. Quantitative real-time assays also exploit this region (Maggi et al. 2001c; Moen et al. 2002). On the other hand, the

Table 3 *Methods currently in use for the diagnosis of TTV and TTMV*

Virus	Purpose	Type of test	Target region
TTV	Detection	Qualitative universal PCR	UTR
	Quantitation	Real-time universal PCR	UTR
	Typing	Group-specific PCR	ORF1 (genogroups 1–3)
			UTR (genogroups 4 and 5)
		Sequencing	ORF1 (all genogroups)
TTMV	Detection	Qualitative PCR	UTR
	Quantitation	Real-time PCR	UTR
	Typing	Sequencing	ORF1

genogroup-specific PCR assays that have been proposed for typing purposes as a practical alternative to sequencing methods are UTR- or ORF1-based, depending on the specific genotype targeted. Genogroup- or genotype-specific quantitative assays may also become valuable in future studies attempting to correlate definite viral types to disease (Maggi et al. 2003).

EPIDEMIOLOGY

The viruses discussed in this chapter are certainly among the most widespread viral agents of humans. The use of sensitive and broad-range PCR techniques has indeed shown that over two-thirds of the global population carries TTV in plasma and that active TTMV infection is possibly even more common (Biagini et al. 2000, 2001). Thus, almost everyone is infected with either TTV or TTMV or both. In fact, individuals who carry multiple genetic forms of the two viruses are more the rule than the exception (Umemura et al. 2001a). Significantly, a recent report has described the presence of as many as 15 different genotypes of TTMV in the blood of an immunocompromised subject (Vasconcelos et al. 2002). Prevalence rates are already very high during the first months of life and augment only moderately thereafter (Bendinelli et al. 2001; Maggi et al. 2003), but whether the proportion of individuals who carry multiple types of the two viruses varies with age remains to be established. Gender and socioeconomic conditions appear to be of little importance for spread of the infection. Geographical variations in total and genotype-specific prevalence rates would appear to exist (Gallian et al. 2000; Muljono et al. 2001; Umemura et al. 2001a); however, systematic studies conducted using uniform protocols that might permit really meaningful comparisons are lacking.

That anelloviruses can be transmitted via blood and blood products is obvious and has been repeatedly documented. However, their amazing diffusion in the general population implies the existence of much more frequent occasions of contagion, as also corroborated by frequent virus detection in saliva, nasal and genital secretions, tears, and feces. Intrauterine transmission is a clear possibility and has been repeatedly demonstrated with the detection of TTV in cord blood (Gerner et al. 2000; Inami et al. 2000; Matsubara et al. 2000; Fornai et al. 2001). Another route that has been clearly documented is through the respiratory tract (Maggi et al. 2003). Based on indirect evidence, fecal–oral spread is also very likely (Gallian et al. 2000; Lin et al. 2000; Tawara et al. 2000). The role in human epidemiology of the TTV-like viruses detected in other species, including pet and livestock animals, is unclear (Leary et al. 1999; Okamoto et al. 2002).

There are no available assays that permit the discrimination of whether viremia-negative subjects have skipped or have resolved the infection. Investigating this issue serologically is complicated by the poor definition of viral antigens and by the fact that virus in blood is frequently heavily immunocomplexed (Nishizawa et al. 1999; Ott et al. 2000; Tsuda et al. 2001; Kakkola et al. 2002).

ASSOCIATION WITH DISEASE

To date, there are no clinical manifestations that have been unequivocally linked to anelloviruses. As discussed in detail elsewhere (Bendinelli et al. 2001), early attempts to implicate TTV in those forms of liver disease that have a putative viral cause but are unrelated to known viruses have been frustrated, albeit it is still considered probable that, in some cases, TTV infection is associated with transient and mild elevations of liver enzyme levels (Nishizawa et al. 1997; Kanda et al. 1999; Tawara et al. 2000). Other cryptogenetic diseases that have been investigated include diabetes, cryoglobulinemia, psoriasis, rheumatoid arthritis, systemic lupus erythematosus, the Kawasaki syndrome, multiple sclerosis, and other neurological diseases. In all cases, results have excluded a TTV etiology or have been inconclusive.

As already mentioned, failure to identify associated diseases, together with the extraordinarily high prevalence rates of both TTV and TTMV active infections in the general population worldwide, has led to the hypothesis that these viruses might be completely nonpathogenic. However, at the time of writing it seems more appropriate to consider anelloviruses as 'orphans of disease,' similar to that previously done for many other viruses which in the early years after discovery could not be linked to any disease but were subsequently found

to produce significant pathologies (e.g. echoviruses, reoviruses, Epstein–Barr virus, and others). Several aspects need investigating more thoroughly. For example, the possible clinical implications of primary infections, especially in infants, have been only marginally explored (Biagini et al. 2003; Maggi et al. 2003). Similarly, only recently is it becoming appreciated that only some types of TTV and TTMV might be pathogenic but their disease potentials might be blurred by many nonpathogenic types. Certain reports suggest that TTV genotypes 1a, 12, and 16 are especially damaging to the liver (Shibata et al. 2000; Umemura et al. 2001a) although others discount these findings (Yoshida et al. 2002). The possible consequences for the host's immune system of having to deal chronically with these viruses should also be attentively investigated, especially if proliferating lymphoid cells are confirmed to be a major site of virus infection. In this regard, recent findings have shown that among a large group of infants hospitalized for acute respiratory illnesses, the ones who exhibited higher plasma and nasal levels of TTV were also the ones who had more severe disease (Maggi et al. 2003). Furthermore, circulating loads of TTV are particularly high in patients with AIDS or other immunocompromising conditions (Christensen et al. 2000; Shibayama et al. 2001), possibly contributing to immune impairment. Accounts implicating TTV or TTMV in some renal ailments (Yokoyama et al. 2002) and in certain forms of anemia, neutropenia, and thrombocytopenia (Kikuchi et al. 2000; Simmonds 2002) are also worth further scrutiny.

CONTROL

As long as their clinical implications remain undefined, there will certainly be little attention paid on how the viruses discussed in this chapter might be controlled. Their epidemiologic features leave, however, little doubt that trying to prevent infections would be extremely difficult in the absence of specific multivalent vaccines. On the other hand, TTV has proven insensitive or only transiently sensitive to interferon in patients treated for other viral infections (Maggi et al. 1999, 2001c; Dai et al. 2002), albeit combined therapy with ribavirine seems more effective and selected viral genotypes more susceptible (Umemura et al. 2002). As expected, antiretroviral drugs have also shown no anti-TTV activity (Takamatsu et al. 2001). Thus, should it one day be regarded as clinically useful, treating established infections would most likely need the development of specific antivirals.

INTRODUCTION AND GENERAL PROPERTIES OF THE *RETROVIRIDAE*

Retroviruses seem to have played a role in the evolution of human genetics, considering the large number of retroviral remnants within the human genome. Why, where, and how these viral residues occurred is a curious enigma of our genome. Did they arise from multiple infections, which over time devastated new evolving species of hominoids? Did such an occurrence result in survivors who either were infected with defective retroviruses or had modified their receptors to be resistant to primary infection? The answers may become apparent if, in several thousand years, remnants of human immunodeficiency virus (HIV) and human T-cell leukemia virus (HTLV) are found 'fixed' in the human genome.

Within the large family of retroviruses, lentiviruses, which include the HIVs, are unusual in that they possess complexities and degeneracies that differ from the biological properties of other, more stable, primate retroviruses, such as the deltaretroviruses and the spumaviruses. Nevertheless, these agents share the common feature of utilizing a reverse transcribing enzyme to replicate their genome. Retroviruses replicate in a unique manner. An enzyme carried by the viruses reverses the usual flow of genetic information (normally from DNA to RNA (messenger RNA) and then to protein) by causing the RNA genetic information to create a DNA (proviral) intermediate. This is a characteristic feature of all retroviruses. Viral genetic information in the DNA form is contained in this 'provirus,' which can be integrated into the genome of the host cell, where it may remain latent or nonexpressing for variable periods. Only when the provirus is activated, often by first messenger signals such as cytokines or antigens, are viral proteins and new viruses made. In the mature virion the genome is diploid, carried as a 60–70S dimer complex of two identical, positive-sense, single-stranded RNA copies, whereas reverse transcriptase (RT) is a meiotic event, resulting in a double-stranded haploid DNA provirus. The proviral genome structure of retroviruses is characterized by repeated sequences at either end of the genome, the long terminal repeats (LTR). These structures play an important role in viral expression because they contain promoter and enhancer elements. The genomes of all retroviruses that are able to replicate fully always include three genes coding for the three sets of structural proteins: those of the core proteins (gag), the envelope proteins (env) and the polymerase enzyme (pol). The genome arrangement LTR–gag–pol–env–LTR is common to all known retroviruses. A simplified retroviral life cycle is depicted in Figure 1.

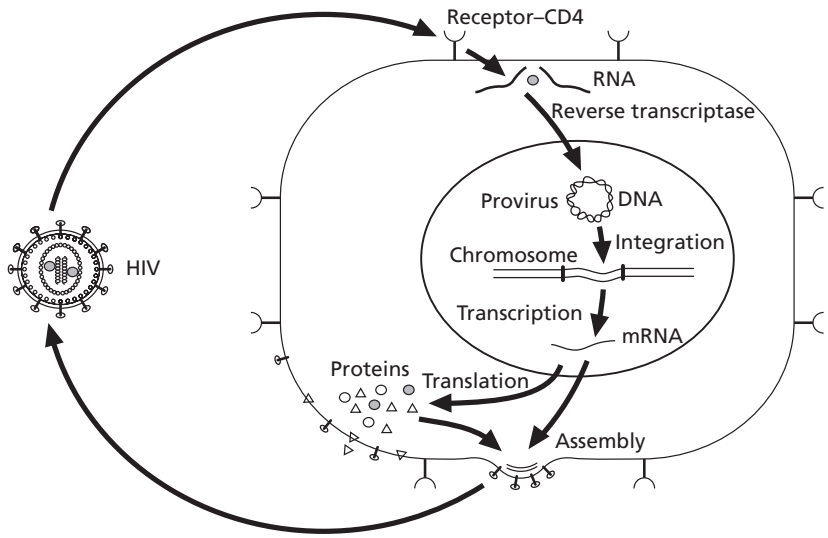

Figure 1 *Schematic representation of the life cycle of HIV. Virions attach to specific cell surface receptors. Following internalization and uncoating either via receptor-mediated endocytosis or by fusion at the plasma membrane, the reverse transcriptase in the core of the virion becomes activated and synthesizes a double-stranded DNA provirus. Circularized and linear forms of the provirus migrate to the nucleus and integrate in host chromosomal DNA. The integrated proviral genome may remain latent, but, if active, particularly in proliferating cells, it expresses positive-strand RNA. Full-length transcripts become packaged into progeny virions budding from the plasma membrane. Messenger RNA (mRNA) transcripts encode the structural and regulatory viral proteins, which can be recognized as antigens within infected cells.*

Among the viruses, retroviruses and the diseases they cause were some of the earliest to be described in detail (Weiss 1984). At the turn of the century, equine infectious anemia was one of the first animal infections recognized as having a viral etiology. Shortly afterwards, there were descriptions of filterable, transmissible agents associated with cancers among chickens that related both leukemias (avian leukosis, 1908) and solid tumours (Rous sarcoma, 1911) to infections with viruses. In 1936, breast cancer in mice was found to be transmitted by a virus in the animal's breast milk, and from the 1950s onwards leukemias in mice, cats, fish, apes, and other vertebrate hosts were found to be caused by retroviruses. Knowledge of these cancer-causing viruses has yielded important insights into the nature of neoplasia and catalyzed the search for similar agents as a cause of malignancy in humans. Despite the attraction of this idea, which implied the possibility of vaccines to prevent cancer, it was not until 1980 that the relationship between a retrovirus infection and human neoplasia was documented, leading to the eventual characterization of HTLV.

Recently, the family of *Retroviridae* has been reclassified into seven different genera (Table 1). Viruses from the genera *Lentivirus* and *Deltaretrovirus* are known to cause disease in humans while viruses from the genus *Spumavirus* have been shown to infect humans, but no disease associations yet have been found. The chapter presented here deals primarily with those non-HIV retroviruses that cause or are associated with human disease.

HUMAN T-LYMPHOTROPIC VIRUS TYPE 1 AND HUMAN T-LYMPHOTROPIC VIRUS TYPE 2

Morphology

Human T-lymphotropic virus type 1 (HTLV-1) was the first human retrovirus isolated in 1981 (Kalyanaraman et al. 1981; Poiesz et al. 1981). Shortly thereafter, Human T-lymphotropic virus type 2 (HTLV-2) was isolated from a person with hairy cell leukemia (Kalyanaraman et al. 1982). Both viruses are part of the *Orthoretrovirinae* subfamily. HTLV-1 and HTLV-2 are typical C-type retroviruses; they contain an electron-dense, centrally located nuclear core and they bud from the cell surface. Within the core are two positive-sense single-stranded RNA genomes. A unique feature about HTLV-1 and HTLV-2 is their inefficient ability to infect via cell-free virus. Rather, these viruses require cell-to-cell contact for productive infection. Despite this, electron microscopy has shown that chronically infected cells form normal viral particles that are assembled at the plasma membrane and released (Poiesz et al. 1980; Miyoshi et al. 1981; Ohtsuki et al. 1982). It is currently unknown why cell-free virus has reduced infectivity.

Genome organization

HTLV-1 and HTLV-2 are more than 9 kb in length and have similar genomic organization: *gag*, *pro*/*pol*, *env*, p*X*,

Table 1 Retroviridae *family*

Genus	Virus	Host	Growth in human cells in vitro	Mode of transmission to humans	Human disease or infection
Alpharetrovirus					
Avian leukosis virus	ALV	Birds			
Rous sarcoma virus	RSV	Birds			
Gammaretrovirus					
Moloney murine leukemia virus	MoMLV	Mice			
Feline leukemia virus	FeLV	Cats	Yes		
Porcine endogenous retrovirus	PoEV	Pigs	Yes	?[a]	?
Baboon endogenous virus	BaEV	Baboons	Yes	?[a]	?
Betaretrovirus					
Mouse mammary tumor virus	MMTV	Mice			
Mason–Pfizer monkey virus	MPMV	Monkeys	Yes	?	Infection
Deltaretrovirus					
Bovine leukemia virus	BLV	Cows			
Primate T-lymphotropic virus 1	HTLV-1	Humans	Yes	Mother to child, sexual transmission, blood	T-cell lymphoma, neurological disorders, HAM/TSP[b]
Primate T-lymphotropic virus 2	HTLV-2	Humans	Yes		
Epsilonretrovirus					
Walleye dermal sarcoma virus	WDSV	Fish			
Lentivirus					
Human immunodeficiency virus type 1	HIV-1	Humans	Yes	Mother to child, sexual transmission, blood	AIDS
Human immunodeficiency virus type 2	HIV-2	Humans	Yes		
Simian immunodeficiency virus	SIV	Monkeys	Yes	(biting, blood, other?)	Infection
Visna/maedi virus	VISNA	Sheep			
Equine infectious anemia virus	EIAV	Horses		(biting, blood, other?)	
Feline immunodeficiency virus	FIV	Cats	Yes		
Caprine arthritis encephalitis virus	CAEV	Goats			
Spumavirus					
Simian foamy virus	SFV_{CPZ}[c]	Nonhuman primate	Yes	(biting, blood, other?)	Infection

a) Risk of transmission to human from xenotransplantation.
b) TSP, tropical spastic paraparesis; HAM, HTLV-associated myelopathy.
c) No human species of *Spumavirus* (foamy) is known. Simian foamy viruses from a number of simian species have been isolated or sequences identified in humans (see section below on Zoonotic retroviral infections).

and are flanked by the LTRs (Figure 2). Further, they share approximately 65 percent of their nucleotide sequences. The *gag* gene encodes for a polypeptide precursor that contains the structural proteins, p19 (MA), p24 (CA), and p15 (NC). Sera from infected patients generally have antibodies that recognize p19 and p24. The *pro* gene encodes for the viral protease. Synthesis of the protease as part of the gag polyprotein

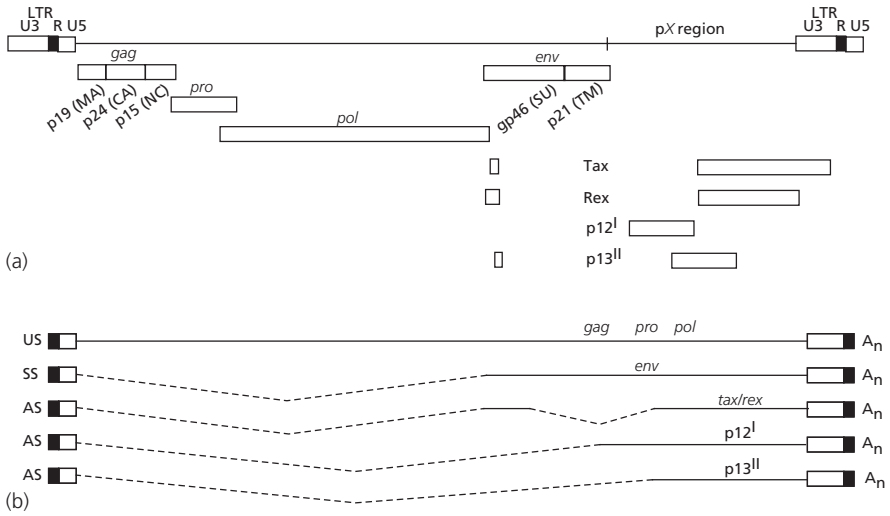

Figure 2 *Molecular genetic organization of HTLV.* **(a)** *Genomic organization. The 8.3-kb genome is flanked by long terminal repeats (LTR). Open reading frames are shown for the structural proteins, viral enzymes, and regulatory proteins.* **(b)** *RNA species. Unspliced, singly spliced, and multiply spliced RNA species are produced. Solid lines represent the exons and the dotted lines represent the intervening sequences.*

precursor is done by ribosomal frameshifting (Nam et al. 1988). The *pol* gene encodes the reverse transcriptase. The *env* gene encodes the transmembrane and external envelope glycoproteins, gp21 and gp46. The HTLV LTR is structured in a similar manner as other retroviral LTRs and contains three regions, U3, R, and U5. The U3 region contains transcriptional control sequences including the three imperfect 21 nt repeats that make up the Tax response element 1 (TRE-1), which is required for the *trans*-activation by Tax (see below) (Shimotohno et al. 1986). The U3 region also contains sequences for polyadenylation and termination of mRNAs. The R and U5 regions form the leader sequence encoded at the 5′ mRNAs. The R region is important for post-transcriptional control by Rex (see below).

As a complex retrovirus, HTLV-1 and HTLV-2 use alternative splicing and internal initiation codons to produce several regulatory and accessory proteins encoded by four open reading frames (ORF) located in the p*X* region of the viral genome between *env* and the 3′ LTR.

TAX (*TRANS*-ACTIVATING GENE)

The two originally described regulatory proteins, Tax and Rex, are generated from a doubly spliced, 2.1 kb mRNA encoded by ORF IV. The HTLV-1 *trans*-activator, Tax, is a 40 kDa protein. Tax contains a nuclear localization sequence that interacts with the cellular transcription factors, cyclic AMP-responsive element-binding protein (CREB) (Franklin and Nyborg 1995), nuclear factor-κB (NF-κB) (Sun and Ballard 1999), AP-1 (Jeang et al. 1991), and serum-response factor (SRF) (Fujii et al. 1992), and thus is a potent transcriptional activator not only from the viral promoter (Tax-responsive element), but also from enhancer elements of many cellular genes involved in host-cell proliferation. These genes include the *IL-2*, *IL-2R*, *GM-CSF*, *Lck*, and others. On its own, Tax has been shown to immortalize T lymphocytes (Rosin et al. 1998) and transform rat fibroblasts (Tanaka et al. 1990). When HTLV-1 with mutations in the CREB region or the NF-κB region of Tax was introduced into primary T lymphocytes, the NF-κB mutant lost its ability to transform the cells, indicating that the NF-κB pathway may play a critical role in the transformation process (Robek and Ratner 1999). Collectively, these data suggest that Tax plays a direct role in the development of HTLV-1-associated leukemia, adult T-cell leukemia (ATL).

REX (REGULATOR OF VIRAL EXPRESSION)

Rex is a 27 kDa phosphoprotein encoded by the ORF IV. Rex has an essential role in viral replication and the regulation of viral structural genes by functioning as a post-transcriptional regulator that increases the expression of singly spliced and unspliced viral mRNAs (Hidaka et al. 1988). Rex binds to the mRNA through a *cis*-acting stem–loop structure, Rex responsive element, which is located within the R region of the viral LTR (Ballaun et al. 1991; Bar-Shira et al. 1991; Unge et al. 1991). For the production of infectious virus, Rex-mediated regulation is required to balance the spliced and unspliced mRNAs.

ADDITIONAL HTLV-1 ACCESSORY GENES

Additional gene products have recently been identified from the two other ORFs. ORF I encodes $p12^{I}$. $p12^{I}$ is a highly hydrophobic protein that has been shown to localize to the endoplasmic reticulum with calcium-binding proteins (Ding et al. 2001). It has been shown that $p12^{I}$ is necessary for optimal viral infectivity in nondividing lymphocytes (Collins et al. 1998; Albrecht et al. 2000)

and activates NFAT-mediated transcription in lymphoid cells (Albrecht et al. 2002). Collectively these data suggest that $p12^{I}$ is important during early infection of T cells to facilitate cellular activation and viral replication. Much less is known about the ORF II product, $p13^{II}$. Recent reports have shown that $p13^{II}$ localizes to the mitochondria, altering the inner-membrane morphology and disrupting the inner-membrane potential (Ciminale et al. 1999; D'Agostino et al. 2002). These data suggest that $p13^{II}$ induces apoptosis of infected cells; however, this has not been observed, suggesting this viral protein may affect other mitochondrial functions.

Replication strategy

HTLV RECEPTOR

The identity of the HTLV-1 and HTLV-2 receptor(s) remains an enigma. It is unknown if both viruses share the same receptor, but mutual interference studies suggest that they may (Sommerfelt and Weiss 1990). Early work had proposed that the receptor may be located on human chromosome 17 (Sommerfelt et al. 1988; Gavalchin et al. 1995; Li et al. 1996); however, subsequent work failed to substantiate these results (Sutton and Littman 1996; Okuma et al. 1999; Jassal et al. 2001). Furthermore, this work has shown that the HTLV surface glycoprotein, gp46, can bind to cell lines derived from numerous species and cell types which implies broad expression of a common cellular antigen or possibly use of distinct cellular antigens for use as a receptor. It is currently unknown if one receptor or multiple receptors are required for HTLV binding and infection. Using an HTLV surface adhesion glycoprotein that binds to cell surface proteins important for HTLV-1-mediated entry, Nath et al. (Nath et al. 2003) showed binding to T cells, B cells, NK cells, and macrophage. Further, immune activation increased binding to $CD4^{+}$ and $CD8^{+}$ T cells, suggesting that the receptor(s) is up-regulated after activation of T cells (Manel et al. 2003a). Recent work has shown that treating susceptible cells with trypsin reduces infectivity, and entry was partially inhibited by ammonium chloride, suggesting that pH may play a role in entry (Trejo and Ratner 2000).

Cells infected with HTLV typically have metabolic alterations. Moreover, gammaretroviruses (Table 1) utilize receptors that belong to the multimembrane-spanning transporter family (Overbaugh et al. 2001). Together with this evidence and that presented above, Manel et al. (Manel et al. 2003b) showed that a ubiquitous glucose transporter, GLUT-1, was utilized as a receptor for HTLV-1 and HTLV-2. Interfering with the expression of GLUT-1, but not other similar proteins, reduced the binding of the HTLV-1 and HTLV-2 envelopes. In support of Igakura et al. (Igakura et al. 2003) data, the GLUT-1 expression is concentrated to the mobile membrane regions and should be involved in the 'virological synapse' (see below). Further work needs to confirm these results.

CELLULAR INFECTION

While the previous data suggest that HTLV has the potential to infect and replicate in a multitude of host species and cell types, in humans, HTLV-1 has shown a preferential tropism for $CD4^{+}$ T cells (Richardson et al. 1990). Recently, HTLV-1 was detected in $CD8^{+}$ T cells, and it was suggested that they might be a reservoir since there is low-level replication in these cells (Nagai et al. 2001). Like HTLV-1, HTLV-2 infects $CD4^{+}$ and $CD8^{+}$ T cells, but it has a broader cellular tropism in vivo as shown by detection of HTLV-2 genome in B cells, macrophage, and NK cells (Lal et al. 1995). However, the ability to replicate in non-T cells is poor as reflected in the lower proviral copy number in those non-T-cell types (Lal et al. 1995). It is currently unknown what factors in T cells, as opposed to other cell types, are required for optimal replication of HTLV-1 and HTLV-2.

HTLV rarely infects cells through cell-free virus as typified by the lack of HTLV transmission using serum/plasma as opposed to whole blood (Donegan et al. 1994). Direct cell-to-cell contact is required for efficient HTLV infection and results in syncytium formation between the infected cell and the uninfected cell. Cellular adhesion molecules that include ICAM-1, ICAM-3, and VCAM, have been shown to enhance syncytium formation (Hildreth et al. 1997; Daenke et al. 1999). It has been thought that the syncytium formation is involved in cell-to-cell infection, but until recently, how infection occurs has not been explained. Work by Igakura et al. (Igakura et al. 2003), showed that there is the formation of a 'virological synapse' that transfers HTLV between lymphocytes. These authors show that viral proteins and nucleic acids are polarized to the cell–cell junction within 40 minutes of cell contact. The polarization is accompanied by microtubule reorientation that transports Gag/nucleic acid complexes toward the cell–cell junction. The HTLV Env may have a role in the initiation of the virological synapse, but the formation of the synapse may be due to the up-regulation of certain adhesion molecules such as integrins (Dezzutti et al. 1995; Valentin et al. 1997; Yamamoto et al. 1997).

The kinetics of HTLV infection are thought to occur in a two-step process. Early after cell entry, there is a transient phase of RT followed by integration into the host's genome with subsequent persistent multiplication of infected cells. Integration is a requisite for expression of progeny virus and is responsible for persistence of the infection. In vitro studies have suggested that retroviruses may prefer to integrate into areas of the host genome that are transcriptionally active (Scherdin et al. 1990). It was also suggested that in persistently HTLV-infected cell lines, the provirus may integrate into GC-rich regions (Glukhova et al. 1999). However, in vivo work has shown

that HTLV preferentially integrates into AT-rich regions and is not associated with transcriptionally active or GC-rich regions (Leclercq et al. 2000a, b).

Genetic diversity

As mentioned earlier, HTLV-1 and HTLV-2 share 65 percent genetic identity, and have minimal genetic variability (<10 percent) among different geographical isolates. The genetic stability of HTLV-1 and HTLV-2, despite long latency periods and high proviral load, is mainly attributed to clonal expansion of HTLV-harboring cells (Cavrois et al. 1996; Wattel et al. 1996). While the misincorporation rate of the HTLV RT is much lower than that of the HIV-1 RT (Mansky and Temin 1995; Mansky 2000), this is believed to play a lesser role in the genetic stability of these viruses. The LTR region has the lowest nucleotide homology, while the regulatory genes, *tax* and *rex*, have the highest nucleotide homology. The stability of the *env* gene may be due to its inability to tolerate mutations well. Pique et al. (Pique et al. 1990) performed insertion mutational analysis and showed that the majority of the mutations resulted in a nonfunctional envelope as shown by the lack of syncytia. These data suggest that the conformational constraints for processing and fusion abilities tend to limit the variability of the HTLV-1 envelope. Further, the utilization of the 'virological synapse' may allow HTLV-1 and perhaps HTLV-2 to escape the immune pressures that result in viral evolution.

While the overall genome of HTLV is highly conserved, nucleotide divergence in the LTR has been exploited to genotypically subtype both HTLV-1 and HTLV-2 (Slattery et al. 1999). There are four genetic subtypes of HTLV-1 based on the geographical origin of the virus: cosmopolitan (subtype A), Central African (subtype B), Australo-Melanesian (subtype C), and New Central African (subtype D) (Mahieux et al. 1997; Slattery et al. 1999). Likewise, HTLV-2 has four subtypes: IIa, IIb, IIc, and IId (Switzer et al. 1995; Slattery et al. 1999). Subtype IIa is commonly found among injecting drug users (IDU) worldwide, whereas subtype IIb is found primarily among Amerindians. This genetic heterogeneity within HTLV-1 and HTLV-2 has provided valuable information on geographical clustering and viral transmission (Switzer et al. 1995; Slattery et al. 1999).

Clinical and pathological aspects

Less than 5 percent of those persons infected with HTLV-1 develop the known diseases. Approximately 1–2 percent develops an aggressive T-cell malignancy known as ATL, and about 2–3 percent develop a chronic inflammatory disease called HTLV-1-associated myelopathy/tropical spastic paraparesis (HAM/TSP). Additional inflammatory diseases are also associated with HTLV-1 infection and they affect the skin (infective dermatitis), joints (HTLV-associated arthropathy), or the eye (uveitis). Rarely do persons concurrently develop ATL and HAM/TSP; however, there are documented cases of HAM/TSP with the other inflammatory diseases. It is currently unknown why there are distinct disease manifestations, but it may be due to the HTLV proviral load (Nagai et al. 1998; Manns et al. 1999b; Grant et al. 2002), the host immune response to HTLV (Jacobson et al. 1990), or the genetic background of the infected persons (Manns et al. 1998; Jeffery et al. 2000; Nishimura et al. 2000). For instance, studies calculating proviral load demonstrate that the proviral load is low among asymptomatic carriers compared to persons with HAM/TSP and ATL (Nagai et al. 1998; Manns et al. 1999b), suggesting that proviral load may be an indicator for future disease development.

ADULT T-CELL LEUKEMIA

An HTLV-1-infected person has an estimated 1 percent chance of developing adult T-cell leukemia (ATL) over their lifetime. Males are approximately 1.5 times more likely to develop ATL as females. ATL is diagnosed by seropositivity for HTLV-1, the presence of morphologically distinct $CD3^+/4^+/25^+$ lymphocytes with cleaved nuclei (flower cells)(Figure 3), and elevated serum lactate dehydrogenase activity. A comprehensive study on ATL published the outcome of 818 patients (Shimoyama 1991). That study characterized four clinically distinct subtypes of ATL. Smoldering ATL has the best prognosis with a mean survival time (MST) of >2 years and a projected 4-year survival of 62.8 percent. Smoldering ATL is characterized by skin and lung infiltration of leukemic cells and a normal leukocyte count with a low number of leukemic cells. Often it is hard to diagnose from the asymptomatic carrier since in both cases abnormal lymphocytes (flower cells) are detected in blood smears. However, only in ATL can clonal integration of HTLV-1 be detected by Southern blot. Chronic ATL has a MST of 24.3 months and a projected 4-year survival of 26.9 percent. In chronic ATL, there is a high leukocyte count, and it is associated with lymphadenopathy and hepatosplenomegaly. In both smoldering and chronic ATL, there is no association with hypercalcemia and no leukemic infiltration into the central nervous system, gastrointestinal tract, or bones. Lymphoma has a MST of 10.2 months with a projected 4-year survival of 5.7 percent. Acute ATL has a MST of 6 months and projected 4-year survival of 5 percent. These are both aggressive malignancies and are associated with massive lymphadenopathy, hepatosplenomegaly, lytic bone lesions, and multiple visceral lesions with skin and lung inflitration. Lymphoma and acute ATL patients are functionally immunosuppressed and

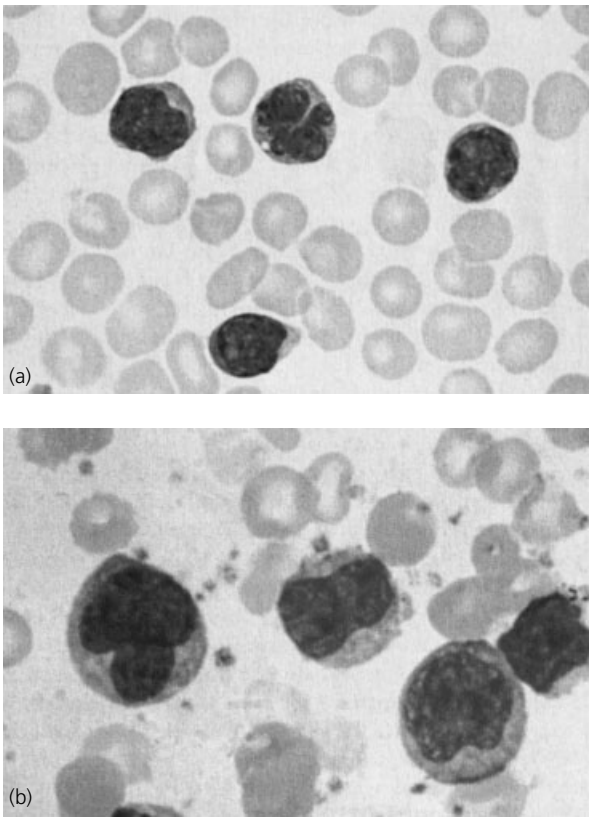

Figure 3 *Peripheral blood film of retrovirus infected patients.* **(a)** *Peripheral film of a patient with HTLV-I-associated adult T cell leukaemia/lymphoma (ATLL) showing lymphocytes with cleaved nuclei ×1000. (Courtesy of Professor D Gatovsky.)* **(b)** *Film of patient presenting with acute glandular fever illness during HIV seroconversion. Marked lymphocytosis with many abnormal immature-looking lymphocytes ×1500. (Courtesy of Dr C Ludlam.)*

may develop a variety of opportunistic infections. The difference between the lymphoma and acute types is whether or not the majority of leukemic cells is in the peripheral blood compartment. Lymphoma ATL has less than 1 percent leukemic cells present on a blood smear whereas acute ATL has a massive leukemic infiltrate in the peripheral blood.

HTLV-ASSOCIATED MYELOPATHY/TROPICAL SPASTIC PARAPARESIS

HTLV-1-infected persons have a lifetime risk of 0.25 percent for developing HTLV-associated myelopathy (HAM)/tropical spastic paraparesis (TSP) (Kaplan et al. 1990). Interestingly, females are three times as likely to develop HAM/TSP as are males. HAM/TSP is a slowly progressing myelopathy. The clinical features include the gradual onset of muscle weakness in the legs, hyperreflexia, clonus, extensor plantar responses, sensory disturbances, bowel and bladder dysfunction, impotence, and low back pain (Nagai and Jacobson 2001). However, unlike multiple sclerosis, HAM/TSP does not show periods of spontaneous improvement without treatment. Diagnosis includes the presence of virus or HTLV-specific antibodies in the cerebrospinal fluid, brain, and spinal cord tissues. ATL flower cells are found in about half of HAM/TSP patients' peripheral blood and cerebrospinal fluid with a frequency of approximately 1 percent (Osame et al. 1987). Autopsy material from HAM/TSP patients shows loss of myelin and axons in the lateral, anterior, and posterior columns of the thoracic level of the spinal cord. This pathology is associated with an inflammatory infiltrate consisting of lymphocytes, predominately $CD8^+$ T cells, and foamy macrophages. The cytotoxic $CD8^+$ T cells are specific for HTLV-1 proteins, typically the p*X* gene products. It is thought that these HTLV-1-specific $CD8^+$ cytotoxic T lymphocytes are involved in the development of HAM/TSP by either directly lyzing infected astrocytes (Kuroda et al. 1994; Lehky et al. 1995) or indirectly by secreting proinflammatory cytokines (Tendler et al. 1991; Kuroda and Matsui 1993).

OTHER INFLAMMATORY DISEASE ASSOCIATIONS

Other inflammatory disease associations include HTLV-associated uveitis (HU), HTLV-associated arthropathy (HAA), Sjögren's syndrome, and infective dermatitis (ID). HU, literally the inflammation of the uvea, is clinically characterized by the sudden onset of moderate or severe vitreous opacities with mild iritis and retinal vasculitis in one or both eyes (Mochizuki et al. 1996). Women are affected by HU twice as often as men. Patients with HU generally have a higher proviral load than asymptomatic HTLV-1 carriers, have viral particles and HTLV-1 provirus in their eyes, and accumulate HTLV-1-infected cells in their eyes (Ono et al. 1995; Sagawa et al. 1995). HU is self-limiting or responds well to treatment with topical or systemic corticosteroids; however, up to half of affected patients relapse. Generally, the visual prognosis is good after resolution (Takahashi et al. 2000).

HAA is indistinguishable from idiopathic rheumatoid arthritis with marked thickening of the synovial lining cells and lymphocytic infiltration of the sublining layer. The characteristic histopathological finding of an accumulation of HTLV-1 atypical lymphocytes in the synovial tissue and fluid as well as antibodies against HTLV-1 antigens in synovial fluid indicates that this is HAA (Sato et al. 1991). Epidemiologically, HTLV-1-infected persons are more likely to develop a polyarthropathy resembling rheumatoid arthritis than HTLV-1 negative persons (Motokawa et al. 1996). Furthermore, the arthropathy in the HTLV-1-infected persons was milder and onset was at a more advanced age compared to HTLV-1-negative persons with rheumatoid arthritis. The presence of HTLV-1 *Tax* is a common finding in synovial cells from persons with HAA. *Tax* expression is associated with increased inflammatory cytokine expression and synovial cell proliferation (Kitajima et al. 1991;

Miyasaka et al. 1991). Subsequent work with transgenic mice expressing the HTLV-1 *Tax* gene has shown the development of a polyarthropathy resembling rheumatoid arthritis (Iwakura et al. 1991, 1998) and it was associated with inflammatory cytokine expression (Iwakura et al. 1995).

Sjögren's syndrome is an autoimmune disorder characterized by a T-lymphocytic infiltration of salivary glands leading to ductal structure destruction (Eguchi et al. 1992; Ohyama et al. 1998). Epidemiologic reports have shown high seroprevalence of HTLV-1 among patients with Sjögren's syndrome in areas endemic for HTLV-1 (Eguchi et al. 1992; Terada et al. 1994). T-lymphocytic infiltrate in the salivary glands correlates to the clinical findings of Sjögren's syndrome (Nakamura et al. 2000). Furthermore, there is an accumulation of polyclonal HTLV-1-infected T cells expressing conserved T-cell receptor motifs in the salivary glands (Sasaki et al. 2000). The *Tax* gene sequence is detected in some salivary gland specimens, and expression of gene sequences homologous to HTLV-1 *Tax* may lead to the activation of autoreactive T cells in patients with Sjögren's syndrome (Sumida et al. 1994; Mariette et al. 2000).

ID is found commonly among children in the Caribbean and Japan. The average age at disease onset is 2 years with >50 percent of patients being female. Five major criteria are used for the diagnosis of ID (La Grenade et al. 1998) and include:

1. eczema of the scalp, axillae and groin, external ear and retroauricular areas, eyelid margins, paranasal skin, and/or neck
2. chronic watery nasal discharge without other signs of rhinitis and/or crusting of the anterior nares
3. chronic relapsing dermatitis with prompt response to appropriate therapy but prompt recurrence on withdrawal of antibiotics
4. usual onset in early childhood
5. HTLV-1 antibody seropositivity.

Skin lesions associated with ID become less severe with age, presumably due to the maturation of the immune system. Epidemiologic data indicate that ID is predictive of later ATL or HAM/TSP development (Hanchard et al. 1991; Tsukasaki et al. 1994; LaGrenade et al. 1995).

HTLV-2 ASSOCIATED DISEASES

Because of the genetic relatedness between HTLV-1 and HTLV-2, it was assumed that similar diseases would be associated with both viruses. However, no diseases have been definitively associated with HTLV-2. The estimated lifetime risk of disease development for HTLV-2-infected persons is unknown, but is less than that estimated for persons with HTLV-1 infection. A few reports have described forms of leukemia/lymphoma in HTLV-2-infected persons (Rosenblatt et al. 1986, 1987; Kaplan et al. 1991), but this is rare. There also has been a report on a $CD8^+$ lymphocytosis associated with high HTLV-2 proviral copy numbers in intravenous drug users (Rosenblatt et al. 1990), but this has not been confirmed in other cohorts. Recently, HTLV-2 has been associated with a neurological disease resembling HAM/TSP (Jacobson et al. 1993; Murphy et al. 1997a; Silva et al. 2002) and ataxia (Harrington et al. 1993; Sheremata et al. 1993). These data suggest that HTLV-2-infected persons rarely develop disease; however, they should be followed up more closely for potential disease development.

IMMUNOSUPPRESSIVE NATURE OF HTLV-1 AND HTLV-2

While the majority of infected persons remain asymptomatic (>95 percent), recent studies report an increased incidence of infectious diseases (such as bronchitis and kidney and/or bladder infections) in HTLV-1- and HTLV-2-infected persons (Modahl et al. 1997; Murphy et al. 1997b, 1999) and an increased association with mortality, especially those persons with a high anti-HTLV-1 antibody titer (Arisawa et al. 1998). Higher rates of primary neoplasias have been reported in ATL patients, their siblings, and mothers as compared to HTLV-1-negative non-Hodgkin's lymphoma patients and their respective relatives in Japan (Kozuru et al. 1996). Clinical laboratory findings from asymptomatic HTLV-1 and HTLV-2-infected persons show altered blood chemistries and elevated absolute lymphocyte counts, but these findings were not significant enough to change their clinical evaluation or counseling of otherwise healthy HTLV-infected subjects (Glynn et al. 2000b). Some elderly HTLV-1-infected persons have anergic responses to purified protein derivative (PPD) (Suzuki et al. 1999). The inability to respond to PPD was found to be due in part to their inability to respond to IL-12. However, a more recent report showed that testing middle-aged HTLV-1- and HTLV-2-infected persons demonstrated no anergy to PPD, mumps, or *Candida albicans* antigens (Murphy et al. 2001). The wide spectrum of diseases indicates that further work is necessary to determine the full public health impact of HTLV infection in the general population.

Treatment

To date, therapy for ATL has had limited success. A combination of interferon-alpha (IFN-α) and zidovudine has been effective in a limited number of cases (Gill et al. 1995; Hermine et al. 1995). For persons with HAM/TSP, early disease can be alleviated by corticosteroids, and some relief is seen with zidovudine and danazol (Gout et al. 1991; Harrington et al. 1991). Lamivudine has been shown to decrease HTLV-1 proviral load, but has not been shown to clinically improve HAM/TSP patients who have established disease (Taylor et al. 1999). Despite a recent study showing that

HTLV-1 RT was equally susceptible to zidovudine, zalcitabine, didanosine, and stavudine, but resistant to lamivudine (Garcia-Lerma et al. 2001), lack of sustained clinical remission suggests that alternative treatments need to be found.

Long-term, high dose IFN-α therapy has been shown to reduce HTLV-1 proviral load and improve motor performance in six patients (Yamasaki et al. 1997). However, no randomized trials have been done to compare the effectiveness of these therapies for ATL or HAM/TSP treatment. Arsenic trioxide (As_2O_3), which causes apoptosis of HTLV-1-infected cell lines or fresh ATL cells from patients, has been proposed for the treatment of ATL (Ishitsuka et al. 1998). Its combination with IFN-α appears to have a high synergistic effect in vitro (Bazarbachi et al. 1999). The clinical application of IL-2R-directed therapy, using a humanized monoclonal antibody (or that antibody armed with radionuclides), provides a new perspective for the treatment of autoimmune disorders such as HAM/TSP and certain neoplastic diseases including ATL (Waldmann 1996). Antibodies directed toward both IL-15 and IL-2, or their receptors, inhibit almost completely the proliferation of peripheral blood mononuclear cells (PBMC) from HAM/TSP patients in vitro (Azimi et al. 1999). While these treatments show promise, they still need to be tested in a clinical setting.

Epidemiology

HTLV-1 and HTLV-2 share approximately 60 percent of their nucleotide sequences; yet they have distinct evolutionary and geographical distributions. HTLV-1 infects 15–20 million people worldwide, with endemic foci in southern Japan, the Caribbean, Melanesia, sub-Saharan Africa, and Central and South America (de The and Bomford 1993; Madeleine et al. 1993). The seroprevalence rate ranges from 3–6 percent in the Caribbean islands (Murphy et al. 1991) to approximately 27 percent in southern Japan (Mueller et al. 1996). HTLV-2 is endemic in Amerindian tribes throughout North and South America as well as pygmy tribes in Central Africa with seroprevalences ranging from 3 to 33 percent (Maloney et al. 1992; Hjelle et al. 1994). In the USA and Europe, the seroprevalence for both HTLV-1 and HTLV-2 among low-risk populations is less than 1 percent (Manns et al. 1999a). However, high-risk populations such as IDUs, who are predominately HTLV-2 infected, have a seroprevalence ranging from 0.4 to 20 percent (Kaplan and Khabbaz 1993).

HTLV-1 and HTLV-2 infections are spread through sexual, vertical, and parenteral transmission. Sexual transmission of HTLV-1 has been shown to primarily occur from male to female; however, female-to-male transmission does occur, albeit at a lower efficiency (Murphy et al. 1989; Stuver et al. 1993; Sullivan et al. 1993). Sexual transmission has been associated with older male partners, length of relationship, high anti-HTLV antibody titers, and high proviral load (Stuver et al. 1993; Kaplan et al. 1996). Less is known about the sexual acquisition of HTLV-2; however, in an HTLV-2 endemic area, there was a strong concordance of seropositivity between spouses (Vitek et al. 1995). The role of other sexually transmitted diseases in the spread of HTLV-1 or HTLV-2 is less clear. Persons engaging in high-risk sexual relationships have been shown to have a higher seroprevalence of HTLV-1 (Murphy et al. 1989; Wiktor et al. 1990; Nakashima et al. 1995). A history of having both ulcerative and nonulcerative sexually transmitted diseases has been associated with a higher prevalence of antibodies to HTLV-1, suggesting that they may affect HTLV-1 transmission (Murphy et al. 1989; Nakashima et al. 1995). Recently, cervicitis was shown to be associated with cervical shedding of HTLV-1 and thus may increase HTLV transmission (Zunt et al. 2002). More work is needed to fully address the role of sexually transmitted diseases in the sexual transmission of HTLV-1 and HTLV-2.

Vertical transmission, also known as mother-to-child transmission, primarily occurs through postnatal breastfeeding. HTLV-1 and HTLV-2-infected lymphocytes have been isolated from breast milk (Kinoshita et al. 1984; Heneine et al. 1992b). Mothers that have been shown to transmit HTLV to their children have higher viral antigen-producing capacity from isolated breast milk mononuclear cells as well as proviral load (Yoshinaga et al. 1995; Ureta-Vidal et al. 1999). Additional maternal factors that are important for transmission are high titer of HTLV antibodies (Hino et al. 1987; Hirata et al. 1992), and breastfeeding for more than 12 months (Takahashi et al. 1991; Wiktor et al. 1993; Hino et al. 1996). It was shown that reducing the length of breastfeeding significantly reduces the transmission of HTLV-1 (Takahashi et al. 1991; Wiktor et al. 1993). While the majority of vertical transmission occurs through breast milk, there is a minor population of children that becomes infected even if not breastfed. In utero transmission has been proposed as a secondary route for mother-to-child transmission. Several groups inconsistently found HTLV-1 proviral DNA in cord blood mononuclear cells from the HTLV-1-infected children, suggesting that in utero infection may not be a major route of transmission in children who were not breast-fed (Kawase et al. 1992; Katamine et al. 1994; Nyambi et al. 1996).

Transmission via saliva is considered possible but studies presenting direct evidence for this mode of transmission have not been published. HTLV-1 proviral DNA has been detected in saliva or mouthwashes from ATL (Taniguchi et al. 1993) and HAM/TSP patients (Soto-Ramirez et al. 1995; Achiron et al. 1996; Offen et al. 1998), and asymptomatic HTLV-infected carriers (Yamamoto et al. 1995; Achiron et al. 1996; Belec et al. 1996; Offen et al. 1998). Antibodies against HTLV-1 are

also present in saliva (Archibald et al. 1987; Soto-Ramirez et al. 1995; Yamamoto et al. 1995). The association of the presence of viral RNA and local IgA in saliva has been thought to provide evidence that viral replication may occur in the oral cavity of HAM/TSP patients and some asymptomatic carriers (Soto-Ramirez et al. 1995). However, the neutralizing effect of saliva IgG on syncytium formation in vitro and the saliva's ability, even in the absence of antibodies, to inhibit cell-to-cell transmission of HTLV-1 in vitro demonstrate that transmission through the saliva, if it occurs at all, would be rare (Yamamoto et al. 1995).

Injecting drug use and sex with IDUs are the most important risk factors for HTLV-2 transmission (Kaplan and Khabbaz 1993). Because of the high risk of transfusion-related transmission of HTLV-1 and HTLV-2, screening of volunteer blood donors has been implemented in Japan, several Caribbean countries, various European countries, and the USA and Canada (Whyte 1997; Courouce et al. 1999; Glynn et al. 2000a). The effectiveness of these screening programs is manifested by reduced risk of transfusion-related transmission. In the USA, the incidence rates of seroconversion associated with HTLV in blood donors is estimated to be 1.59 per 100 000 persons per year (Glynn et al. 2000a), and the residual risk of transmitting HTLV infection by transfusing screened blood is estimated to be 1 in 641 000 (Schreiber et al. 1996).

Laboratory diagnosis

The most common assays used for screening persons detect antibodies in serum or plasma. However, such assays detect only past exposure to the viruses. Direct detection of HTLV-1 and HTLV-2 is achieved through the use of nucleic acid assays such as the polymerase chain reaction (PCR).

SEROLOGICAL DETECTION

The immunodominant regions of structural proteins and regulatory gene regions have been well characterized (Lal 1996) and are the basis for the development of diagnostic assays both for detection and differentiation of HTLV-1 and HTLV-2. Typically, an enzyme immunoassay (EIA) is used as the primary screening assay, and western blot (WB) is used as a confirmatory test. Particle agglutination assays, which are based on the agglutination of HTLV-1 lysate-coated gelatin particles by antibodies in a test specimen, are also used in various countries as screening assays.

The EIA is a colorimetric test that is both sensitive and simple to perform and generally now uses purified HTLV-1 and HTLV-2-infected cell lysates and/or HTLV-1 and HTLV-2 recombinant antigens or synthetic peptides. The addition of HTLV-2 antigens to test kits significantly improved the detection of antibodies to HTLV-2, compared with results using kits that contained only HTLV-1 antigens (Andersson et al. 1999; Liu et al. 1999; Poiesz et al. 2000). Comparative analysis of various commercial screening assays containing both HTLV-1 and HTLV-2 antigens indicates that sensitivity ranges from 98.9 to 100 percent for confirmed HTLV-1-positive specimens and 91.5 to 100 percent for confirmed HTLV-2 positive specimens. Specificity ranges from 90.2 to 100 percent for both infections (Andersson et al. 1999; Poiesz et al. 2000). These assays are used for both blood donor screening and as an aid in clinical diagnosis of HTLV-1 and HTLV-2 infection and related diseases. However, the EIAs cannot differentiate between infection with HTLV-1 and HTLV-2 because of the significant homology in structural proteins between the two viruses (Courouce et al. 1999). To serologically differentiate between these viruses, WB is used.

Although WB assays using purified viral lysates are highly sensitive for detecting $p24^{gag}$ antibodies, they do not always detect antibodies to native envelope glycoproteins. Several approaches have addressed this issue in second-generation WB assays. In one, viral lysates have been spiked with recombinant p21e protein (p21e). Antibodies to p21e are detected more easily compared to those to $gp46^{env}$; however, some false-positive specimens have been identified by this test (Lal et al. 1992a; Busch et al. 1994; Kleinman et al. 1994). A second approach is a modified WB that contains type-specific $gp46^{env}$ recombinant proteins from HTLV-1 and HTLV-2, as well as a truncated form of p21e (gd21) that reduces nonspecific reactivity (Varma et al. 1995) (Figure 3). This assay not only serves as a confirmatory serological test but also permits the differentiation of infection between HTLV-1 and HTLV-2 (Varma et al. 1995). The modified WB has improved specificity and is sensitive for most subtypes of HTLV-1 and HTLV-2 (Varma et al. 1995). Specimens with reactivity to $p24^{gag}$ and p21e, but no reactivity to either $rgp46^{I}$ or $rgp46^{II}$, are referred to as HTLV-positive untypeable. PCR analysis of these untypeable specimens has identified the presence of HTLV-specific sequences (Varma et al. 1995). In rare instances, specimens with confirmed HTLV infection have reactivity to $p19^{gag}$ (in the absence of p24) and p21e (Cesaire et al. 1999; Rouet et al. 2001). Likewise, in some instances, antibody to p21e may represent an early antibody response during the 6-month seroconversion window period, and individuals with such reactivity should be retested in 6 months (Manns et al. 1992). It is the current policy of the US Public Health Service to recommend that the diagnostic criteria for WB tests require that a specimen demonstrating antibodies to $p24^{gag}$ and to native $gp46^{env}$ and/or recombinant p21e are considered seropositive for HTLV-1 or HTLV-2 (CDC and the U.S.P.H.S. Working Group 1993). Specimens reacting with any of the bands, but not satisfying the above criteria, are designated indetermi-

nate. Specimens with no immunoreactivity to any bands are considered negative for antibodies to HTLV-1 and HTLV-2 (false-positive EIA specimens).

Both of the WB assays can give indeterminate results or show immunoreactivity to a single HTLV gene product, conditions which do not meet the criteria of seropositivity (Busch et al. 1994; Varma et al. 1995). Antibody to only Gag proteins (p24, p19) is the most common indeterminate pattern that is observed in EIA-reactive specimens, and extensive PCR analysis using primers to detect multiple gene regions have failed to detect HTLV-1 or HTLV-2 proviral sequences in these seroindeterminate persons thus indicating that these individuals are not likely to be infected with HTLV-1 or HTLV-2 (Lal et al. 1992b; Medrano et al. 1997; Cesaire et al. 1999; Rouet et al. 2001). Limited studies have also established that individuals with indeterminate WB profiles generally do not have risk factors for HTLV infection (Mauclere et al. 1997; Medrano et al. 1997; Cesaire et al. 1999; Rouet et al. 2001). Such indeterminate WB results appear to represent antibodies to different viral and cellular antigens that cross-react with HTLV proteins (Mahieux et al. 2000). However, recent data suggest that a small number of patients with chronic progressive neurological disease and HTLV-indeterminate WB patterns may be due to infection with a defective HTLV or have HTLV-1 in low copy numbers (Soldan et al. 1999; Waziri et al. 2000). The possibility that such indeterminate WB results may represent a novel retrovirus with partial homology to HTLV has also been explored; however, no amplification was observed using generic PCR primers that would amplify HTLV-related viruses (Vandamme et al. 1997; Busch et al. 2000).

NUCLEIC ACID DETECTION

Amplification of proviral DNA by PCR is the preferred method for determining infection status, testing the validity of serological assays, distinguishing between HTLV-1 and HTLV-2, and studying the in vivo tissue distribution. These qualitative and quantitative PCR techniques can be used to identify HTLV infections for subtyping purposes or for determining viral load.

Two quantitative PCR procedures have been successfully used on PBMCs to confirm and differentiate between HTLV-1 and HTLV-2 infections. The first uses HTLV consensus primers that allow amplification of both viruses; typing is achieved either by hybridizing the product to an HTLV-1-specific or HTLV-2-specific probe (Heneine et al. 1992a) (Figure 4) or by specific restriction digestion patterns (Tuke et al. 1992). A second approach employs type-specific primers and probes in separate amplifications (Heneine et al. 1992a). The PCR products can be detected with labeled internal probes by Southern blot hybridization. A solid-phase, nonradioactive, EIA-based detection system has been

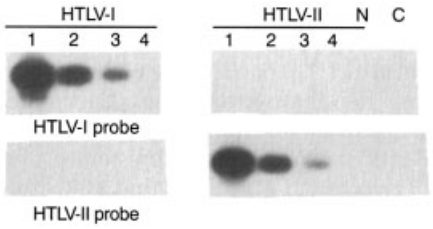

Figure 4 *Generic PCR amplification of HTLV-I and HTLV-II by SK110/SK111 and differentiation by type-specific probing. Numbers 1, 2, 3 and 4 refer to lysates of uninfected Hut-78 cells containing 1500, 150, 2 and 0 HTLV-I infected (MT-2) or HTLV-II (MO-T) cells, respectively. C, reagent cocktail control; N, Hut-78. The HTLV-I specific probe is SK112, and the HTLV-II probe is SK188.*

developed which seems highly sensitive and specific for detection and differentiation of both HTLV-1 and HTLV-2 (Dyster et al. 1994; Dezzutti et al. 1996).

Multiplex DNA PCR is a semiquantitative technique used for the simultaneous amplification, detection, and discrimination of different target sequences in one tube. In addition to primers for HTLV-1/HTLV-2 detection, primers for HIV-1/HIV-2 detection are also included. Primers for the *gag* region of HIV-1, *env* region of HIV-2, *pol* region of HTLV-1, and *Tax* of HTLV-2 are used to provide specific and sensitive coamplification of proviral sequences (Heredia et al. 1996; Vet et al. 1999). Multiplex PCR can detect fewer than ten proviral copies for each virus per sample and thus can provide an accurate measure of the number of copies of each proviral sequence that were originally present in the sample.

Additional quantitative nucleic acid assays have been developed to determine proviral DNA load. These assays include nested PCR with limiting dilution (Tosswill et al. 1998), quantitative competitive PCR (Albrecht et al. 1998), and real-time PCR (Kamihira et al. 2000; Miley et al. 2000). Primers have been designed for the *gag*, *tax*, or *pol* genes, and all are highly sensitive.

VIRUS ISOLATION, ANTIGEN DETECTION, AND REVERSE TRANSCRIPTASE ASSAYS

Viral isolation of HTLV-1 or HTLV-2 has been difficult due to the cell-associated nature of this virus. Nevertheless, cocultivation of HTLV-1- and HTLV-2-infected PBMCs with activated, allogeneic HTLV-negative PBMCs is used to obtain viral isolates. The culture supernatants are collected weekly, for up to 4 weeks, and the presence of $p19^{gag}$ antigen in the supernatant is tested using an antigen-capture EIA. Alternatively, detection of viral replication in cultures supernatants is accomplished by detecting HTLV reverse transcriptase activity using an amplified reverse transcriptase (AMP-RT) assay (Yamamoto et al. 1996). This assay was shown to detect the presence of HTLV-1 and HTLV-2 in culture supernatants that were not detected by EIA.

ZOONOTIC RETROVIRUS INFECTIONS

The identification of isolated infections with either simian immunodeficiency virus (SIV) or simian foamy virus (SFV) in occupationally exposed workers suggested that occupational contact with nonhuman primates (NHP) may be associated with risks of transmission of simian retroviruses (Khabbaz et al. 1992, 1994; Schweizer et al. 1995, 1997). The recognition that human HIV-1 and HIV-2 infections originated from simian-to-human transmission of SIV has heightened concerns of cross-species transmission of animal retroviruses. Such transmissions could occur in various settings: occupational exposures to NHPs (e.g. in biomedical research), exposures to NHPs as pets or in zoological gardens, or in occasions when NHP organs have been used in xenotransplantation. In addition to SIV and SFV, NHP are natural hosts to several exogenous retroviruses including simian T-lymphotropic viruses (STLV) and simian type D viruses (SRV) (Lowenstine and Lerche 1988).

Foamy viruses (FV), including SFV, belong to the *Spumavirus* genus in the family *Retroviridae*. FVs cause cytopathic effects with syncytium formation in vitro, but appear to be nonpathogenic in vivo. They establish persistent infections in many animal species, including nonhuman primates, cats, cows, and sea lions. SFVs infect more than 70 percent of captive nonhuman primates (Hooks and Gibbs 1975; Neumann-Haefelin et al. 1993; Schweizer et al. 1995; Meiering and Linial 2001), in which they appear to cause latent infection in almost all organs – spleen, liver, kidney, salivary gland, brain (Swack and Hsiung 1975) – and can be readily detected by PCR in PBMCs. Minimal viral replication appears to occur in the oral mucosa (Falcone et al. 1999).

Human infection with SFV

A foamy virus referred to as human foamy virus (HFV), now called prototype foamy virus (PFV), was isolated from a nasopharyngeal carcinoma specimen from a Kenyan man (Achong et al. 1971). Following its detection, seroepidemiologic studies in human populations have shown controversial results. Most studies did not find antibodies to PFV even in populations exposed to NHPs (Brown et al. 1978; Nemo et al. 1978; Schweizer et al. 1995). Some earlier serological studies reported seropositivity among certain populations from 6.9 percent among Pacific Islanders (Loh et al. 1980) to 17 percent in Kenyans (Achong and Epstein 1978) but later studies using confirmatory testing could not confirm PFV antibody presence even in sera highly reactive by enzyme-linked immunosorbent assay (ELISA) (Ali et al. 1996; Heneine et al. 2003). Most of the earlier studies did not always use adequate methods to control for false-positive results or additional confirmatory methods were not available at that time (Heneine et al. 2003).

The failure to find antibodies to PFV in sera from 250 persons, including 50 with nasopharyngeal carcinoma and Burkitt's lymphoma (Brown et al. 1978), the cross-reactivity of PFV with antibodies to SFV (Nemo et al. 1978), and sequence analyses all suggested that the PFV was most likely of chimpanzee origin (Herchenroder et al. 1994).

Recent studies, using WB for detection of antibodies and confirmatory testing for viral DNA, have documented seropositivity to SFV in 19 persons from Germany, the USA, and Canada (Schweizer et al. 1995, 1997; Heneine et al. 1998; Sandstrom et al. 2000; Brooks et al. 2002; Switzer et al. 2004). All of them have been occupationally exposed to nonhuman primates, their biological fluids, or to simian viruses in the laboratory. Sequence analysis confirmed that SFV infection has originated from baboons, chimpanzees, macaques, and African green monkeys (Heneine et al. 1998) (Figure 5). A study of Cameroonians who reported contact with nonhuman primates through hunting and butchering demonstrated SFV infection in natural settings (Wolfe et al. 2004). Ten of 1 099 (1 percent) persons had SFV WB positive results. Three WB-positive persons were also PCR-positive. Sequence analysis indicated that SFV was acquired from a mandrill, gorilla, and a DeBrazza guenon.

Characteristics of human infection with foamy viruses

Early studies raised questions about possible associations between PFV infection and a variety of human diseases (e.g. thyroiditis, amyotrophic lateral sclerosis, hemodialysis encephalopathy) (Cameron et al. 1978; Werner and Gelderblom 1979; Lagaye et al. 1992; Westphal et al. 1992; Stancek et al. 1995). Later studies, using more precise diagnostic methods, did not confirm such associations or endemic human infection (Heneine 1995; Schweizer et al. 1995, 1997; Ali et al. 1996; Rosener et al. 1996; Winkler et al. 2000).

Humans infected with SFV show persistent seropositivity by WB; testing of stored sera revealed that some persons have been seropositive for more than 20 years (Heneine et al. 1998; Switzer et al. 2004). The identification, by PCR, of two conserved SFV proviral DNA sequences in PBMCs confirms the persistent nature of the SFV infection (Heneine et al. 1998).

Although PFV can cause transient immunosuppression in experimentally infected mice and rabbits (Santillana-Hayat et al. 1993), currently there is no evidence that SFVs are pathogenic in their natural host (Weiss 1996; Linial 2000). Available data on the SFV-infected persons show that no obvious disease can be attributed to these infections at the time of their detec-

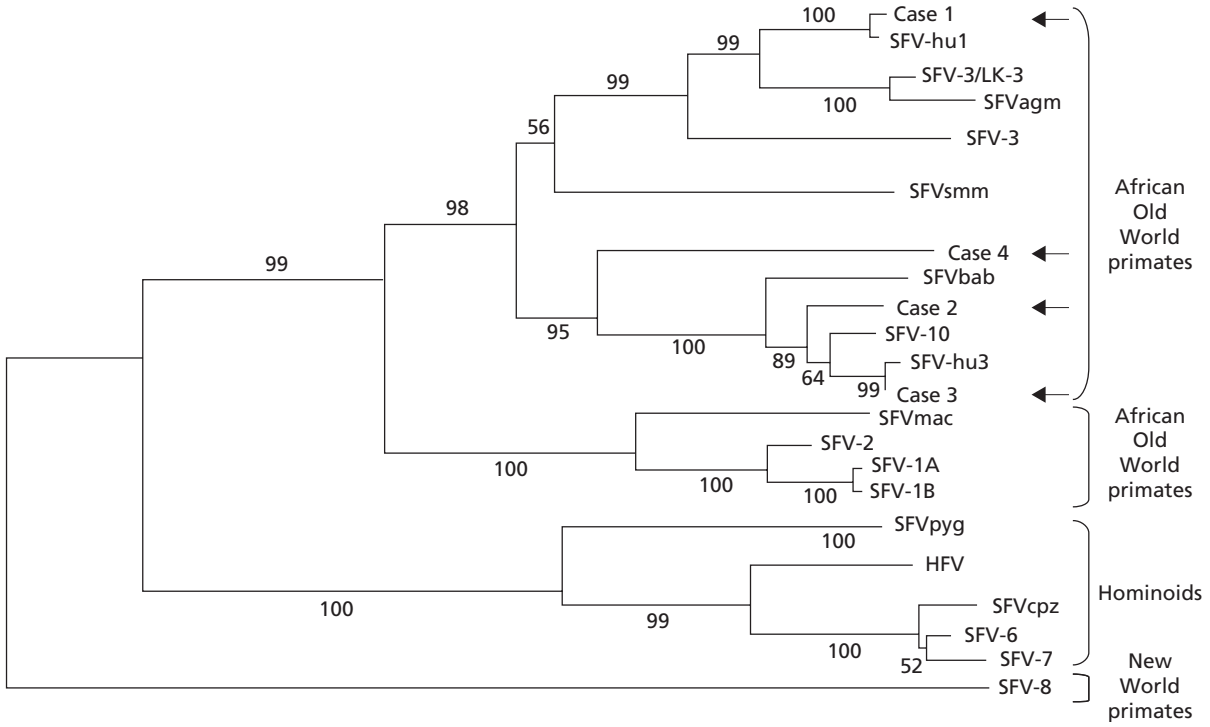

Figure 5 *NHP species origin of SFV infections in workers occupationally exposed to NHPs. Phylogenetic analysis by neighbor-joining of SFV* pol *sequences derived from peripheral blood lymphocytes of four case workers and from SFVhu1 and SFVh3, two SFV isolates obtained from case 1 and case 3, respectively. SFV sequences of different NHP species shown are SFVagm, SFVsmm, SFVbab, SFVmac, SFVpyg, obtained from African green monkey, sooty mangabey, baboon, and pygmy chimpanzee, respectively. SFVcpz and SFV-6 and SFV-7, from chimpanzees, SFV-8 from spider monkey (a New World monkey species). Numbers shown at branch nodes represent bootstrap percent values.*

tion (Schweizer et al. 1995, 1997; Heneine et al. 1998; Sandstrom et al. 2000; Brooks et al. 2002). Because FV are considered nonpathogenic and because they can infect a broad range of human cells and human cell lines in the laboratory (Meiering and Linial 2001), they are considered as potential candidates for gene transfer therapy (Bieniasz et al. 1997; Hill et al. 1999).

HTLV infections are an example that retroviruses may cause a disease in a small proportion of infected individuals and after a long latent period. To better characterize the course of SFV infection in humans, the US Centers for Disease Control and Prevention (CDC) has initiated a long-term follow-up of SFV-infected persons.

Human-to-human transmission

No evidence of male-to-female transmission in wives of six SFV-infected workers was found, suggesting that transmission of SFV among humans by sexual or less intimate contact may not occur easily (Schweizer et al. 1997; Heneine et al. 1998; Switzer et al. 2004). Four recipients of blood components from one SFV-infected donor were tested 1.9 to 7 years after transfusion and are not infected (Boneva et al. 2002). Although preliminary, these data suggest that secondary SFV transmission among humans appears unlikely and humans may be a dead-end host of the SFV infection – as is often the case with zoonoses. However, a larger number of SFV-infected persons and their contacts need to be followed for a longer period of time to confirm lack of human-to-human transmission and benign nature of the SFV infection in humans.

Other animal retroviruses

The observation that SFV appears to be readily transmissible to humans raises concerns that human contact with other domestic animals such as cats, all of which are known to harbor FV and other retroviruses (Tobaly-Tapiero et al. 2001), may be accompanied with risk of zoonosis. A study of persons occupationally exposed to cats by Butera et al. (Butera et al. 2000) found no evidence of infection with either feline foamy virus (FFV), feline leukemia virus (FeLV) or feline immunodeficiency virus (FIV) in 203 North American feline veterinary practitioners. Persons studied reported extensive duration of work with cats and multiple high-risk exposures. Similarly, Winkler et al. (1999) found no evidence of FFV zoonosis among Australian veterinarians, although exposure to felines were not clearly defined in that study.

XENOTRANSPLANTATION AND OTHER IATROGENIC RISKS OF INFECTION WITH ANIMAL RETROVIRUSES

Particular attention has been given to risks of transfer of animal retroviruses to humans through xenotransplantation – the use of live animal tissues or cells as xenografts. Interest in xenotransplantation has increased because of its potential to provide a solution for the chronic shortage of allotransplants or to provide porcine pancreatic islet cells for treatment of diabetes, or neuron cells for treatment of Parkinson's disease. Organs from NHPs have been used with some success in the past but currently pigs are the preferred source of animal xenografts. Both NHPs and pigs harbor endogenous retroviruses, which cannot be eliminated from source animals by pretransplant screening because their DNA is part of the cell's DNA. For example, porcine endogenous retroviruses (PoEV) and baboon endogenous viruses (BaEV) can infect human cells and have been extensively studied recently as potential causes of zoonotic infections in relation to xenotransplantation. SFV and BaEV sequences were detected in multiple tissue compartments of two human recipients of baboon livers (Allan et al. 1998). The presence of baboon mitochondrial DNA was also detected in these same tissues, suggesting that xenogeneic 'passenger leukocytes' harboring latent or active viral infections had migrated from the xenografts to distant sites within the human recipients. The persistence of SFV and BaEV in human recipients in the post-transplant period reveals the potential infectious risks associated with xenotransplantation (Allan et al. 1998). More than 200 persons exposed to various porcine xenografts have been tested for PoEV without evidence for infection (Herring et al. 2001). In one of the studies, about 23 percent of persons exposed to live porcine tissue had proviral sequences detected in quantities consistent with microchimerism but not infection (Paradis et al. 1999). PoEV has also been found as a contaminant of porcine factor VIII concentrates, which are used to treat hemophiliacs (Heneine et al. 2001); however, there was no evidence for PoEV infection in 88 recipients of this product (Heneine et al. 2001).

The identification of RT activity in chick-cell-derived vaccines including measles, mumps, and yellow fever vaccines has led to studies to identify the source of the RT activity and assess the risks it poses to vaccine recipients (Boni et al. 1996; Tsang et al. 1999). These investigations indicated that the RT activity in the measles, mumps, and rubella (MMR) vaccines and in yellow fever (YF) vaccines was found to be associated with viral particles containing RNA from the endogenous avian leukosis virus subgoup E (ALV-E) and the endogenous avian virus (EAV) (Weissmahr et al. 1997; Tsang et al. 1999; Johnson and Heneine 2001; Hussain et al. 2003). Both ALV-E and EAV originate from the chick embryonic fibroblasts used to propagate the measles and mumps vaccines, or from the chick embryos used for YF vaccine production. The detection of RT activity in all vaccine lots suggested that vaccine recipients might be universally exposed to these endogenous chicken retroviral particles. However, testing of MMR and YF vaccine recipients has thus far revealed no evidence of transmission of ALV-E or EAV to vaccine recipients. No antibody reactivity to either ALV-E or EAV was found in 206 US recipients of MMR vaccine and in 43 Brazilian recipients of YF vaccine (Hussain et al. 2001; Johnson and Heneine 2001). No ALV-E and EAV sequences were also detected by PCR in serum and peripheral blood lymphocyte samples from these vaccinees (Hussain et al. 2001; Johnson and Heneine 2001). While current data continue to support the use of chick-cell-derived MMR and YF vaccines, the presence of adventitious avian retroviral particles in these vaccines has raised questions about the suitability of primary chicken cell substrates for vaccine production.

Using retroviral vectors such as the Moloney murine leukemia virus for retrovirally mediated gene transfer has proven successful in treating certain genetic conditions. However, the recently reported lymphoproliferative disease in two of ten children treated for X-linked severe combined immunodeficiency demonstrates the risks that may be associated with retroviral integration and insertional mutagenesis (Hacein-Bey-Abina et al. 2003).

RETROVIRUSES, CANCER, AND DISEASES OF UNKNOWN ETIOLOGY

Interestingly, the literature is replete with studies showing the associations of cancer with retroviruses in animals. With the exception of the HTLV, humans are somewhat void of such associations. Our genome, on the other hand, contains remnants of retroviral elements (as endogenous retroviruses), suggesting that during our evolution we encountered and symbiotically associated with these viruses, which now provides a resistance to retroviral-mediated cancers. Retroviruses and/or retroviral components have been investigated for years as the putative agent in other diseases of unknown etiology. Numerous papers attempt to assign a retrovirus, its insertion, or gene product to the cause and association with many diseases such as multiple sclerosis, osteoarthritis, systemic lupus erythematosus, Sjögren's disease, Graves' disease, just to name a few. It has been neither the intent nor the aim of this chapter to refute those claims here, but rather to present the most scientifically accepted associations of retroviruses with human disease and infection. Retroviruses are constantly emerging and their ability to zoonotically transmit, recombine, mutate,

and 'trap' other genes makes them a constant concern for the stewards of public health.

INTRODUCTION

The family of *Retroviridae* is taxonomically divided into two subfamilies: the *Orthoretrovirinae* and the *Spumaretrovirinae,* the latter are better known as foamy viruses (FV) (Table 1). The separation of the previously homogenous group of retroviruses into the two subfamilies by the International Committee of the Taxonomy of Viruses (ICTV) reflected the molecular biology of FVs and their replication pathway, which appears to be significantly different from all other retroviruses, and have common aspects with the replication strategy of hepadnaviruses (Linial 1999; Lecellier and Saïb 2000; Rethwilm 2003b; Flint et al. 2004). In this chapter, these findings will be reviewed and the general biology of FVs will be summarized.

NATURAL HISTORY AND GENERAL PROPERTIES OF FV

FVs have been known for more than 50 years. After long term cultivation of primary monkey cells a typical foamy cytopathic effect (CPE) emerged (Figure 1) that could be transferred in a cell-free manner to uninfected cell cultures (Enders and Peebles 1954; Rustigian et al. 1955; Lepine and Paccaud 1957; Paccaud 1957; Falke 1958; Plummer 1962). Following the detection of a reverse transcriptase activity in gradient-purified virions, FV were classified among the *Retroviridae* (Parks et al. 1971). Curiously the question of the molecular basis of the FV-specific foamy degeneration of cells has not been addressed yet.

FVs have been found in the mammalian species which also naturally harbor lentiviruses, namely nonhuman primates (Hooks and Gibbs 1975; Swack 1981), felines (Lutz 1990; Pedersen 1990), bovines (Johnson et al. 1988; Amborski et al. 1989), equines (Tobaly-Tapiero et al. 2000), ovines (Flanagan 1992), and occasionally others (Hruska and Takemoto 1975; Rossignol et al. 1975; Kennedy-Stoskopf et al. 1986; Amborski et al. 1987; Meiering and Linial 2001; Saïb 2003). An overview is shown in Table 2. In particular, FVs from monkeys and great apes have been studied since the early years of FV research (Hooks and Gibbs 1975). It is a common experience that these simian foamy viruses (SFV) can influence studies on other simian (retro-) viruses, such as the immunodeficiency viruses, by reactivation from latency and destroying primary cell cultures (Voss et al. 1992; Feldmann et al. 1997).

Virus is shed in the saliva and can be easily isolated by throat swabs from infected monkeys and cats (Hooks and Gibbs 1975; Shroyer and Shalaby 1978; Alke et al. 2000). Transmission in monkeys is believed to occur by social contacts involving biting during juvenility (Meiering and Linial 2001; Falcone et al. 2003). After infection, the virus persists lifelong and can be isolated from many tissues (Hooks and Gibbs 1975; Falcone et al. 1999a; Falcone et al. 2003). Viral DNA at approximately one copy number per 10^2–10^3 cells can be found in most organs of perfused animals, although cellfree virus has not been detected in the plasma (Falcone et al. 1999a;

Table 1 *The ICTV nomenclature of the* Retroviridae

Subfamily	Genus	Example	Genome
Orthoretrovirinae	*Alpharetrovirus*	Avian leukosis virus (ALV)	Simple
	Betaretrovirus	Mouse mammary tumor virus (MMTV), Mason–Pfizer monkey virus (MPMV)	Simple
	Gammaretrovirus	Murine leukemia virus (MuLV)	Simple
	Deltaretrovirus	Bovine leukemia virus (BLV), Human T-cell leukemia virus (HTLV)	Complex
	Epsilonretrovirus	Walleye dermal sarcoma virus (WDSV)	Complex
	Lentivirus	Human immunodeficiency virus (HIV)	Complex
Spumaretrovirinae	Foamyviruses	Prototype foamy virus (PFV)	Complex

Falcone et al. 2003). The conservation of viral sequences over time is also suggestive of poor replication in vivo (Schweizer et al. 1999). Despite the prominent CPE FVs exhibit in adherent cell cultures, the in vivo infection is nonpathogenic (Linial 2000; Meiering and Linial 2001; Falcone et al. 2003). Continuous virus isolations by throat swabs and from peripheral blood lymphocytes (PBL) many years after primary infection indicate virus persistence (Hooks and Gibbs 1975; Hooks and Detrick-Hooks 1981; Meiering and Linial 2001; Falcone et al. 2003). More recently, the sequences of bovine foamy virus (BFV), feline foamy virus (FFV), and equine foamy virus (EFV) have also become available (Renshaw et al. 1991; Renshaw and Casey 1994a, 1994b; Helps and Harbour 1997; Winkler et al. 1997a; Tobaly-Tapiero et al. 2000; Hatama et al. 2001) and studies into the molecular biology, epidemiology, and persistence of FFV were performed (Winkler et al. 1998; Winkler et al. 1999; Alke et al. 2000; Hatama et al. 2001; Roy et al. 2003; Bodem et al. 2004).

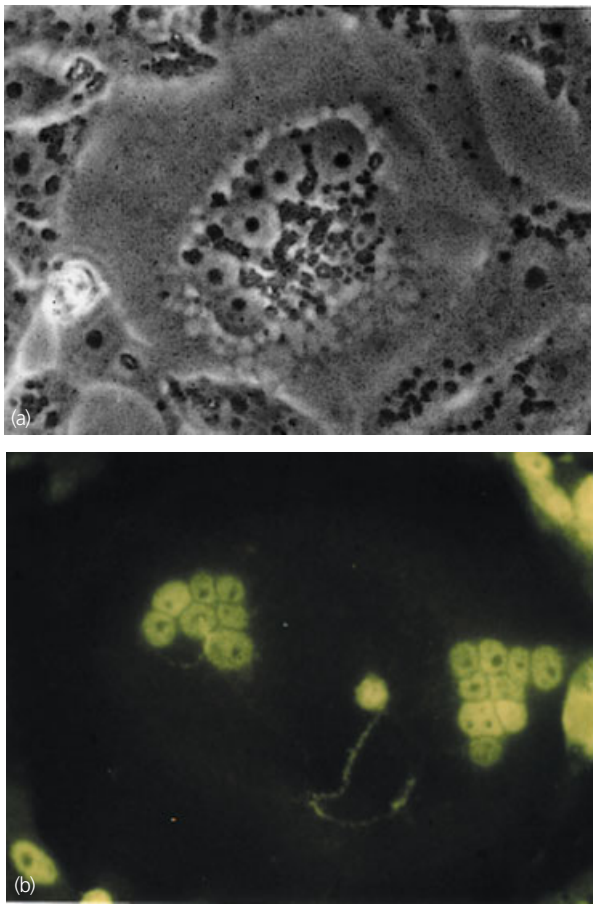

Figure 1 (a) *Micrograph of a typical FV cytopathic effect with the formation of multinucleated syncytia and vacuolation. SFVagm-infected Vero cell culture.* **(b)** *Nuclear staining in indirect immunofluorescence of SFVagm-infected cells with a SFVagm-positive monkey serum.*

In particular, the analysis of cats which were co-infected by FFV and feline immunodeficiency virus (FIV) did not reveal FFV-related diseases, which were triggered by FIV-induced immunosuppression (Zenger et al. 1993). Furthermore, the artificial immunosuppression in a limited number of SFV-infected monkeys by cyclosporin A resulted only in a higher rate of FV isolations by throat swabs, but not in disease that could be attributed to the virus (D. Neumann-Haefelin, personal communication). Similar results on virus isolation frequencies were obtained when analyzing cats co-infected with FFV and FIV (Bandecchi et al. 1992). The infection of laboratory animals, such as mice and rabbits, by FV of primate origin also leads to virus persistence in the absence of recognizable pathogenicity (Swack and Hsiung 1975; Hooks and Detrick-Hooks 1979; Brown et al. 1982; Santillana-Hayat et al. 1993; Saïb et al. 1997a; Schmidt et al. 1997b; Falcone et al. 2003).

Since human immunodeficiency virus (HIV) arose by trans-species transmissions from nonhuman primates to men (Hahn et al. 2000; Sharp et al. 2001; Peeters et al. 2002), much effort has been undertaken in identifying genuine human FV infections and a potential linkage with human diseases of a suspected infectious origin. In particular, neurological diseases were investigated after the discovery that mice transgenic for FV genes developed brain pathology (Bothe et al. 1991; Aguzzi et al. 1992; Aguzzi et al. 1993). Taking together the results from several studies, in which populations potentially at risk of contracting retroviral infections

Table 2 *Foamy virus isolates*[a]

Host species	Isolate	Key references
Macaque (*M. cyclopsis*, *M. mulatta*, *M. fascicularis*)	SFVmac	(Johnston 1961; Kupiec et al. 1991)
African green monkey (*C. aethiops*)	SFVagm	(Stiles et al. 1964)

Equines	EFV	(Tobaly-Tapiero et al. 2000)

a) Modified from Meiering and Linial (2001); Falcone et al. (2003).

were screened for FV antibodies, humans do not appear to be a natural reservoir of FV (Hunsmann et al. 1990; Landay et al. 1991; Flügel et al. 1992; Folks et al. 1993; Heneine et al. 1994; Pyykkö et al. 1994; Schweizer et al. 1994; Simonsen et al. 1994; Heneine et al. 1995; Schweizer et al. 1995; Ali et al. 1996; Rösener et al. 1996).

However, additional studies identified a small population of FV-infected humans who were mostly people in contact with nonhuman primates, or material derived from them or African monkey hunters (Schweizer et al. 1997; Heneine et al. 1998; Sandstrom et al. 2000; Switzer et al. 2004; Wolfe et al. 2004). These trans-species infections were never caused by a hypothetical 'human' FV, but could always be traced back to a particular monkey virus (Heneine et al. 2003; Wolfe et al. 2004). Therefore, these isolates are called, for instance, SFVagm(hu) or SFVcpz(hu) to indicate that they were derived from humans zoonotically infected by SFV from African green monkey or chimpanzee, respectively. Virus isolations from FV-infected humans were unsuccessful from throat swabs and required PBL (Heneine et al. 1998; Heneine et al. 2003). Positive results twenty or more years after infection indicate lifelong persistence (Schweizer et al. 1997; Heneine et al. 2003; Switzer et al. 2004). As in their natural hosts, the infections of humans occur in the absence of any pathogenicity (Heneine et al. 2003). Furthermore, so far there is no indication that the virus is transmitted to other humans even by intimate contact or that FV other than those of primate origin can infect humans (Boneva et al. 2002; Heneine et al. 2003; Switzer et al. 2004). Thus humans are likely to represent a dead-end host to primate FV.

The absolute number of humans identified to be infected by SFV is small. A careful follow-up of these cases is required to ensure early recognition of a possible risk of a newly emerging pathogenic human retrovirus. However, given the very slow mutation rate of FV and their general apathogenicity, this scenario appears to be unlikely.

Curiously, the first FV that was molecularly cloned and is still the best-studied virus of this group was initially called 'human' FV, because it was reported to be derived from a human source (Achong et al. 1971; Rethwilm et al. 1987). Following sequencing of chimpanzee FVs, which revealed an almost identical nucleotide sequence (Herchenröder et al. 1994), and the large-scale sero-epidemiological studies with negative results mentioned above, the name 'human' FV was found to be inappropriate and misleading (Rethwilm 2003a). Instead, the name prototypic foamy virus (PFV) for this virus, which most likely is a chimpanzee FV, was coined (Rethwilm 2003a).

FV can infect a very large range of cell cultures (Hooks and Gibbs 1975; Hooks and Detrick-Hooks 1981). Pseudotyping experiments of vesicular stomatitis virus (VSV) with PFV envelope indicated that the unknown receptor must be ubiquitous, since even reptile cells could be infected (Hill et al. 1999). FVs make use of a pH-dependent endocytotic entrance pathway, which is vulnerable to various lysosomotropic agents (Picard-Maureau et al. 2003). Despite the ubiquitous presence of the receptor, not all cells support active virus replication. Reasons other than lack of receptor appear to be responsible for this (Meiering et al. 2001). In adherent cells, lytic infection results in cellfree virus titers of around 10^5–10^6 infectious units/ml (Yu and Linial 1993; Schmidt and Rethwilm 1995). Thus, any given cell produces only 0.1–1 cellfree progeny virus. However, the amount of cell-bound virus is approximately ten times higher (Neumann-Haefelin et al. 1983; Yu and Linial

1993). Of particular interest are cell lines of hematopoietic origin, because these cells often do not show the FV-typical giant cell CPE (Mikovits et al. 1996; Yu et al. 1996a). Yet these cells can be persistently infected and virus production is often low in the range of 10^2–10^3 infectious units/ml (Yu et al. 1996a). The virus–cell interaction in lymphoid cell lines may reflect the in vivo situation closer than fibroblastoid cells. In natural infection, lymphocytes probably disseminate the virus in the body. Active virus replication appears to be restricted to a few organs, like the oral mucosa (Falcone et al. 1999a; Falcone et al. 2003). Furthermore, gamma interferon (γ-IFN) secreted by activated lymphocytes is a potent suppressive factor of FVs that restricts virus replication in a species-specific manner (Falcone et al. 1999b). FV replication was shown to induce apoptosis (Ikeda et al. 1997; Mergia et al. 1997). However, this has not been further elucidated.

MOLECULAR BIOLOGY OF THE *SPUMARETROVIRINAE*

Morphology and composition of the FV particle

Electron microscopy studies revealed most of the details of the FV ultrastructure (Gelderblom and Frank 1987). Extracellular infectious particles are approximately 110 nm in diameter (Figure 2). They consist of an immature core of approximately 65 nm consisting of capsid (Gag) protein, which is either uncleaved or processed at the C-terminus where a 3 kD peptide is cleaved by the viral protease (see below). In primate FVs these two moieties are of 71 and 68 kD MW, which are present in around equimolar amounts in the viral particle (Hahn et al. 1994; Fischer et al. 1998). The capsid is surrounded by an envelope, in which the prominent viral glycoproteins (Env) are embedded in a trimeric arrangement (Wilk et al. 2000). In PFV the precursor of Env is of apparent 130 kD MW. Cellular proteases cleave this protein into three subunits, the 18-kDa leader peptide ($gp18^{LP}$), an around 80-kDa surface protein ($gp80^{SU}$), and the 48-kDa transmembrane subunit ($gp48^{TM}$). All three proteins are integral parts of the virion (Lindemann et al. 2001). At least in PFV another glycoprotein ($gp170^{Env\text{-}Bet}$) can be found at approximately 50 percent of the amount of $gp130^{Env}$ (Giron et al. 1998; Lindemann and Rethwilm 1998). The $gp170^{Env\text{-}Bet}$ which is only loosely, if at all, associated with the virion appears not to be required for in vitro replication (Lindemann and Rethwilm 1998). It is generated from an alternatively spliced mRNA (Giron et al. 1998; Lindemann and Rethwilm 1998) which consists of the majority of the env open reading frame (ORF) fused to the bet ORF (see below). The polymerase (pol) ORF is expressed as a 127-kDa apparent MW precursor which is cleaved by the viral protease into the 85-kDa protease-reverse transcriptase/RNase H (PR-RT/RN) and the 41-kDa integrase (IN). All three proteins are found in virions (Netzer et al. 1993; Pfrepper et al. 1998). The molar ratio of Gag to Pol proteins approximates 15:1 (M. Cartellieri and A. Rethwilm, unpublished observation).

The genomes of FVs have been studied in detail for PFV and FFV (Moebes et al. 1997; Yu et al. 1999; Roy

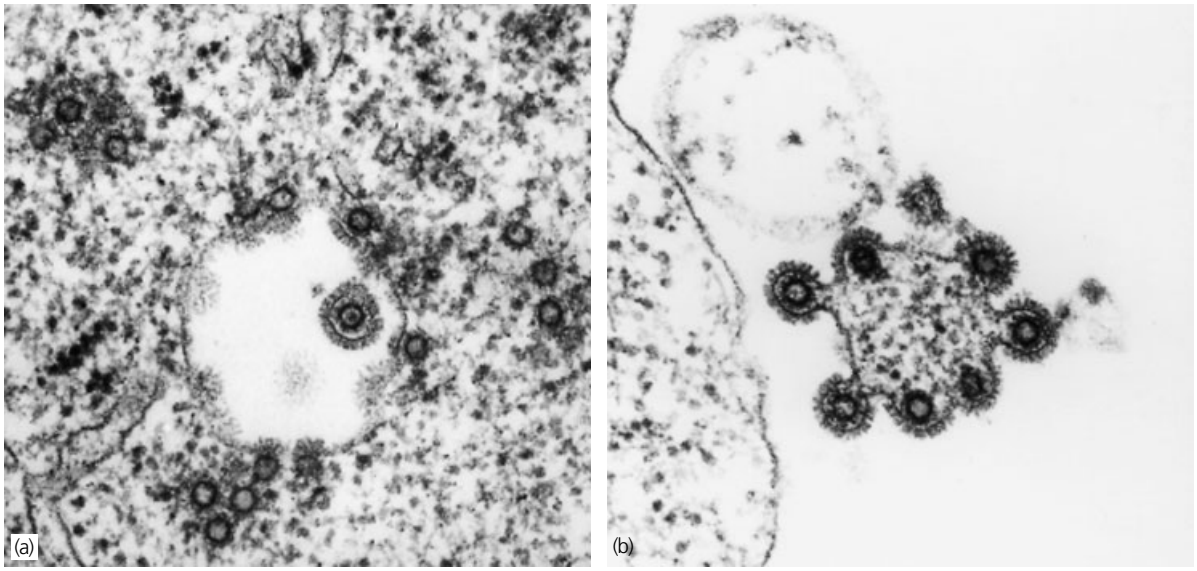

Figure 2 (a) *Electron micrograph of intracellular capsids, particles budding into intracellular compartments, and mature foamy virus.* **(b)** *Electron micrograph of budding foamy viruses revealing the prominent envelope glycoprotein spikes. et al. 2003). Interestingly, FVs contain a large amount of already reverse transcribed, mostly linear, cDNA (Yu et al. 1996a, 1999; Moebes et al. 1997; Roy et al. 2003). In orthoretroviruses, the ratio of DNA to RNA (late reverse transcripts of the *pol* or *gag* genes) is approximately one in 4×10^5 molecules. In spumaretroviruses, it was determined to be as high as one DNA in six RNA molecules (Yu et al. 1999; Roy et al. 2003). While some reports indicate that only the DNA form of the genome is relevant for replication (Moebes et al. 1997; Yu et al. 1999; Roy et al. 2003), others point to a role of RNA as well (Delelis et al. 2003).

Genome organization and expression

FV genomes are large; the PFV genome (linear viral DNA) is 13.2 kb (Figure 3) and the FFV genome 11.7 kb long. The viral genes are flanked by long terminal repeats (LTR) (of 1770 bp in PFV), subdivided into U3 (1423-bp), R (194-bp), and U5 (153-bp) regions (Maurer et al. 1988; Schmidt et al. 1997a). Adjacent to the 5′ LTR a short untranslated sequence is positioned, which is followed by the canonical *gag*, *pol*, and *env* genes. The protease is encoded in the *pol* gene. Downstream of env and overlapping the 3′ LTR, two accessory ORFs can be found in all sequenced FVs. The first harbors the *tas* gene (for *t*rans*a*ctivator of *s*pumaretroviruses) and ORF-2 gives rise to Bet, an abundant protein of ill-defined function (see below).

After provirus integration an internal promoter (IP), which is located in the *env* gene upstream of the accessory ORFs gives rise to two major transcripts (Löchelt et al. 1993b; Campbell et al. 1994; Löchelt et al. 1994; Mergia 1994; Bodem et al. 1998a) which are often spliced in the 5′ untranslated region (Figure 3). To do this the IP has some weak basal activity (Löchelt et al. 1993a). The activity of the IP is essential for the remainder of the replication cycle (Löchelt et al. 1995). One of the IP transcripts leads to the Tas protein and the other to Bet (Löchelt et al. 1994). Bet is derived from a multispliced mRNA. The most significant splice uses a splice donor (SD) in ORF-1 and an ORF-2 splice acceptor (SA). Tas activates transcription from the IP and the 5′ LTR U3 promoter. The U3 promoter has no detectable activity in the absence of Tas (Keller et al. 1991). The Gag protein is translated from a (pre-)genome length transcript. Instead of being expressed as a Gag–Pol fusion protein, FV Pol uses its own mRNA for translation as an authentic protein (Bodem et al. 1996; Enssle et al. 1996; Löchelt and Flügel 1996; Yu et al. 1996a). This transcript is spliced from the major 5′ SD in U5 to an SA which is located in the *gag* gene (Figure 3). The *pol* gene-specific splicing event appears to be critical for viral replication (Jordan et al. 1996). The transcripts for the Env protein also make use of the major 5′ SD and a major (or one of the minor) SA sites at the 3′ end of the *pol* gene (Muranyi and Flügel 1991). Despite this complex splicing pattern, a post-transcriptional regulator of FV gene expression has not been detected (Baunach et al. 1993; Yu and Linial 1993; Lee et al. 1994; Adachi et al. 1995). However, an RNA element within the *pol* gene has been described to facilitate Gag protein expression of HIV (Wodrich et al. 2001). This result awaits further substantiation.

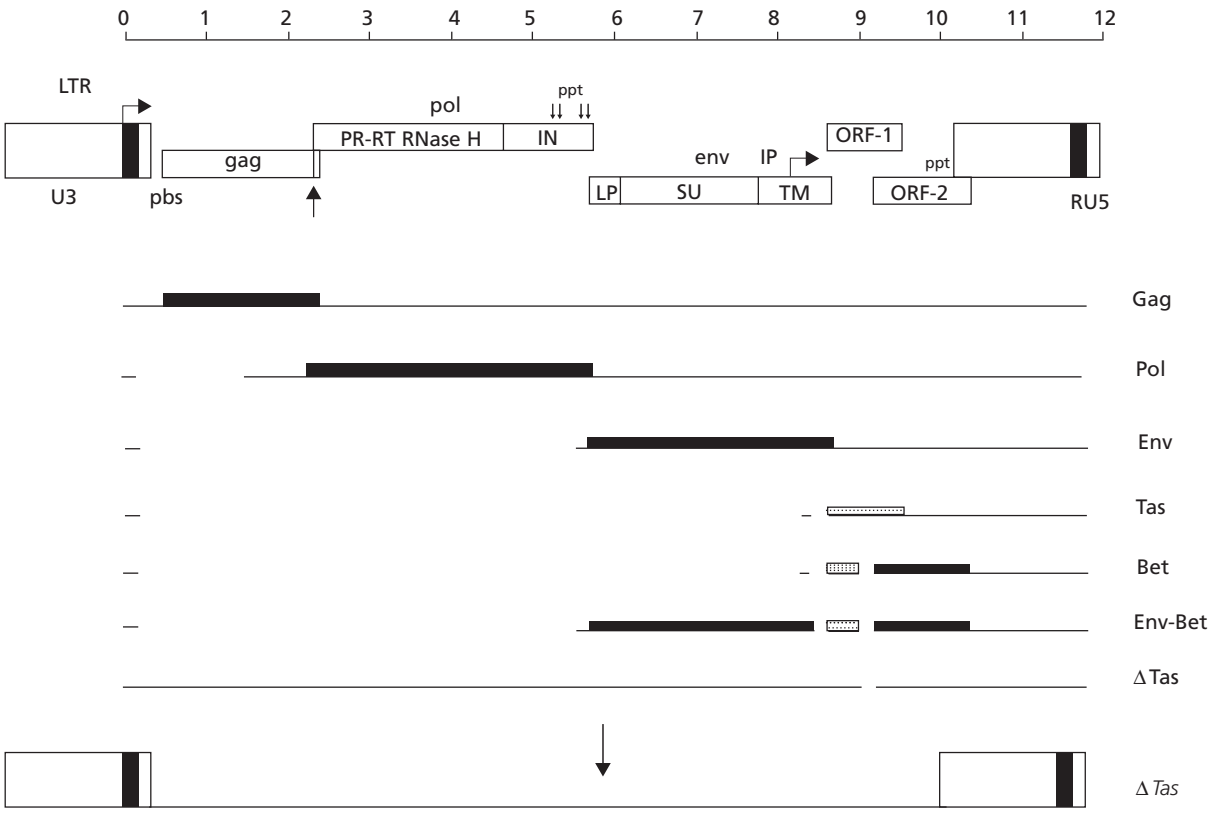

Figure 3 *Foamy virus genome organization (upper panel), main transcripts (middle panel), and ΔTas virus (bottom panel). Foamy virus genomes contain long terminal repeats (LTRs) at their ends, which are typically subdivided into U3, R, and U5 regions. First strand reverse transcription is initiated at the primer binding site (pbs). There are two polypurine tracts (ppt) for the initiation of second strand synthesis. RNA transcription initiates at the internal promoter (IP) or in the 5′ LTR. The canonical* gag, pol, *end* env *genes are indicated. Only one cleavage site for the viral protease has been identified in* gag *(arrow). The Pol precursor protein is expressed from a spliced mRNA and is also cleaved once between protease-reverse transcriptase and integrase. The Env precursor bears two cleavage sites for cellular proteases, one between the leader peptide (LP) and the surface (SU) domain and one between the latter and the transmembrane (TM) subunit. In addition, there are two further open reading frames (ORFs) downstream of* env. *ORF-1 gives rise to the Tas protein, which* trans*-activates transcription from the IP and the LTR promoter. Orf-1 transcripts are often spliced in the 5′ untranslated region (UTR) and can be generated from the IP or the 5′ LTR. This depends on the viral isolate. ORF-2 is expressed from a multispliced mRNA and gives rise to the Bet protein, which is highly expressed in infected cells, but of unknown function. Bet transcripts can also start from the IP or the main 5′ promoter. An Env–Bet fusion-protein is generated from the env mRNA that also uses the splice sites in the 5′ UTR of IP transcripts and splice sites in ORF-1 which lead to authentic Bet protein. These splicing events lead to an Env–ORF-2 fusion-protein in FFV. The function of Env–Bet (or Env–ORF-2) is ill-defined. The ΔTas transcript is of pregenomic length except for the small ORF-1 intron that has been spliced out. The ΔTas genome is transactivator-negative and helper virus-dependent (see text for details).*

Additional transcripts can be found in some FVs. Spliced tas and bet mRNAs originating in the 5′ LTR have been described for PFV, but not for FFV (Muranyi and Flügel 1991; Bodem et al. 1998a). The use of the *env* gene-located splice sites described above can give rise to a PFV Env-Bet fusion protein (Figure 3) from which the part of env coding for the membrane-spanning region of TM has been spliced out (Giron et al. 1998; Lindemann and Rethwilm 1998), or to an Env–ORF-2 fusion protein in FFV (Bodem et al. 1998a).

Aside from the (pre-)genomic transcript, a further transcript of almost (pre-)genomic length exists, from which only the small intron in the *tas* gene has been spliced out (Saïb et al. 1993). After reverse transcription this RNA leads to ΔTas virus (Saïb et al. 1993) which requires a helper virus for replication (see below).

Additional structural nucleic acid features include the primer binding side (pbs) 3′ of the 5′ LTR, which is specific for the t-RNA lysine[1,2] (Maurer et al. 1988), a dimer linkage site (Erlwein et al. 1997; Cain et al. 2001), the polypurine tract (ppt) 5′ of the 3′ LTR, and an internal stretch of purine-rich sequences which is located in the *pol* gene (Kupiec et al. 1988; Tobaly-Tapiero et al. 1991). The functional significance of this central ppt has not been completely determined yet, however, it is believed to have analogous functions to the ppt in HIV (Charneau and Clavel 1991; Charneau et al. 1992). Furthermore, RNA sequences involved in expression of structural proteins and in packaging the (pre-)genomic

transcript and the Pol protein have been identified (Erlwein et al. 1998; Heinkelein et al. 1998, 2000b; Wu et al. 1998; Park and Mergia 2000; Russell et al. 2001; Heinkelein et al. 2002b). Full functional characterization of these sequences has not yet been carried out.

Antigens and function of individual proteins

CORE ANTIGEN (GAG)

Cleavage of the Gag precursor into matrix, capsid, and nucleocapsid subunits is a feature that is conserved among *Orthoretrovirinae* and is responsible for the maturation of the viruses. The process which can be viewed as condensation of the capsid after budding (Swanstrom and Wills 1997), does not occur in FVs (Figure 2). Instead, only a small peptide is chopped of the C-terminus of FV Gag by the viral protease. This cleavage is essential for virus replication (Enssle et al. 1997; Zemba et al. 1998) and capsids consisting only of the precursor tend not to close and to show an irregular morphology (Konvalinka et al. 1995; Fischer et al. 1998).

Viral capsids serve two antagonistic roles: on the one hand they must be stable enough to protect the nucleic acid from the hostile environment and, on the other, they must easily free this nucleic acid once uptake into a susceptible cell has occurred. Orthoretroviruses have solved this problem by using protease-mediated defined cleavages of their Gag proteins, which prepare the capsids for disassembly (Wills and Craven 1991; Boulanger and Jones 1996; Kräusslich and Welker 1996; Swanstrom and Wills 1997). Therefore, the question arises how spumaretroviruses meet this challenge. In one possible scenario, disassembly of capsids occurs by FV protease-mediated cleavages of Gag early following the viral uptake (Giron et al. 1997). The identification of further Gag cleavage sites in addition to the C-terminal p3 cleavage site by in vitro PR assays and the vulnerability of the virus by mutagenesis of these sites is consistent with this hypothesis (Pfrepper et al. 1999). However, in the respective study, other possible alterations on Gag morphogenesis have not been excluded. Furthermore, recent evidence indicates that the FV capsid structure is maintained in the first phase after infection (Petit et al. 2003).

FV Gag proteins also lack other conserved sequence motifs, such as the major homology region, or the nucleic acid-binding cysteine-histidine-boxes (Wills and Craven 1991; Swanstrom and Wills 1997). Instead, PFV Gag harbors three so-called glycine–arginine-rich (GR) boxes at the C terminus (Schliephake and Rethwilm 1994). The first of these boxes binds with equal affinity to RNA and DNA (Yu et al. 1996b), the second box harbors a nuclear localization signal which is responsible for primate FV Gag proteins being transiently transported into the nucleus of infected cells (Figure 1) (Schliephake and Rethwilm 1994), while no function has been assigned to the third box. Nuclear localization of Gag, however, does not seem to be essential for FV cell culture replication (Yu et al. 1996b). In sharp contrast to the lentiviruses FV Gag proteins are much less well conserved compared to Pol and Env proteins (Figure 4). It is, therefore, not surprising that even the GR-boxes of primate FV are not conserved in the equine, bovine, and feline isolates. Furthermore, FFV Gag has been shown not to have a nuclear phase (Bodem et al. 1998b).

FV capsids assemble in the cytoplasma (Baldwin and Linial 1998; Fischer et al. 1998). A coiled-coil domain in the N-terminal half of FV Gag has been identified as being required for Gag–Gag interactions (Tobaly-Tapiero et al. 2001). While orthoretroviral Gag proteins bear all the information required for particle budding from the plasma membrane (Wills and Craven 1991; Boulanger and Jones 1996), this is not the case in FVs where Gag depends on the presence of autologous Env to export the particles, either from the plasma membrane or from the endoplasmic reticulum (ER) (Baldwin and Linial 1998; Fischer et al. 1998; Pietschmann et al. 1999). However, the addition of a heterologous plasma membrane-targeting signal to the FV Gag N-terminus, together with the change of an arginine at position 50 to alanine, leads to Env-independent budding of Gag (Eastman and Linial 2001). The mutation of an arginine in a similar position of the *gag* gene of Mason–Pfizer virus, an orthoretrovirus that, like FVs, shows cytoplasmic capsid assembly (D-type morphology), has been reported previously to redirect capsid assembly to the plasma membrane (C-type morphology) (Rhee and Hunter 1990). Thus, like orthoretrovirus capsids, the FV Gag proteins show some flexibility in the intracellular location of particle assembly.

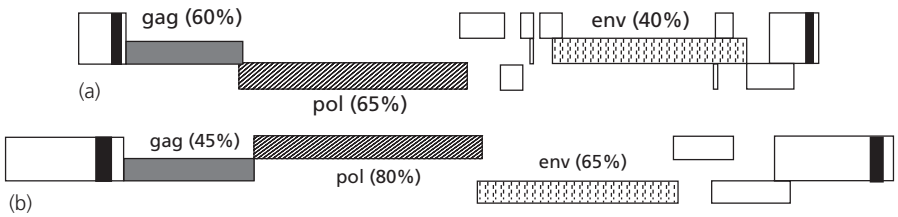

Figure 4 *Amino acids conservation among primate lentiviruses* **(a)** *and foamy viruses* **(b)**. *While in lentiviruses the Env protein is the most divergent structural viral protein, in primate FVs Gag is much more heterogenous than Env.*

RT ANTIGENS (POL)

FV Pol protein uses its own ATG start codon for expression from a spliced mRNA (Bodem et al. 1996; Jordan et al. 1996; Löchelt and Flügel 1996; Yu et al. 1996a). Sequences specifying protease, reverse transcriptase proper, RNase H, and integrase can be clearly identified on the basis of the conserved motifs of the active centers of the respective enzymes (Kögel et al. 1995a, 1995b). Unusually, the FV protease is not cleaved from the RT/RN (Pfrepper et al. 1998). The only consistent cleavage occurs between PR/RT/RN and IN (Pfrepper et al. 1998). A minor cleavage site has also been described between RT and RN of PFV (Pfrepper et al. 1998). Another peculiarity has been detected in the FFV PR. While the active center of retroviral proteases bears the strictly conserved DS/TG motif, FFV contains in this position a DSQ (Winkler et al. 1997a; Flügel and Pfrepper 2003). Nonetheless, the FFV PR containing this amino acid is enzymatically active (Flügel and Pfrepper 2003). The PFV Pol protein precursor, as well as its PR/RT/RN and IN subunits, were reported to be nuclear proteins when cells were transfected with eucaryotic expression constructs of the respective ORFs (Imrich et al. 2000). The functional significances of these findings have not been elucidated.

Since the Pol precursor protein of FVs is expressed independently from the Gag protein, FVs must have found a way of Pol incorporation into the particle in the absence of a Gag fusion partner. Interestingly, the presence of (pre-)genomic RNA is required in order to assemble Pol into viral capsids (Heinkelein et al. 2002b). In contrast to the hepadnaviruses, this RNA is incorporated in the absence of Pol into FV capsids (Baldwin and Linial 1998, 1999). Therefore, it is highly likely that in FVs (pre-)genomic RNA serves as a bridging molecule, which interacts with Gag on the one side and Pol on the other and, thereby, facilitates completion of particle assembly. The identification of separate sequences in the (pre-)genomic RNA for the interaction with Gag and Pol is consistent with this hypothesis (K. Peters, M. Heinkelein, and A. Rethwilm, unpublished results).

FV reverse transcriptase appears to be much more processive than orthoretroviral RT (Rinke et al. 2002). This is probably a prerequisite for FV reverse transcription prior to budding (see below).

ENVELOPE ANTIGENS (ENV)

The glycoproteins of FVs are another example of the highly divergent replication pathway that these viruses have developed. All orthoretroviral Env proteins are synthesized as precursors that are cleaved by cellular proteases into SU and TM subdomains which are part of the mature virion. TM is an MHC class I transmembrane protein (Einfeld 1996; Hunter 1997). It is anchored in the viral membrane and makes contacts to the SU subdomain (Swanstrom and Wills 1997). In murine leukaemia virus (MLV) and in Mason–Pfizer monkey virus, small peptides are cleaved from the cytoplasmic tail of TM to activate its fusogenic activity (Green et al. 1981; Henderson et al. 1984; Brody et al. 1992, 1994; Sommerfelt et al. 1992; Rein et al. 1994). However, this does not change the general organization of the glycoprotein complex. The orthoretroviral Env precursor bears a signal peptide sequence at the N-terminus that is responsible for ER translocation. This rather short sequence is cleaved from the remainder of the protein in the ER and degraded or further processed (Martoglio et al. 1997; Swanstrom and Wills 1997).

The signal or leader peptide of FV Env proteins is rather long and is also cleaved from the rest of the protein, however, in striking contrast to the situation in orthoretroviruses, the LP remains associated with the virion (Lindemann et al. 2001). Thus, FVs posses three glycosylated Env proteins (LP, SU, and TM), and two of these cross the viral membrane, LP at the N terminus and TM at the C terminus. Being initially synthesized as an MHC class III membrane protein (precursor), the mature Env consists of an MHC class II membrane protein (LP), the extraviral SU, and an MHC class I membrane protein (TM) (Lindemann et al. 2001). Furthermore, the LP points with its N-terminus to the viral capsid and makes contact to Gag (Lindemann et al. 2001; Wilk et al. 2001; Geiselhart et al. 2003). This is the reason for the specificity of the FV capsid–glycoprotein interaction and the molecular basis of the inability to pseudotype unmodified FV capsids with heterologous envelopes (Pietschmann et al. 1999). The mutation of only one conserved tryptophane residue in the cytoplasmic part of LP abrogates infectivity and the ability of Env to interact with Gag (Lindemann et al. 2001; Wilk et al. 2001), although the specific molecular way in which this interaction takes place is not yet known. Biophysical experiments point to contacts of LP with the Gag N terminus, which is believed to form a layer underneath the viral membrane akin to the matrix protein of orthoretrovirus Gag proteins (Wilk et al. 2001).

Not only is Env required to export FV capsids, Gag protein appears similarly to stimulate the quantitative release of Env from the plasma membrane (Pietschmann et al. 2000). The equine virus may represent an exception, because it was reported to bud exclusively from the plasma membrane (Tobaly-Tapiero et al. 2000; Lecellier et al. 2002a), while the other known FVs preferentially bud from intracellular membranes. Except in the case of EFV, an ER retrieval signal has been identified in the cytoplasmic tail of all FV TM proteins (Goepfert et al. 1995; Tobaly-Tapiero et al. 2000). This may, in the absence of Gag, hold back Env in intracellular compartments (Goepfert et al. 1997). However, additional elements in the membrane-spanning region of TM and the FV LP are at least equally important for this

retrieval (Pietschmann et al. 2000; Lindemann et al. 2001).

Another interesting feature of FV Env is the ability to self-associate and form subviral particles (SVP). Such SVPs arise by self aggregation of hepatitis B virus (HBV) surface protein in HBV infection in numbers exceeding the infectious virus and are believed to deflect the anti-HBV immune response (Gerlich 1991). While the SVPs of HBV are abundantly shed from infected cells, the PFV SVPs are, probably due to the retention of Env in cytoplasmic compartments, less abundant (Shaw et al. 2003).

NONSTRUCTURAL PROTEINS

Tas

The FV Tas proteins are approximately 209–300 amino acids in length, depending on the specific virus isolate (Rethwilm 1995; Löchelt 2003). They act as transactivators of gene expression from the two FV promoters and are required for virus replication (Baunach et al. 1993; Rethwilm 1995; Löchelt 2003). Tas augments gene expression by direct binding to DNA motifs in the IP and the U3 region of the LTR (He et al. 1996; Zou and Luciw 1996; Kang et al. 1998; Kang and Cullen 1998; Bodem et al. 2004). Tas binds to the IP with higher affinity than to the U3 promoter and to the U3 promoter with higher avidity than to the IP (Kang et al. 1998; Löchelt 2003). Between FV promoters and Tas proteins from different species there is only little conservation and almost no cross-transactivation (Löchelt 2003; Bodem et al. 2004). Tas proteins have been dissected into several subdomains: at the N terminus a region is shared with the Bet protein. The variable length of this region is responsible for the length variability of Tas proteins from different species (Löchelt 2003). The promoter-targeting domain that shows a low degree of conservation between different Tas proteins and is responsible for recognition of the DNA target sites follows the domain shared with Bet (Löchelt 2003). Between this region and the C-terminal activation domain is located the nuclear localization signal (NLS), consisting of an accumulation of basic residues (Keller et al. 1991; Chang et al. 1995; Rethwilm 1995; Bodem et al. 1998b). The approximately 30 amino acids activation domain stimulates gene expression in a wide variety of lower and higher eukaryotic cells when targeted to a heterologous promoter via an unrelated DNA-binding motif (He et al. 1993).

The DNA-binding regions and the activation domains show no homology to known motifs. However, genetic evidence indicates that FV Tas proteins belong to the acidic class of transcriptional activators (Blair et al. 1994). FV Tas proteins are believed to interact with conserved components of the transcriptional machinery. In yeast cells the ADA2 transcriptional adapter molecule has been identified and shown to be required for activation by the PFV Tas activation domain (Blair et al. 1994). FV Tas proteins can also activate gene expression by binding to recognition sequences located elsewhere in the FV or in the host cellular genome (Campbell et al. 1996; Wagner et al. 2000; Kido et al. 2002).

Since the elements in the U3 region of the LTR, which are responsive to Tas, do not completely match with the DNA-binding sites (Mergia et al. 1992; Erlwein and Rethwilm 1993; Lee et al. 1993; Renne et al. 1993), it is likely that mechanisms in addition to direct binding of Tas are involved in the transcriptional regulation of FV promoters (He et al. 1996). Possibly, Tas has DNA-binding and protein–protein interaction capabilities. The cellular promyelocytic leukaemia protein (PML) complexes with and strongly inhibits PFV Tas function (Regad et al. 2001). PML is induced by IFN and this may explain the IFN-responsiveness of FVs. However, it was shown by others that on a cellular level PML is not involved in the establishment of viral latency (Meiering and Linial 2003). Viral latency appears to be the dominant form of persistence in the infected host (Falcone et al. 2003). Nuclear factor I (NFI) was identified as another element to repress FV gene expression (Kido et al. 2003). Its contribution to the state of viral latency remains to be determined.

Bet

Because Bet is a protein derived from an mRNA spliced from ORF-1 into ORF-2 (Figure 3), only one (Tas or Bet) of the two accessory FV proteins can be expressed at a time. In lytically infected cells there appears to be a strong preference to generate the Bet protein, while Tas is relatively rare (Baunach et al. 1993). The function of PFV Bet remains elusive, since the part of Bet (ORF-2) that is nonoverlapping with Tas (ORF-1) or with other sequences, such as the downstream ppt and 3′ LTR motifs required for integration, can be deleted or functionally ablated from infectious plasmids without adversely affecting their replication competence (Baunach et al. 1993; Yu and Linial 1993; Schmidt and Rethwilm 1995). Bet is mainly cytoplasmically located, however, a small portion of PFV Bet has been reported to enter the nucleus, as well as being shed from infected cells and taken up by other cells (Lecellier et al. 2002b). In FFV, Bet is required for the release of FFV particles in a cell-type dependent manner (Alke et al. 2001).

Using a reactivation system from viral latency by the addition of the phorbol ester PMA, it was shown that Bet counteracts IP activity (Meiering and Linial 2002). As outlined above, IP activity is the start of a series of events leading to progeny virus. It is possible that in latent infection the relative expression levels of Tas and Bet, even more than in lytic infection, shift in favour of Bet. Thus, the generation of Tas versus Bet is supposed to be the molecular switch that controls the outcome of an infection: lytic (little expression of

Tas, major expression of Bet) versus latent (no expression of Tas, exclusive expression of Bet) (Meiering and Linial 2002). However, the mechanisms controlling this switch remain to be determined. In addition, it is likely that Bet serves additional functions than controlling viral latency.

Interestingly, the overexpression of PFV Bet renders cells resistant to superinfection by the autologous virus (Saïb et al. 1995; Bock et al. 1998). Once delivered as plasmid DNA into the cells, establishment of the resistant phenotype was found to be unrelated to down-regulation of viral uptake or the activity of viral promoters (Bock et al. 1998). It was, therefore, concluded that the block in replication most likely occurred between virus entry and provirus establishment (Bock et al. 1998). Any functional consequences of this for the viral replication cycle have not yet been analyzed.

Overview of the FV replication strategy

FVs appear to have acquired a unique replication strategy that has adopted aspects of the orthoretroviral and the hepadnaviral replication pathways (Nassal and Schaller 1993; Linial 1999; Lecellier and Saïb 2000; Rethwilm 2003b). An overview is presented in Figure 5. Although at first sight the FV genome organization looks like a typical complex retrovirus, the unique features cover any aspect of the replication strategy and the functions of individual proteins (Rethwilm 2003b). From provirus integration (Enssle et al. 1999; Juretzek et al. 2004), regulation of gene expression (Löchelt 2003), packaging of (pre-)genomic RNA and Pol proteins (Heinkelein et al. 2000b; Heinkelein et al. 2002b), capsid assembly (Linial and Eastman 2003), and cleavage by the viral protease (Flügel and Pfrepper 2003) to budding and Gag–Env interaction (Lindemann and Goepfert 2003), FV replication deviates from what are believed to be the standard rules of retrovirology (Vogt 1997).

Most striking is the generation of infectious full-length cDNA late in the replication cycle before budding of the particle (Yu et al. 1996a, 1999; Moebes et al. 1997; Roy et al. 2003). Aside from exiting the infected cell, this DNA can also recycle to the nucleus and integrate, resulting in the delivery of additional proviruses, at least in the absence of FV glycoprotein (Heinkelein et al. 2000a, 2003) (Figure 5). While this phenomenon is reminiscent of the life cycle of retrotransposons (Boeke and Stoye 1997), its significance for the FV replication cycle remains to be determined. The extent to which cDNA synthesis in the virus-producing cell is complete may depend on the actual cell type, which can explain why reverse transcription can also be detected early in the replication cycle (Delelis et al. 2003).

In addition, FVs generate a reverse-transcribed defective cDNA (the ΔTas genome in Figure 3) to an extent that is likely to affect biological function (Saïb et al. 1993). The ΔTas is generated from an almost pregenomic length RNA, from which ORF-1 intron, normally used to generate Bet mRNA, has been spliced out (Figure 3). Thus, ΔTas are replication-defected. Depending on the number of ΔTas proviruses, which can express some Bet protein, cells become resistant to the infection by wildtype virus (Saïb et al. 1995). However, the exact relationship between wild-type and ΔTas genome, and whether this type of interference is taking place in vivo, is not known.

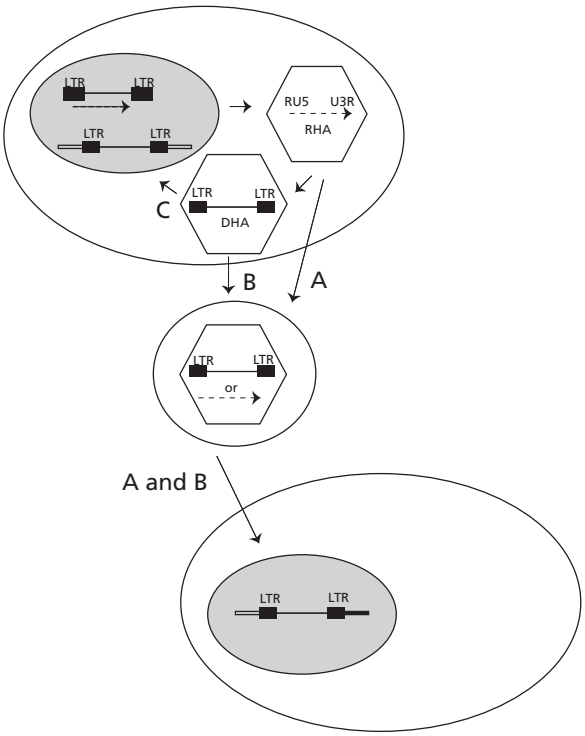

Figure 5 *Principal retroviral replication strategies. Orthoretroviruses make use of pathway A regardless of intracellular capsid assembly or assembly at the plasma membrane. Obligatory FV capsid assemble occurs in the cytoplasm. Furthermore, reverse transcription of the pregenomic RNA takes place at this stage and cDNA is exported (pathway B) or can recycle to the nucleus and integrate into the host cell genome to give rise to additional proviruses (pathway C). (Modified from Heinkelein et al. 2000a)*

While orthoretroviruses are RNA viruses replicating through a DNA intermediate, where the step of reverse transcription occurs early in the replication cycle, FVs, like hepadnaviruses, are DNA viruses, which replicate through an RNA intermediate with a reverse transcription step late in the replication cycle. Unlike the hepadnaviruses, they require integration into the host cell genome for replication, similar to orthoretroviruses (Enssle et al. 1999; Meiering et al. 2000). This raises the question as to whether FVs may represent a functional or evolutionary link between these reverse transcribing virus families (Flint et al. 2004).

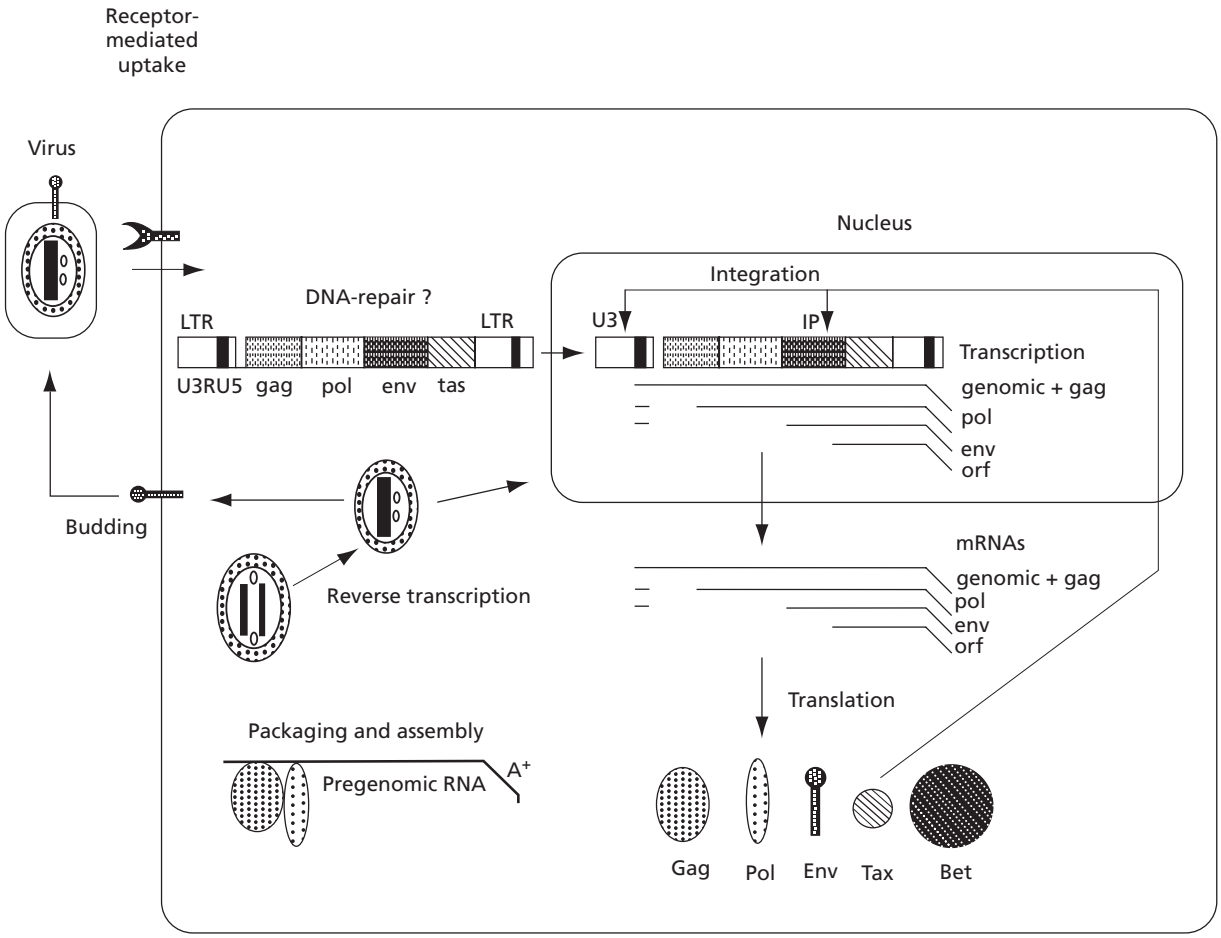

Figure 6 *Overview of the FV replication strategy. (Modified from Rethwilm 2003a)*

FV VECTORS

FV vectors based on PFV, SFV-1, and FFV have been developed over the last years (Mergia and Heinkelein 2003). Some of the vectors were replication-competent, taking advantage of the generally nonpathogenic nature of FV infection (Schmidt and Rethwilm 1995; Schwantes et al. 2002). These vectors may be used to deliver, for instance, suicide genes or genes for immunogenic proteins in vivo (Nestler et al. 1997; Schwantes et al. 2003). However, since the virus has no advantage from the additional genetic burden, these genes are usually lost quickly during replication, at least in vivo (Nestler et al. 1997; Schwantes et al. 2003).

More promising for future applications are replication-incompetent vectors based on FVs. There are several theoretical advantages of using FV vectors than MLV-derived vectors, which are the most widely and most successful retroviral vectors currently in use in clinical trials (Cavazzana-Calvo et al. 2004). First of all, the parental virus is nonpathogenic. As a consequence gene therapy with FV vectors should be safe, even in the unlikely event of generating replication-competent vector-derived retroviruses by recombination (Schenk et al. 1999; Bastone and Löchelt 2004). Furthermore, by separation of the packaging plasmids in three instead of two expression units (orthoretroviruses generate a Gag/Pol fusion protein) a further safety profile can be added to FV vectors (Heinkelein et al. 2002a; Trobridge et al. 2002a). Secondly, the genome of FVs is larger than that of MLV, possibly enabling the packaging of larger fragments of foreign DNA (Heinkelein et al. 2002a; Park et al. 2002; Trobridge et al. 2002a). Thirdly, FV can be concentrated without significant loss of infectivity, e.g. by centrifugation (Hill et al. 1999; Trobridge et al. 2002b). The receptor for FVs, although not currently known, is widespread, which allows targeting of a wide variety of cells (Mergia et al. 1996; Hill et al. 1999; Lindemann et al. 2000).

However, FVs do not infect resting cells (Bieniasz et al. 1995b; Trobridge and Russell 2004). The incoming capsid appears to be transported into the vicinity of the nucleus (Saïb et al. 1997b; Petit et al. 2003), but similar to MLV FVs appear to require the breakdown of the nuclear membrane for integration and subsequent gene expression (Hajihosseini et al. 1993). The difference from MLV is that, since FV reverse transcription has already taken place in the virus- or vector-producing

cell, the form of the nucleic acid that is delivered into the target cell consists of DNA instead of RNA. Reverse transcription can be regarded as the most vulnerable step in retrovirus replication, and due to the greater stability of double-stranded DNA compared to single-stranded RNA, FVs may be ideal to target rarely cycling cells, such as hematopoietic progenitors.

In a variety of seminal experiments it has been shown that FV vectors can target CD34 antigen-positive human hematopoietic progenitors of different sources that are able to repopulate sublethally irradiated NOD/SCID mice with an efficiency comparable to vectors derived from lentiviruses and much superior to MLV vectors, provided that the target cells were not prestimulated (Hirata et al. 1996; Josephson et al. 2002; Leurs et al. 2003; Josephson et al. 2004). The transduction of hematopoietic stem cells was demonstrated by analysis of transgene expression and vector integration site determination in lymphoid and myeloid compartments after long-term engraftment (Josephson et al. 2002; Leurs et al. 2003; Josephson et al. 2004).

However, it must be noted that packaging cells for FV vectors, which would allow to better control for the quality of the vector preparations by standard means, are not yet available (Mergia and Heinkelein 2003). Furthermore, FV capsids do not currently allow the efficient pseudotyping by heterologous glycoproteins and the FV envelope glycoprotein complex exhibits considerable cell toxicity, which makes the handling of FV vectors painstaking. It remains to be seen whether the development of adenovirus–foamy virus hybrid vectors, which create a form of in vivo packaging cell line can overcome this problem (Picard-Maureau et al. 2004; Russell et al. 2004) or whether batches of FV vectors will have to be produced by the repeated transient transfection of cells.

Furthermore, the packaging signal on the (pre-)genomic RNA and the mechanism of RNA, as well as Pol protein packaging have not yet been completely resolved (Heinkelein et al. 2000b, 2002b). It is known that at least two regions on the RNA are required for efficient packaging into particles (Erlwein et al. 1998; Heinkelein et al. 1998; Wu et al. 1998; Heinkelein et al. 2000b; Russell et al. 2001). One element resides in the 5′ leader region and extends into the *gag* gene, while the other element is located in the 3′ *pol* gene region. Thus, there is a need for a better understanding of the biochemical basis of RNA and Pol protein packaging and the mechanism of FV particle assembly to further improve current vectors and packaging constructs.

EPIDEMIOLOGY AND LABORATORY DIAGNOSIS

FV are highly prevalent in many monkey species from the Old and the New World (Hooks and Gibbs 1975; Hooks and Detrick-Hooks 1981; Swack 1981; Meiering and Linial 2001; Falcone et al. 2003). Of these, only Old World FVs are characterized in greater detail. The rate of infection in the wild can be as high as 30 percent or above (Hooks and Gibbs 1975; Swack 1981; Meiering and Linial 2001). In captivity, infection rates may be anywhere between 70 percent and close to 100 percent (Hooks and Gibbs 1975; Hooks and Detrick-Hooks 1981; Swack 1981; Rösener et al. 1996; Meiering and Linial 2001; Falcone et al. 2003). Only a weak cross-neutralization was reported for SFVs originating from different species. Trans-species transmissions in captive monkeys and even dual infections with two different SFVs has been described (Hooks et al. 1972; Hooks and Gibbs 1975; Swack 1981; Meiering and Linial 2001).

As in monkeys, the FV prevalence in cats increases with age to an incidence of over 70–80 percent in domestic or feral animals over the age of nine (Bandecchi et al. 1992). Social contact is suspected to be the most likely mode of FFV transmission (Bandecchi et al. 1992). Two FFV serotypes which do not cross-neutralize and which have substantial differences in the env *SU* genes are documented (Winkler et al. 1998; Zemba et al. 2000). Because the Gag sequences are conserved, diagnostic tests rely on the detection of antibodies to this protein (Winkler et al. 1997b).

As already mentioned above, so far there is no indication of a naturally circulating human FV. However, since the detection of an SFV infection in a monkey caretaker (Schweizer et al. 1997), more extensive investigations led by the Centers for Disease Control and Prevention (CDC) in Atlanta, GA, USA on occupationally acquired FV infections were carried out (Heneine et al. 1998; Switzer et al. 2004). Altogether, approximately 5 percent of animal caretakers or laboratory personnel handling infected material were found to be sero- and PCR-positive (Brooks et al. 2002; Heneine et al. 2003; Switzer et al. 2004). Thus, the risk of occupational acquisition of an SFV infection appears to be much higher than that of contracting an infection with other nonhuman primate viruses (Brooks et al. 2002; Heneine et al. 2003; Switzer et al. 2004). No risk of attracting an FFV infection was found for veterinarians handling FV-infected cats (Butera et al. 2000).

Another population potentially at risk of FV infection are monkey hunters in the African bush. While an earlier investigation found no evidence of infection in a rather small sample (Goepfert et al. 1996), a more recent study identified 1 percent positives when screening over 1 000 human sera (Wolfe et al. 2004). Samples positive for FV antibodies were confirmed by nucleic acid detection and sequencing (Wolfe et al. 2004). Besides differences in the sample size, it should be noted that the methods of screening were also different in the two studies (Goepfert et al. 1996; Wolfe et al. 2004).

The method of choice to detect FV infections in humans consists of screening sera for antibody against a

cocktail of antigens derived from the SFVs potentially being transmitted. An immunoblot coated with antigen derived from two SFVs (SFVagm and SFVcpz) has beenshown to react with serum samples, which are positive for a wide variety of different SFVs (Hussain et al. 2003). Antibody response in an immunoblot against the Gag antigens usually indicates positivity (Hahn et al. 1994; Hussain et al. 2003). The detection of an antibody response against the nonstructural Bet protein (Figure 2) corroborates serological diagnosis of infection (Hahn et al. 1994). Antiglycoprotein antibodies are only detected reliably by radio-immunoprecipitation (Netzer et al. 1990). In any case positive results in antibody tests should be confirmed by PCR diagnosis using primers from regions conserved in the FV genome, such as from the integrase gene (Schweizer and Neumann-Haefelin 1995; Khan et al. 1999). When the infecting virus is known and in culture, indirect immunofluorescence also reliably detect infection (Neumann-Haefelin et al. 1983). In this case a strong nuclear fluorescence should be visible, at least in some cells when dealing with FVs of primate origin (Figure 1).

Virus isolation can be done relatively easily from throat swabs of infected monkeys or cats using a wide variety of target cells, but preferably fibroblasts, to monitor the development of CPE (Hooks and Gibbs 1975; Swack 1981). Indicator cell lines bearing the *lacZ* gene under the control of different FV LTRs have been established for easy and quick monitoring of infection (Yu and Linial 1993; Bock et al. 1998; Roy et al. 2003). However, such cell lines are not available for all FVs. Virus isolation from humans requires particular conditions, such as the isolation from PBLs and potentially the addition of anti-interferon (Heneine et al. 1998; Falcone et al. 1999b).

The methods to diagnose FV infections are not generally in use and in the case of a suspected human SFV infection, one should refer to a more specialized and experienced laboratory. SFV-infected humans should not donate organs, blood or blood products (Allan et al. 1998; Boneva et al. 2002). Whenever possible, such individuals and their close contacts should be followed for the unlikely event of the emergence of a new retrovirus adapted to replicate efficiently in the human host (Peeters et al. 2002).

Zidovudine (AZT) is the only known antiretroviral drug that efficiently blocks FV replication (Rosenblum et al. 2001). In the event of reactivating latent FVs when culturing primary monkey cells, AZT at a concentration of 5–10 μm can be tried in order to block SFV replication.

Infections with foamy viruses are not of medical importance, but the study of their molecular biology has contributed much to our understanding of the ways retroviruses replicate and the use of foamy virus vectors may open a new field in somatic gene therapy.

INTRODUCTION

Since the beginning of the 1980s millions of people have been infected with human immunodeficiency virus (HIV) the causative agent of the acquired immune deficiency syndrome (AIDS), a multi-systemic, deadly, and so far incurable disease. HIV infections remain one of the most devastating diseases that humanity has ever faced. Unfortunately, there is little hope that an effective vaccine will be developed in the near future, nor are there other mechanisms available to stimulate the natural immunity against HIV. Current antiretroviral treatment is based on drugs that target either the viral reverse transcriptase (RT) or the protease (PR) or the viral envelope (gp41). A drawback to these treatments is that with HIV's high rate of mutation and replication, dynamic, drug-resistant mutants are evolving, particularly when anti-retroviral treatment suppresses virus replication to only marginal levels. Cellular genes have much lower mutation rates, and a potential solution to this problem is to target host cellular factors required for HIV replication. These include enzymes and interactive proteins that are essential for replication of HIV in host cells, which can be selectively manipulated without interfering with the vital functions of the organism.

GENOMIC ORGANIZATION AND REPLICATION CYCLE OF HIV

The *Retroviridae*, a family of viruses, which include the *Human immunodeficiency virus type 1* (HIV-1) and *Human immunodeficiency virus type 2* (HIV-2), belong to the gigantic group of eukaryotic retrotransposable elements (for review see Doolittle et al. 1990). Retroviruses are distinguished by their ability to reverse transcribe their RNA genomes into DNA intermediates by using the enzyme RT. The DNA form of the provirus genome is then integrated into a host cell chromosome by action of the viral enzyme integrase (Int). All retroviruses contain at least three major genes that encode the main virion structural components which are each synthesized as three polyproteins that produce either the inner virion interior (Gag, group specific antigen), the viral enzymes (Pol, *pol*ymerase), or the glycoproteins of the virion *env*elope (Env). In addition to virus structural proteins and viral enzymes, some retroviruses code for mostly small proteins with regulatory and auxiliary

functions. While retroviruses share the same fundamental replication cycle and have the same basic genomic organization (e.g. the canonical *gag*, *pol*, and *env* genes) they do vary in the content of additional small regulatory genes and they have evolved different structures of their Gag proteins (for review see Coffin et al. 1997). The retroviral *gag* gene encodes the major structural protein and is entirely sufficient for virus particle formation (for review see Swanstrom and Wills 1997). According to the nomenclature defined by the International Committee on Taxonomy of Viruses (ICTV) convention (Hull 2001), orthoretroviruses contain RNA inside virus particles and are released from the plasma membrane. However, the assembly of orthoretroviruses follows two different strategies: Alpha-, gamma-, delta-, and lentiviruses (ICTV nomenclature) assemble on the inner leaflet of the plasma membrane and are released as immature virions. In contrast, betaretroviruses and spumaviruses first assemble in the cytoplasm to form immature particles that are then transported to the plasma membrane where virus budding occurs.

Viruses of the genus *Lentivirus* including HIV-1, HIV-2, and *Simian immunodeficiency virus* (SIV), replicate preferentially in lymphocytes and in differentiated macrophages and cause long-lasting and mostly incurable chronic diseases. In contrast to gamma-retroviruses (ICTV nomenclature for oncoretroviruses) that require the breakdown of the nuclear membrane during mitosis for viral integration into host-cell chromosomes, lentiviruses are uniquely capable of infecting nondividing cells, preferentially nondividing macrophages and resting T-cells, as is the case for HIV-1 (Lewis and Emerman 1994).

As for other retroviruses, the HIV replication cycle begins with virus attachment and penetration through the plasma membrane. HIV binds to different cell-receptors, among them the differentiation antigen, CD4, acting as primary receptor, as well as different specific chemokine receptors that act as coreceptors after binding to CD4 (for review see Weiss 2002). The first retroviral receptor ever identified was the CD4 receptor on T-cells. It was established as the primary receptor for HIV-1 and HIV-2 and SIVs in 1984 (for review see Bour et al. 1995). However, the CD4 molecule alone is not adequate to allow Env-mediated membrane fusion and virus entry, as certain primary isolates of HIV-1 preferentially replicate in T-cell lines (T-cell-line trophic, 'TCL'-tropic), while others establish productive replication only in macrophage cultures ('M'-trophic). Thus, a second class of HIV receptors was predicted and finally identified as a member of the G protein-coupled seven transmembrane domain receptor superfamily acting as so called 'coreceptors' during HIV entry (for review see Berger et al. 1999). Coreceptors, in general, function as cellular receptors for α- and β-chemokines. Two types of coreceptors arbitrate the disparity in cell-type trophism: the α-chemokine receptor CXCR4 (first described as 'fusin') that is typically present in T-cell lines, and the β-chemokine receptor CCR5 that is present on macrophages. In tissue culture, primary lymphocytes support replication of HIV, irrespective of its trophism. This phenomenon is demonstrated by the fact that cultures of activated peripheral blood mononuclear cells (PBMC) express both coreceptors, CXCR4 and CCR5. Notably, coreceptors symbolize an attractive target for antiretroviral therapy. For example, the genetic heterogeneity in coreceptor alleles determines the vulnerability to HIV infection or disease progression. A well-characterized example is the identification of a truncated form of CCR5 (termed as the 'CCR5/d32' mutation) that in its homozygous form can protect individuals from HIV infection (Deng et al. 1996; Samson et al. 1996).

Following virus entry, the viral RNA genome is transcribed into double-stranded DNA, which as part of the preintegration complex (PIC) is transported to the nucleus where the proviral genome is integrated into chromosomes. Virus entry starts with the so-called 'uncoating' of the virus which is the fusion between the virus and host cell membrane followed by the release of the viral core into the cytoplasm. The virus core comprises all viral components that remain intact after the virus membrane is removed. Following membrane fusion, the reverse transcription complex (RTC) and the PIC is released from the virus core complex. While there is evidence that the CA molecules of the incoming virus are degraded via the ubiquitin proteasome system (UPS) (Schwartz et al. 1998), the three virus proteins Int, the matrix (MA), and the viral protein R (Vpr) molecules together with the provirus genome form the PIC. Although the PIC components comprise various nuclear import signals (for review see Sherman and Greene 2002), it is assumed that additional cellular and viral factors, including a central DNA flap, which is formed during reverse transcription (Zennou et al. 2000), facilitate the import of the PIC into the nucleus. It is worth noting that virus entry involves a number of consecutive and highly organized multistep events that might explain why approximately only one out of a thousand mature HIV-1 particles is capable of establishing a productive infection.

Further postentry events such as the reverse transcription of the viral genome, the nuclear import of the PIC, the integration of proviral DNA, the activation of HIV-1 LTR promoter driven retroviral gene expression, the export, the transport, and the splicing of viral RNA will not be described in detail in this review. Rather, late steps of the HIV-1 replication cycle, such as membrane targeting of Gag and Gag–Pol polyproteins, virus assembly, as well as budding and maturation will be explained in more detail. Following the early steps of the replication cycle and upon activation of integrated provirus, viral RNAs are processed and transported into the cytosol for translation of newly synthesized

structural proteins that assemble at the plasma membrane into budding particles. The Gag polyprotein in HIV-1 and HIV-2 consists of different functional domains that mediate the recognition and binding of viral RNA, the membrane targeting of Gag and Gag–Pol polyproteins, virion assembly, and efficient particle release from the plasma membrane as the final step of virus budding (for review see Kräusslich and Welker 1996; Swanstrom and Wills 1997; Vogt 1997, 2000). The Gag polyprotein is the single viral protein sufficient and strictly required for virus particle assembly and budding, although further viral components such as the genomic RNA, the envelope, and the Gag–Pol precursor proteins are required for production of infectious progeny virions. The processing of the HIV-1 Gag polyprotein Pr55 by the viral PR generates the MA, CA, nucleocapsid (NC), and $p6^{Gag}$ proteins (Swanstrom and Wills 1997). During proteolytic processing of HIV-1 $Pr55^{Gag}$ two spacer peptides, p2 and p1, are also generated. The HIV-1 *pol*-encoded enzymes, PR, RT, and Int are proteolytically released from a large polyprotein precursor, $Pr160^{GagPol}$, the expression of which is the outcome from a rare frameshift event during $Pr55^{Gag}$ translation (for review see Freed 2001). Similar to the Gag proteins, the Env glycoproteins are also synthesized from a polyprotein precursor protein. The resulting surface (SU) gp120 and transmembrane (TM) gp41 glycoproteins are produced by a cellular protease during trafficking of gp160 to the cell membrane. While gp120 harbors the domains that mediates virus binding to CD4 and coreceptors, the gp41 anchors the TM/SU complex in the virus membrane and includes the determinants that regulate fusion between cellular and virus membranes during virus entry. The N-terminus of the extra cellular ecto domain of gp41 harbors the hydrophobic domain, the so called 'fusion peptide' that in concert with two helical motifs of gp41 regulates membrane fusion by formation of a six-helix bundle (Weissenhorn et al. 1997). The highly polymorphic SU protein gp120 is organized into five conserved domains (C1 to C5), and five highly variable domains that in most of the known SU sequences are concentrated near loop structures and are stabilized by disulfide-bond formation.

In general, Gag proteins of different retroviruses exhibit a certain structural and functional similarity: MA mediates the plasma membrane targeting of the Gag polyprotein and lines the inner shell of the mature virus particle, CA regulates assembly of Gag and forms the core shell of the infectious virus, and NC regulates packaging and condensation of the viral genome. In addition to those canonical mature retrovirus proteins, other Gag domains have been described, such as the HIV-1 $p6^{Gag}$ region that directs the incorporation of the regulatory protein Vpr into budding virions. Furthermore, $p6^{Gag}$ harbors the late (L) domain required for efficient virus budding (Göttlinger et al. 1991).

HIV particles bud from the plasma membrane as immature noninfectious viruses consisting predominantly of uncleaved polyproteins. After virus release and in concert with PR activation which is autocatalytically released from the Gag–Pol polyprotein, processing of Gag and Gag–Pol polyproteins into its mature proteins and condensation of the inner core structure occurs resulting in the formation of mature infectious virus. Besides PR and Env, at least two other viral factors are known to promote efficient virus release: the HIV-1 specific accessory protein Vpu (Strebel et al. 1988) and the $p6^{Gag}$ domain (Gottlinger et al. 1991). While Vpu supports virus release by an ion channel activity (Schubert et al. 1996b, c), $p6^{Gag}$ contains the late assembly (L) domain that is required for efficient separation of assembled virions from the cell surface by a yet undefined mechanism that is further detailed below and involves the cellular UPS (Vogt 2000).

ROLE OF CELLULAR FACTORS IN HIV REPLICATION

From entry to release and maturation into infectious progeny virions, each individual step in the HIV replication cycle exploits cellular pathways. As for most other intracellular parasites, the replication of HIV is dependent on interaction with host cell factors, and some of these are specifically incorporated into progeny virions. Among the most abundant cellular proteins, and the first ever found in HIV-1 virions, is the peptidyl-prolyl isomerase (PPIase) cyclophilin A (CypA). This protein is specifically incorporated into HIV-1 virions, but not into virions of other lentiviruses, through an interaction with a proline-rich region that is conserved in the CA of all HIV-1 Gag polyproteins. In particular, Pro-222, which is conserved in the CA region of all HIV-1 Gag polyproteins appears to be important for the interaction of HIV-1 Gag with CypA (for review see Luban 1996). Earlier studies using two-hybrid screens found that HIV-1 Gag binds to most of the known members of the family of CyPs. CyPs were originally described as binding partners of cyclosporin A (CsA), an immunosuppressive cyclic undecapeptide used clinically to prevent allograft rejection. CsA binds with nanomolar affinity to CypA and this complex inhibits calcineurin, a calcium-dependent phosphatase that regulates gene expression of various cytokine genes in activated T-cells (for review see Ivery 2000). CyPs belong to the PPIases, a group of enzymes found in organisms ranging from prokaryotes to humans that catalyze the otherwise relatively slow *cis*/*trans* isomerization of peptidyl–prolyl bonds in vitro. A large body of evidence supports a function of CypA in formation of infectious HIV-1 viruses (for review see Ott 2002; Luban 1996). These studies were based either on mutation within *gag* or the use of competitive CypA inhibitors, such as CsA that

interfere with the CypA–Gag interaction. A more conclusive proof that among the other 14 known members of mammalian CyPs, only CypA plays a functional role in supporting HIV-1 replication, was provided by selective genetic inactivation of the gene encoding CypA in human $CD4^+$ T-cells (Braaten and Luban 2001). The immunosuppressive activity of CsA is not correlated with anti-HIV activity as the non-immunosuppressive derivative NIM811 ([methyl-Ile^4]-cyclosporin) represents an even more potent inhibitor of CypA-mediated HIV-1 replication than the parental CsA. Thus, CsA and related non-immunosuppressive derivatives form an interesting class of drugs that can modulate the interaction of CypA with other proteins.

Recent investigation of the conformational heterogeneity of the proline residues in the N terminus of the HIV-1 accessory protein Vpr suggested a functional interaction between Vpr and a host peptidyl–prolyl *cis/trans* isomerase (PPIase) that might regulate the *cis*/*trans* interconversion of the imidic bond within the conserved proline residues of Vpr in vivo (Bruns et al. 2003). The physical interaction between Vpr and the major host PPIase CypA involves the N-terminal region of Vpr and includes an essential role for proline in position 35 (Zander et al. 2003). The CypA inhibitor CsA, and non-immunosuppressive PPIase inhibitors, such as NIM811 and sanglifehrin A (SFA), block expression of Vpr without affecting pre- or post-translational events, such as transcription, intracellular transport or virus incorporation of Vpr. Similarly to CypA inhibition, Vpr expression is also reduced in HIV-1-infected $CypA^{-/-}$ knock-out T-cells. These studies provide the first evidence that, in addition to the interaction between CypA and HIV-1 capsid occurring during early steps in virus replication, CypA is also important for the de novo synthesis of Vpr and that in the absence of CypA activity, the Vpr-mediated cell cycle arrest is completely lost in HIV-1 infected T-cells.

Another example of host–virus interaction that has recently received much attention is the role of the UPS in virus budding. Efficient detachment of HIV-1 from the cell membrane is strictly dependent on the function of the L domain, a tetrapeptide motif (Pro–Thr/Ser–Ala–Pro (PT/SAP)) that encompass positions seven to ten of the $p6^{Gag}$ protein (for review see Freed 2002; Greene and Peterlin 2002). This process, which involves fission of the virus particle from the cell surface following envelopment and closing of the virus and cellular membrane, is commonly described as virus budding. L domain-deficient mutants of HIV-1 are characterized by late budding arrest, where virions remaining tethered to the plasma membrane by a thin membranous stalk that does not allow complete membrane fission (Göttlinger et al. 1991; Huang et al. 1995). Similar deficiencies in budding were reported for other retroviruses with L domain mutations within Gag polyproteins (for review see Freed 2002). Although the detailed molecular mechanism(s) of how L domains regulate virus budding remain elusive, it is now generally believed that they function as a docking site for the cellular budding apparatus which normally is involved in the endocytotic recycling of cell surface-receptors (for review see Pornillos et al. 2002). Recent work provided an intriguing insight into the mechanism of how virus budding exploits a cellular machinery that is normally involved in vacuolar lysosomal protein sorting and multivesicular body (MVB) biogenesis (Martin-Serrano et al. 2003; von Schwedler et al. 2003). The recruitment of these cellular factors to the virus assembly site is facilitated by the interaction between the PTAP motif of $p6^{Gag}$ and at least one important factor which is the tumor susceptibility gene product (Tsg101) (Garrus et al. 2001; Martin-Serrano et al. 2001; Myers and Allen 2002; VerPlank et al. 2001), an E2 type ubiquitin ligase. Mechanistically, the interaction between Tsg101 and $p6^{Gag}$ is mediated by the N-terminal ubiquitin-binding domain, designated as ubiquitin E2 variant (UEV) sequence of Tsg101 that binds to the PTAP motif of $p6^{Gag}$ in a process that appears to be up-regulated when upstream lysine residues in $p6^{Gag}$ are mono-ubiquitinylated (Garrus et al. 2001; VerPlank et al. 2001; Pornillos et al. 2002; Demirov et al. 2002; Myers and Allen 2002). Recently, two additional binding partners of Tsg101 have been identified in virus budding: ALix/AIP1, a homologue of the yeast class E Vps protein Bro1 that binds to a C-terminal region of HIV-1 $p6^{Gag}$ and is also involved in L-domain function (Strack et al. 2003; von Schwedler et al. 2003), and Hrs, a regulator of MVB formation involving ESCRT recruitment to endosomes (Bache et al. 2003; Pornillos et al. 2002). The normal function of Tsg101 is to target multi-ubiquitinylated proteins into endosomal vesicles followed by MVB formation in a process that is similar to virus budding and involves the budding into the endosomal vesicles (Babst et al. 2000; Katzmann et al. 2002). Topologically, MVB generation is analogous to virus budding, since in both cases cytoplasmic material is extricated and enveloped by cellular membranes. Thus, it appears that HIV recruits the components of the MVB system to the budding machinery that follows two separate and cell-type-specific pathways: in T-cells HIV-1 buds primarily from the cell surface, while in monocytes/macrophages the virus buds into vacuoles of the MVB system (for review see Amara and Littman 2003). In general, there is mounting evidence that HIV-1 assembly and budding exploits the cellular protein sorting and trafficking pathway which itself is regulated by the UPS (for review see Schnell and Hicke 2003).

Another important example of the interaction of HIV-1 with host factors is the relationship between one HIV-1 accessory protein, the virus infectivity factor (Vif), and apolipoprotein B mRNA editing enzyme (APOBEC3G). APOBEC3G, also known as CEM15, is a member of cellular cytidine deaminase-editing enzyme

family that represents another aspect of the so-called 'innate immune system' (for review see Vartanian et al. 2003; Rose et al. 2004; Navarro and Landau 2004; Schrofelbauer et al. 2004). The antiretroviral activity of APOBEC3G is based on its unique capability to hypermutate retroviruses, including HIV-1, with terminal consequences. This innate block in virus replication is counteracted by Vif, which in the virus producer cell binds to APOBEC3G, induces its polyubiquitination, and thus proteasomal degradation (Yu et al. 2003; Mangeat et al. 2003; Harris et al. 2003; Stopak et al. 2003). In this way Vif is precluding the presence of APOBEC3G in progeny virions. As a cytidine deaminase, APOBEC3G induces G to A hypermutation in proviral DNA and, thus, acts as an inhibitor of HIV-1 replication. Mechanistically, APOBEC3G causes changes of C to T in the viral DNA minus strand (Yu et al. 2004). This, in turn, leads to insertion of G in front of C, and A in front of T during DNA plus strand synthesis. The APOBEC3G induced hypermutation can interfere with HIV-1 replication in several ways: it may cause instability of the viral DNA, interference with plus-strand synthesis, or disturb functional gene expression from the proviral genome. The antiretroviral activity of APOBEC3G depends on its encapsidation into progeny virions, which is mediated through interaction with the NC region of the Gag polyprotein and/or with viral and nonviral RNAs (Alce and Popik 2004; Svarovskaia et al. 2004). It can be assumed that virion incorporation of APOBEC3G would maneuver the enzyme into close proximity with the reverse transcription complex.

Another example for host–virus interaction unraveled recently is the interaction between cellular and viral ion channel forming proteins, namely the HIV-1 specific virus protein u (Vpu) and the widely expressed acid-sensitive two-pore K^+ background channel TASK-1 (Hsu et al. 2004, for review see Strebel 2004). Most intriguingly, this interaction may be the consequence of a so called 'molecular piracy' as the N-terminal TM domain of TASK-1 shares striking similarity to that of Vpu. Further, the physical interaction between both TM domains may cause the intercalation of TASK-1 and Vpu into hetero-oligomeric channel complexes and, thus, may explain why TASK-1 suppresses Vpu-mediated virus release while Vpu abolishes TASK-1 channel conductance. This hypothesis was supported by the observation that sole expression of the homology sharing TM domain of TASK-1 can functionally complement the virus release function of Vpu. However, independent of whether Vpu itself acts as an ion channel or instead regulates the activity of a cellular ion channel, it remains an open question how the host cell membrane conductance controls late steps in virus budding.

A further accessory HIV protein was recently shown to interact specifically with a cellular factor: the HIV-1 Nef mimics an integrin receptor signal and thus recruits a nuclear transcription repressor host protein to the cell membrane (Witte et al. 2004). As detailed below, Nef is thought to obstruct T-cell activation by recruiting certain cellular factors into a so far undefined signaling complex to the cell membrane. Specifically, Nef directs the Polycomb Group (PcG) protein Eed, which represents a nuclear repressor of transcription, to the inner leaflet of the cell membrane. The Nef-mediated re-translocation of Eed causes activation of the Tat-dependent HIV-1 LTR promoter driven transcription, most likely because of the depletion of Eed repressor from the nucleus.

Further well-characterized examples for host virus protein interaction are the virus receptors (CD4 and chemokine receptors) which enable virus entry into specific host cells (Berger et al. 1999), the role of the chromatin-remodeling system (Yung et al. 2001) and the HMG I family proteins (Farnet and Bushman 1997) for proviral DNA integration, as well as the requirement of different factors of the endosomal protein trafficking and ubiquitinglation systems for virus release (for review see Perez and Nolan 2001; Vogt 2000; Luban 2001).

MOLECULAR STRUCTURE AND FUNCTION OF HIV REGULATOR PROTEINS

In addition to the canonical retroviral Gag, Pol, and Env proteins common to replication-competent retroviruses, HIV-1 and other lentiviruses encode further small proteins with either essential regulatory (Tat and Rev) or accessory (Vpu, Vif, Nef, and Vpr) functions that serve to accelerate viral replication. While Tat is critical for transcription driven by the HIV-1 LTR promoter, Rev is essential for transport of viral RNAs from the nucleus to the cytoplasm. The function of these essential regulatory HIV genes will not be discussed in this review. The focus will be on the accessory regulator proteins, with special emphasis on Vpr and Vpu. These proteins also called 'auxiliary,' since they are not essential for HIV-1 replication in certain cell lines, yet a growing number of in vivo studies report important roles of these HIV-1 gene products in the pathology and spread of HIV-1 (for review see Cohen et al. 1996).

THE LENTIVIRUS PROTEIN R (VPR)

The highly conserved 96-amino acid, 14-kDa viral protein R (Vpr), has received considerable attention and a number of biological functions have been attributed to its presence in various cellular and extra cellular compartments. The most intensively investigated biological functions of Vpr are those affecting the translocation of the PIC of the incoming virus from the cytoplasm to the nucleus, and the arrest in the G_2 phase of the cell cycle (for a recent comprehensive resume see Sherman and Greene 2002; Sherman et al. 2002; Bukrinsky and Adzhubei 1999). The nuclear targeting

function of Vpr has been associated with HIV-1 infection of terminally differentiated macrophages. Regarding the second function of Vpr, that leads to G_2 cell cycle arrest in HIV-1-infected and/or Vpr-transfected human cells, it was suggested that this activity provides an intracellular milieu conducive to enhanced viral replication by increasing HIV-1 LTR-driven gene expression (Goh et al. 1998). This response has recently been linked with the capacity of Vpr to alter the structure of the nuclear lamina leading to transient, DNA-containing herniations of the nuclear envelope that intermittently rupture (de Noronha et al. 2001). Other studies suggest that the prolonged G_2 arrest induced by Vpr ultimately leads to apoptosis of the infected cell (Poon et al. 1998; Stewart et al. 2000). Conversely, early anti-apoptotic effects of Vpr have been described which are overlayed by its pro-apoptotic effects (Conti et al. 2000). These pro-apoptotic effects of Vpr may result from either effects on the integrity of the nuclear envelope or direct mitochondrial membrane permeabilization (Jacotot et al. 2001), perhaps involving Vpr-mediated formation of ion channels in cellular membranes (Piller et al. 1996).

Vpr is a virion-associated (Paxton et al. 1993), nucleocytoplasmic shuttling (Sherman et al. 2001) regulatory protein that is encoded by (and conserved among) primate lentiviruses, HIV-1, HIV-2, and the SIVs. Although dispensable for growth of HIV-1 in dividing cultured T cells, Vpr appears to play an important role in virus replication in vivo, since deletion of *vpr* and the related *vpx* genes in SIV severely compromises the pathogenic properties in experimentally infected rhesus macaques (Gibbs et al. 1995; Lang et al. 1993). Furthermore, HIV-2 and SIV also encode an additional Vpr-related protein, Vpx, that is believed to function synergistically with Vpr. The Vpr of HIV-1 is reported to exhibit numerous biological activities, including nuclear localization (based on the presence of at least two nuclear localization signals) (Heinzinger et al. 1994; Jenkins et al. 1998; Vodicka et al. 1998; Popov et al., 1998a, b; Sherman et al. 2000, 2001), ion channel formation (Piller et al. 1996), transcriptional activation of HIV-1 and heterologous promoters (Stark and Hay 1998; Felzien et al. 1998), co-activation of the glucocorticoid receptor (Kino et al. 1999), regulation of cell differentiation (Levy et al. 1993), induction of apoptosis (Stewart et al. 1997; Ayyavoo et al. 1997), cell cycle arrest (Levy et al. 1993; Rogel et al. 1995), and transduction through cell membranes (Henklein et al. 2000a). Although significant amounts of Vpr (approximately 0.15-fold molar ratio to viral core proteins, Müller et al. 2000) are packaged into budding HIV-1 particles in a process dependent on Vpr's interaction with the C-terminal $p6^{gag}$ domain of the Gag polyprotein precursor Pr55 (Paxton et al. 1993), the biological role(s) of virion associated Vpr remains to be fully elucidated.

As the biologically relevant activity of the multifunctional Vpr has not yet been clarified, the molecular bases for many of its effects remain elusive. To date, structural studies of the full-length molecule have been hampered by the fact that this protein does not crystallize and the use of NMR techniques is complicated by the strong tendency for Vpr to undergo self-association. In addition, Vpr's structure depends critically on the solution conditions, and an unresolved apparent heterogeneity in the oligomeric composition of the polypeptide has been observed (Wecker et al. 2002; Henklein et al. 2000b). Many structural characterizations of Vpr have shown the important influence of environmental factors and indicate that in vivo folding of Vpr will probably require the presence of structure-stabilizing interacting factors (for review see Bukrinsky and Adzhubei 1999). The secondary structures in Vpr emerging from these analyses suggest the presence of an α-helix–turn–α-helix motif between residues 17 and 48 and an amphipathic α-helix located between amino acids 53–55 and 78–83 (Schüler et al. 1999). These helices are highly conserved and most likely play a key role in self-association and the interaction of Vpr with heterologous proteins (Felzien et al. 1998). Various investigations have shown that the C-terminal domain participates in a number of specific protein–protein and protein–nucleic acid interactions, such as that with NCp7 (de Rocquigny et al. 1997), Tat (Sawaya et al. 1999), RNA (de Rocquigny et al. 2000), and adenine nucleotide translocator of the mitochondrial pore (Jacotot et al. 2000).

STRUCTURE AND FUNCTION OF THE HIV-1 SPECIFIC VPU PROTEIN

The 81 amino acid Vpu is encoded exclusively by HIV-1 (Cohen et al. 1988; Strebel et al. 1988), with one exception, the HIV-1 related isolate SIV_{cpz} that encodes a Vpu-like protein similar in length and predicted structure to the Vpu from HIV-1 isolates (Huet et al. 1990). The HIV-1 specific accessory gene *vpu* encodes an integral membrane phosphoprotein with various biological functions (for review see Bour and Strebel 2003): firstly, in the ER Vpu induces degradation of CD4 in a process involving the ubiquitin-proteasome pathway and CK-2 phosphorylation of its cytoplasmic tail (Vpu_{CYTO}) (Schubert et al. 1998; Margottin et al. 1998). In addition, there is evidence that Vpu interferes with the major histocompatibility complex (MHC) class I antigen presentation and regulates Fas-mediated apoptosis (Kerkau et al. 1997; Komoto et al. 2003; Akari et al. 2001). Secondly, Vpu augments virus release from a post-ER compartment by a cation-selective ion channel activity mediated by its transmembrane anchor (Vpu_{TM}) (Schubert et al., 1996a, and references therein). It was shown previously that Vpu can regulate cationic current when inserted into planar lipid bilayers and in *Xenopus*

oocytes (Schubert et al. 1996a; Coady et al. 1998). However, the detailed mechanism how Vpu as a membrane conductance regulator supports virus budding remains elusive. The new insights are indicating that the virus release function of Vpu_{TM} involves the mutually destructive interaction between Vpu and the K^+ channel TASK-1 (Hsu et al. 2004, for review see Strebel 2004). Thus, it is now conceivable that Vpu affects membrane conductance through tuning the activity of host-cell ion channels (for review see Lamb and Pinto 1997).

Vpu is a class I oligomeric membrane-bound phosphoprotein (Maldarelli et al. 1993) composed of an amphipathic sequence of 81 amino acids comprising a hydrophobic N-terminal membrane anchor proximal to a polar C-terminal cytoplasmic domain. The latter contains a highly conserved region, from Glu-47 to Gly-58 that is present in all analyzed Vpu sequences. It also contains the phosphorylation sites for the casein kinase two (CK-2) that regulate Vpu's function in the ER (Schubert et al. 1994; Schubert and Strebel 1994). The structure and the orientation in the membrane of the N-terminal hydrophobic Vpu_{TM}, which is primarily associated with an ion-channel activity, either by itself (Schubert et al. 1996a) or in the context of full-length Vpu (Ewart et al. 1996), was first analyzed using the synthetic peptide Vpu^{1-39} (Wray et al. 1999). The tertiary U-shaped turn structure identified in solution, however, was inconsistent with the formation of ion-conducting membrane pores in planar lipid bilayers (Schubert et al. 1996a) since it is unlikely to be able to span the bilayer. Consequently, proton-decoupled ^{15}N cross-polarization solid-state NMR spectroscopy has been employed to investigate full-length Vpu and its isolated domains oriented in phospholipid bilayers using either synthetic discretely ^{15}N-labeled amino acids (Wray et al. 1999; Henklein et al. 2000b), or uniformly ^{15}N-labeled recombinant material (Marassi et al. 1999; Ma et al. 2002). Those solid state NMR data were consistent with a transmembrane alignment of a helical polypeptide, implying that the nascent helices in the folded solution structure reassemble to form a linear α-helix involving residues 6 to 29 that lies parallel to the bilayer normal with a tilt angle of $\leqslant 30^\circ$ (Wray et al. 1999) and placing Trp^{22} near to and the Glu^{28}-Tyr-Arg-motif that is know to be important for helix termination, anchorage, and pore selectivity. Most recently, attention has focused on the ion channel activity of Vpu and its similarity to other viral ion channels (for review see Fischer and Sansom 2002). Molecular dynamic investigations of various Vpu fragments, combined with conductance measurements, provide evidence for water-filled five-helix bundles. In summary, the monomeric structure model of Vpu provides details of the topology and positions of secondary structure in the membrane bound state. However, more experimental and theoretical work is required to understand Vpu in its functional form in vivo where it exists as the phosphoprotein in multi-protein complexes involving CD4 and β-TrCp (Margottin et al. 1998), or in homo-oligomeric nonphosphorylated form required for its ion-channel activity in the cell membrane.

THE VIRAL INFECTIVITY FACTOR VIF

The 23-kDa phosphoprotein Vif represents a viral infectivity factor that is highly conserved among all lentiviruses with one exception, the equine infectious anemia virus (EIAV). Vif regulates virus infectivity in a cell-type-dependent fashion. Permissive cells like HeLa, Cos 293T, SupT1, CEM-SS, and Jurkat cells support HIV replication independently of Vif. In contrast, primary lymphocytes, macrophages, and certain cell lines that might express a specific cellular Vif interacting factor require Vif for production of fully infectious viruses (Strebel et al. 1987; Simon et al. 1998).

Until recently, the mechanism of how Vif supports formation of infectious virions was enigmatic. Contemporary findings, detailed above, support the intriguing hypothesis that at least one main function of Vif is to neutralize a natural host defense mechanism. This novel innate anti-HIV defense mechanism was recently revealed as the cellular cytidine deaminase APOBEC3G, which together with Vif is encapsidated into progeny virions (for review see Navarro and Landau 2004). Intriguing was the long known fact that Vif can act in *trans* when it is expressed in the virus producer, but not in the target cell, indicating that Vif must be situated at the virus assembly site (von Schwedler 1993). Consistent with this is the fact that relatively low levels of Vif molecules are detected in mature HIV-1 virions, yet its encapsidation is increased when unprocessed Gag or certain Gag mutants are expressed (Sova et al. 2001). Heterokaryon analysis of fusions between permissive and nonpermissive cells revealed that nonpermissive cells must contain a so far unknown, naturally occurring antiviral factor that is neutralized by Vif of the incoming virus (Simon et al. 1998a). This model of a post-entry function for Vif is further supported by the observation that Vif from diverse lentiviruses function in a species specific mode (Simon et al. 1998b). Several hypothesis have been put forward to explain the mechanism of Vif function: the activity of Vif might regulate reverse transcription and proviral DNA synthesis (Dornadula et al. 2000), Vif can support the formation of stable virus cores (Ohagen and Gabuzda 2000), or Vif might bind to viral RNA in order to support post-entry steps of virus replication (Khan et al. 2001). The discovery of the APOBEC3G–Vif interaction provides at least some explanation for these previous observations (Navarro and Landau 2004).

THE MULTIFUNCTIONAL NEF PROTEIN

Originally, the 27 kDa N-terminal myristoylated membrane-associated phosphoprotein Nef was described as a 'negative factor' that suppresses the HIV-LTR promoter activity (for review see Freed 2001; Frankel 1998; Steffens and Hope 2001; Marsh 1999). As one of the most intensively investigated HIV-1 accessory proteins, Nef has been shown to fulfill multiple functions during the viral replication cycle. However, the mechanism(s) of Nef has not yet been fully elucidated. In general, it is now widely accepted that, inconsistent with its originally 'negative' nomenclature, Nef plays an important stimulatory role in the replication and pathogenesis of HIV-1. The broad spectrum of Nef-associated activities so far described can be summarized in distinct classes: (i) modulation of cell activation and apoptosis, (ii) change in intracellular trafficking of cellular proteins, particularly of cell receptor proteins like CD4 and MHC class I, and (iii) increase of virus infectivity.

Well characterized and one of the earliest observation in the course of studying '*Nefology*' is the Nef-induced down-regulation of cell surface CD4 (Garcia and Miller 1991). This mechanism occurs on a post-translational level by augmentation of receptor internalization followed by lysosomal degradation, where Nef is binding to the adapter protein complex in clathrin-coated pits (Aiken et al. 1994). As there are at least two other mechanisms of HIV-1 receptor interference, induced by the envelope and Vpu proteins of HIV-1, it was speculated that intervention with the primary virus receptor, CD4, must be advantageous for HIV-1 replication. Indeed, excess of cell-surface CD4 was shown to interfere with encapsidation of Env and release of infectious HIV progeny viruses (Lama et al. 1999; Ross et al. 1999). Another influence on immune receptors is the Nef-mediated block in the transport of MHC-I antigen complexes to the cell surface, leading to the disturbance in the recognition of HIV-1 infected cells by cytotoxic T_{CD8} lymphocytes (CTL) (Collins et al. 1998; Schwartz et al. 1996, Le Gall et al. 2000). More recent studies described down-regulation of co-stimulatory protein CD28 induced by Nef (Swigut et al. 2001). As it appears, the mechanism(s) by which Nef blocks cell surface expression of CD4, MHC-I, and CD28 are independent and can be genetically separated (Le Gall et al. 2000; Piguet and Trono 2001; Piguet et al. 1999, 2000).

Nef is expressed relatively early in the HIV replication cycle, and there are reports that Nef is incorporated into budding virions where it can be cleaved by the viral protease. Nef is present during almost all steps of the viral lifecycle which might explain the multiple functions deployed by this accessory protein. Major attention has been focused towards the Nef-mediated modulation of the T-cell signal transduction and activation pathways (for review see Fackler and Baur 2002). Several lines of evidence supported the hypothesis that, by affecting the T cell receptor, Nef may support several aspects of the virus replication cycle, including regulation of apoptosis and immune evasion. Earlier studies in transgenic mice indicated Nef-dependent activation in T-cell signaling (Skowronski et al. 1993). Later studies indicate that Nef imitates T-cell receptor signalling motifs (Simmons et al. 2001). The Nef-induced T-cell activation requires the tyrosine kinase Zap70 and the zeta chain of the T-cell receptor (Xu et al. 1999). Further, Nef was shown to activate T-cells by binding to the Nef-associated kinase, also known as the p21-activated kinase 2 (PAK2) (Arora et al. 2000; Renkema et al. 2001). In addition to the activation of T-cells, Nef also induces cell death, although the mechanism and biological relevance of this Nef-function is less clear. It was also shown that expression of the death receptor Fas ligand (FasL) is activated by Nef and that this upregulation might increase killing of CTLs attacking HIV infected cells (Xu et al. 1997).

In terms of HIV related pathogenesis, it is becoming clear that the multifunctional Nef protein represents an attractive target for development of antiviral strategies, since this accessory protein has been explicitly characterized as a viral factor that increases the pathological potential and the replication of lentiviruses in vivo. For instance, virus isolates from so called long-term nonprogressing HIV-1 infected individuals maintain deletion in *nef* alleles (Rhodes et al. 2000). Consistent with the idea that Nef supports virus replication in vivo, Nef of SIV was shown to elevate virus replication and disease progression in SIV-infected rhesus macaques (Kestler et al. 1991).

DYNAMICS OF VIRAL REPLICATION

Before the direct quantification of plasma viral RNA was possible, estimates of viral dynamics were based on indirect parameters such as anti-HIV-1 antibody titer (Gaines et al. 1987), p24 antigenaemia (Paul et al. 1987), CD4 cell count (Goedert et al. 1987) and clinical progression. This lead to the belief that the natural course of HIV-1 infection included a 'latent stage' in which little or no viral replication occurred. It was not until 1989 that Ho et al. showed that viral replication and immune destruction was an on-going and active process. Thereafter, Pantaleo et al. (1993) and Embretson et al. (1993) demonstrated active viral replication during the 'latent' stage in tissues such as lymph nodes, tonsils and adenoids, and in cells such as T-helper cells and macrophages. The availability of drug regimes that could suppress all viral replication facilitated investigation of the dynamics of viral replication. Two groups (Ho et al. 1995; Wei et al. 1995) made use of viral load measurements to assay the rate of decline of plasma viremia in the presence of drug. They found that viral load fell exponentially within two weeks of starting therapy and that this decline was a combination of the clearance of free virus from the plasma and the removal of

infected, productive cells. Both groups independently calculated the half-life of a virion in plasma to be 2–2.1 days, a higher replication rate than previously expected, and estimated viral production to be at least 10^8 or 10^9 virions per day.

Another study (Perelson et al. 1996) exploited the new potent antiretroviral therapy to demonstrate an exponential decrease in plasma viral load and to calculate the half-life of virion clearance to be 6 hours and the daily rate of virus production to be 10.3×10^9, greater than a one-log increase on previous estimations. It was calculated that 99 percent of plasma virus was released by recently infected cells. One year later, using a triple antiretroviral regime, Perelson and co-workers (1997) demonstrated that the therapy-induced viral decline was a two-stage event. This involved loss of plasma virus and virus from recently infected cells, followed by the loss of virus from long-lived infected cells such as tissue macrophages or dendritic cells, the half-life being approximately 1–4 weeks. A third stage was also predicted in which latently-infected cells required activation prior to virus production. Ho's prediction that HIV-1 could be eradicated from latently-infected cells with 3 years of Combined Antiretroviral Therapy (CART) (Ho 1997) was undermined by data showing that virus could still be detected from these latently infected cells after more than 2 years of CART, despite an undetectable plasma viremia (Wong et al. 1997b; Finzi et al. 1997; Chun et al. 1997).

The interplay between the immune response and virion production produces the viral load 'set point', which is prognostic of clinical outcome and disease progression in an infected individual (Mellors et al. 1996). It was proposed that lymphoid tissues trap virions early in infection, but as the lymphoid structure becomes damaged more virus is released to the circulating plasma. Calculations based on CD4 cell dynamics (Ho et al. 1995; Wei et al. 1995) estimated a daily turnover of between 1.8 and 2×10^9 cells, and led David Ho to propose the 'tap and sink' analogy for immune depletion. He hypothesized that the pool of CD4 cells was maintained as fast as it was destroyed during early infection but that, with time, the tap runs dry as new cells become fewer. Eventually the sink empties. Newer techniques using glucose-labeled CD4 cells have provided an insight into real-time CD4 cell dynamics and suggest that, in fact, HIV-1 infection affects the half-life of the CD4 cells, rather than their rate of production (Hellerstein et al. 1999). Hence, although the initial effect of CART is to increase the rate of CD4 cell production, the long-term aim is to increase the lifespan of cells.

ENZYME INFIDELITY AND GENETIC VARIATION

The *Lentiviridae* undergo extensive genetic variation. Variability results in part from RT infidelity combined with a lack of 3′-5′ exonuclease activity, a proof-reading function common in mammalian polymerase enzymes which repairs incorrectly synthesized DNA. HIV-1 has one of the highest mutation rates of retrovirus RTs. In vitro studies on purified RT have estimated the error rate to be one base in every 3.4×10^5 (Preston et al. 1988; Roberts et al. 1988; Mansky and Temin 1995). When this mutation rate is considered in tandem with the estimated replication rate of ten billion new virions each day, the scope for diversity becomes apparent – every possible single point mutation is created daily in each infected individual. As a result, mutations that confer drug resistance may be present at undetectable levels prior to the commencement of anti-viral therapy. The majority of mutations are point mutations consisting of base-pair substitutions, although base insertions and deletions have been identified (Larder et al. 1999).

An alternative means by which variation may be introduced is via recombination. Each virion contains two RNA copies, both of which may contribute to a growing DNA strand during reverse transcription. Two viruses containing unique drug resistance mutations may create a single multidrug resistant virus by recombination (Moutouh et al. 1996). Following infection, the HIV-1 population develops into a 'quasi species' of genetic variants and as infection progresses, the homogeneity of the infecting population increases (McNearney et al. 1992). Viral variants may have different cell tropisms (e.g. brain and lymphoid tissue (Simmonds et al. 1991; Di Stefano et al. 1996) and co-receptor usage (Deng et al. 1996; Oberlin et al. 1996). Such genetic variation is inherent to the evolution of HIV-1 at an individual level, but also on a more global level, as illustrated by the presence of subtypes.

HIV-1 SUBTYPES

Analysis of viral sequences allows HIV-1 to be classified into three groups, representing the distinctive HIV-1 lineages, Main (M), Outlier (O) (Gurtler et al. 1994) and Non-M-Non-O (N) (Simon et al. 1998). The M group was initially subtyped following analyses of *gag* gene sequences from virus isolated in 15 countries (Louwagie et al. 1993), and has been further divided into individual subtypes (A–K) (Figure 1). Isolates containing RNA from more than one subtype are now appearing and have been termed circulating recombinant forms (CRF) (Carr et al. 1998), of which at least 14 have been identified (Robertson et al. 2000). The predominant example of a CRF is subtype AE, prevalent in Thailand. That these viruses might represent recombinants was confirmed from sequence analyses of *gag* and *env* genes (McCutchan et al. 1992; Louwagie et al. 1993), and from analyses of complete subtype AE genomes (Carr et al. 1996; Gao et al. 1996). However, the nonrecombinant subtype E 'source' isolate has yet to be identified, leading to uncertainty concerning the origins of

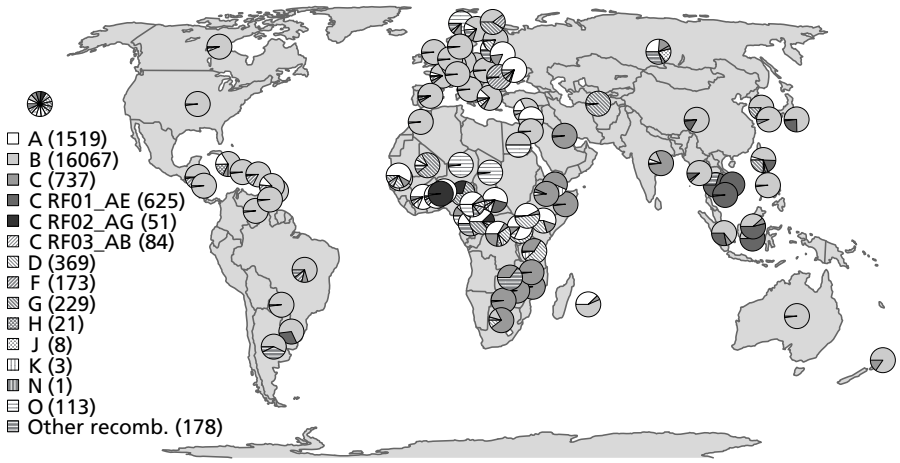

Figure 1 *HIV-1 subtype distribution worldwide. The global distribution of HIV-1 subtypes (from Los Alamos National Laboratory Database (2002) wwwl/:hiv-web.lanl.gov/geography/index.html). Subtypes are represented by color, with the green subtype B predominating in Europe and the USA and the red, blue, and pink of subtypes A, C, and D, respectively, being prevalent in sub-Saharan Africa.*

subtype AE. Sub-subtypes are lineages closely related to particular subtypes, but not genetically distant enough to justify calling a new subtype. For example, subtype F comprises sub-subtype F1 and a newly found lineage sub-subtype F2 (Triques et al. 1999). A third F sub-subtype, F3, was later reclassified as subtype K (Triques et al. 2000). The subtypes of most HIV-1 strains can be determined by sequence analysis of any region of the genome as inter-subtype nucleotide sequence divergence may exceed 20, 15, and 25 percent for *gag*, *pol*, and *env*, respectively (Robertson et al. 2000).

HIV-1 subtypes show different geographical distributions. The majority of HIV-1 infections in Europe and North America are with subtype B, while in sub-Saharan Africa, subtypes A, C, and D predominate (Figure 1). Nevertheless, in the UK 25 percent of HIV-1 infections are estimated to be caused by non-B subtypes (Parry et al. 2001). In East Africa, subtypes A and D are most common, whereas in the south and south-east, subtype C predominates, although this subtype is also spreading eastwards (Koch et al. 2001). Cameroon is a source of Group O (Mauclere et al. 1997) and group N strains (Ayouba et al. 2000). Other continents display subtype variability. For example in India and south-east Asia subtype C is common (Bollinger et al. 1995) and in Thailand subtypes B and AE predominate (Gao et al. 1996; Ou et al. 1993).

In South America subtypes B, C, and F are found (Campodonico et al. 1996; Bongertz et al. 2000), and the developing epidemic in the former Soviet Union comprises subtypes A, B, C, G, and AB (Liitsola et al. 1998; Lukashov et al. 1995).

HIV-1 and HIV-2 show 50 percent genetic similarity (Korber et al. 1995) and demonstrate differing degrees of pathogenicity, transmissibility, and drug susceptibility (Marlink et al. 1994; Pauwels et al. 1990). Subtype variability may impact on issues as diverse as vaccine design, detection, and quantification of HIV-1 infection, transmissibility, and pathogenicity.

THE CLINICAL IMPACT OF VIRAL DIVERSITY

Viral diversity impacts on the diagnosis of HIV-1 infection. The assay that is most widely applied to HIV-1 diagnosis is the enzyme-linked immunosorbent assay (ELISA). Until recently, ELISAs for the detection of antibodies to HIV-1 and HIV-2 were not equally sensitive for all subtypes. The earliest ELISAs failed to detect antibodies to group O and HIV-2, although incorporating antigens from these strains into newer assays overcame the problem (Schable et al. 1994). A recent study of the ability of six ELISAs to detect antibodies from all the major subtypes showed that the assays detected most HIV-1 group M variants (Koch et al. 2001) as well as group N (Masciotra et al. 2000).

Other clinical assays affected by viral diversity are those quantifying HIV infection. Viral load (VL) is the number of HIV-1 RNA copies per milliliter of plasma, and various techniques, based on differing technologies, are available for its quantification. The Roche Amplicor HIV-1 Monitor v1.5 assay (Roche Diagnostics, New Jersey, USA) (Mulder et al. 1994) uses reverse transcription and then PCR to amplify and quantify a region of the *gag* gene. The nucleic acid sequence-based amplification assay (NASBA) (Organon Teknika, Boxtel, The Netherlands) (Kievits et al., 1991; de Baar et al. 2001) directly amplifies RNA from *gag*. The HIV-1 Quantiplex branched DNA (bDNA) assay (Chiron Diagnostics, Emeryville, California, USA) (Pachl et al. 1995; Todd et al. 1995) uses sequential hybridization of probes targeting the *pol* gene to quantify viral RNA and the LCx quantitative assay (Abbott) uses RT-PCR amplification of *pol* (Swanson et al. 2000).

Each technique has a different sensitivity for viral load measurement, according to the subtype being tested (Alaeus et al. 1999; Holguin et al. 1999; Parekh et al. 1999; Clarke et al. 2000). This may preclude the comparison of viral loads from patients infected with different HIV-1 subtypes and, if different assays are used for consecutive readings in the same patient, any change in viral load may be difficult to interpret. For example, early versions of the Amplicor and NASBA assays detected HIV-1 subtypes A and H with lower degrees of sensitivity than other Group M subtypes (Coste et al. 1996), although comparisons of the more recent versions of these assays show that all subtypes are equally quantified (Swanson et al. 2001). As many viral load assays are PCR-based, polymorphic variability may compromise the binding of primers. Accordingly, assays can be improved by utilizing highly conserved regions of the genome, such as *pol* (Ernest et al. 2001) or by exploiting non-PCR amplification techniques, such as the bDNA assay (Parekh et al. 1999).

The influence of subtype on viral transmissibility has also been suggested by a number of studies, although data are limited. The difficulty with interpreting such studies is that there are many confounding factors. For example, coinfection with sexually transmitted pathogens such as *Neisseria gonorrhoeae* or herpes simplex virus also increase transmissibility (del Mar Pujades et al. 2002; Fawzi et al. 2001). There are data that suggest that subtype B isolates are less transmissible than non-B counterparts (Cameron et al. 1989; van Harmelen et al. 1997), and that the maternal transmission rate is lower in Tanzanian mothers infected with HIV-1 subtype D, than in those infected with A or C (Renjifo et al. 2001). Without larger controlled studies, such findings should be regarded with caution, particularly in the light of evidence to suggest that factors, such as viral load, significantly impact on virus transmission (Shaffer et al. 1999).

The degree of pathogenicity associated with HIV-1 infection is also multifactorial and, accordingly, attributing an effect to subtype is difficult. Some studies suggest that the rate of disease progression is similar, regardless of subtype (Alaeus et al. 1999; Weisman et al. 1999; Amornkul et al. 1999), whereas a study in Senegal suggested a survival advantage for those infected with subtype A HIV-1 (Kanki et al. 1999). More recently, in a study from Uganda, viruses with subtype D envelope were associated with faster disease progression (relative risk of death, 1.29; $P = 0.009$) and with a lower CD4 cell count ($P = 0.001$), compared with subtype A (Kaleebu et al. 2002).

SUBTYPE VARIABILITY AND THE PROSPECT OF A VACCINE

The lack of a vaccine for HIV-1 remains one of the major obstacles to controlling the epidemic. A number of approaches have led to clinical trials, including live vectors which express selected HIV-1 genes (Gupta et al. 2002; Corey et al. 1998; Ferrari et al. 1997), DNA vaccines (Caselli et al. 1999; Ayyavoo et al. 2000), live-attenuated *nef*-deleted virions (Khatissian et al. 2001; Wyand et al. 1999), and killed viral constructs (Moss et al. 2001). The high HIV-1 mutation rate and the development of quasi species facilitate the development of 'escape mutants' (Barouch et al. 2002) and restrict vaccine design. By using vaccines that utilize highly conserved regions of the HIV-1 genome, such as Tat and Rev, the impact of genetic variability is reduced and, accordingly, these vaccines have also been shown to be active against a range of subtypes (Goldstein et al. 2001), eliciting humoral and cellular responses (Caselli et al. 1999; Cafaro et al. 1999).

The extent of subtype effect on vaccine design remains unclear, especially as the majority of vaccines are designed to inhibit HIV-1 subtype B. Neutralizing antibodies are subtype-specific (Mascola et al. 1994), although broad cross-reactivity of neutralizing antibody activity to subtypes B and C has been reported (Bures et al. 2002; Dorrell et al. 1999). Cross-clade T-cell responses have been elicited. For example, an HIV-1 gp160-DNA construct encoding subtype B *env*, *tat*, and *rev* genes elicited specific and cross-reactive cell-mediated immune responses in mice (Arora and Seth 2001) and similar responses have been reported in human volunteers in Uganda (Cao et al. 2000; Van der Groen et al. 1998). Vaccines are being developed to express epitopes from a range of subtypes. For example, antibody responses to both subtypes AE and B have been reported using a vaccine that contains gp120 subunits from both (Berman et al. 1999). As many countries are affected by more than one subtype, it is likely that any effective vaccine will be required to induce broad responses (Agwale et al. 2002; Novitsky et al. 2001) and, accordingly, genetic libraries are being developed to document HIV-1 genetic variability with the aim of improving vaccine design (Mukai et al. 2002).

In 1991, antisera from human volunteers immunized with recombinant gp120 immunogens were examined for their capacity to neutralize field isolates of HIV-1 grown in primary peripheral blood mononuclear cells (PBMC) (McCormack et al. 2000; Beddows et al. 1999). None of the vaccine sera neutralized any primary HIV-1 isolates, even when homologous in sequence to the laboratory adapted isolates which could be neutralized by these sera. These data showed that the neutralization of primary isolates could not be achieved by sera raised to recombinant proteins, although these field isolates could be neutralized by human antisera from HIV+ subjects. Further work (Spenlehauer et al. 1998; Zhang et al. 2002) showed that the neutralization of laboratory HIV-1 strains is predominantly through a linear epitope of 33 amino acids at the tip of the third variable domain of gp120, called the V3 loop. The V3 loop is expressed

on the surface of gp120 in cell-line adapted viruses, and is also present and highly immunogenic on the surface of the recombinant gp120 molecules. However, primary isolates of HIV-1 have a more cryptic V3 epitope, and antibodies to V3 do not neutralize these primary isolates if grown in primary cells. The molecular explanation for this phenomenon was published in 1996, with the characterization of the chemokine co-receptors for HIV entry. Primary isolates use CCR5 as the principal co-receptor, which is present on activated $CD4^+$ T cells; laboratory-adapted HIV-1 isolates grown in immortalized, transformed T-cell lines use CXCR4 as the co-receptor, which is responsible for the over-expression of V3 in these isolates (see earlier section for references).

Up to the present, September 2004, it has not been possible to engineer a recombinant envelope gp120 which induces antibodies that can neutralize primary HIV-1 isolates in PBMCs. It is highly likely that such an immunogen will require extensive investigation from structural biologists who may be able to engineer a gp120 molecule in its native trimeric conformation with the capacity to induce neutralizing antibodies against primary isolates. However, no such molecule is currently on the horizon.

Notwithstanding these negative neutralization experiments, the $rgp120_{MN}$ molecule was taken to two full phase III trials in the USA, Holland, and Thailand, by VaxGen. The first of these trials in >7000 HIV-negative subjects at risk of HIV-1 infection reported in March 2003 (www.vaxgen.com/pressrom/index.html 2003; Francis et al. 2003); there was no protection against infection, with equal numbers of infections in the active and placebo groups. The negative results of this VaxGen $rgp120_{MN}$ study have been bitterly disappointing for a world desperate for a prophylactic HIV vaccine, but extremely important for science. The results confirm the predictive value of laboratory-adapted and primary isolate neutralization data, and also support the predictive value of the macaque SHIV animal challenge model (Feinberg and Moore 2002; Moore and Burton 1999).

In the absence of natural immunity to HIV-1, and without an immunogen capable of inducing neutralization of all subtypes, attention turned to other correlates of protection from HIV-1. Immunologists studied children born to HIV-infected mothers, where only 30 percent become infected; long-term survivors of HIV-1 infection who might have beneficial immune responses; the primary immune response to HIV-1 where there is some evidence of immune-mediated viral suppression and the phenomenon of highly HIV-exposed but persistently HIV-sero-negative subjects (HEPS). These HEPS have been repeatedly described throughout the AIDS epidemic in all risk-groups. Rowland-Jones (1999), studying HEPS prostitute women in Nairobi, Kenya, demonstrated that absence of HIV-1 infection, despite repeated exposure to the virus, was associated with the presence of detectable HIV-specific, HLA class-I-restricted $CD8^+$ cytotoxic T-lymphocytes (CTL). When these women ceased regular commercial sex work, exposure to HIV lessened and they became more susceptible to infection. Her hypothesis was that exposure to HIV could, in some circumstances, lead to the induction of a protective cellular immunity.

This observation has subsequently led to a considerable amount of animal and human clinical research on the induction of HIV-specific cellular immunity through immunization. McMichael's group has shown that a priming immunization with DNA followed by boosting with a modified vaccinia virus (such as modified vaccinia Ankara, MVA) bearing the same genetic insert is a potent inducer of HIV-specific CTL (Mwau et al. 2004). In the macaque model, induction of SIV-specific CTL through DNA-MVA prime–boost immunization fails to protect against challenge with a pathogenic $SHIV_{89.6}$, but does lead to significant disease attenuation in the macaques (McMichael and Hanke 2003). There are now several clinical trials in humans at phase I/II of promising CTL-inducing immunogens; these include naked DNA, adenovirus, vaccinia, alphaviruses, peptides, and viruslike particles (VLP). However, the prospect of a prophylactic HIV vaccine which does not protect, but which might slow disease progression in vaccines would be extremely difficult to test in human trials, and would not fully address the world's urgent need for the prevention of HIV infection.

Should an effective HIV vaccine be developed, the immense genetic diversity of the HIV epidemic will place great evolutionary pressure on the virus to escape from vaccine-induced immunity. As with the emergence of point mutations conferring resistance to antiretroviral drugs, so vaccine-induced immunity is likely to promote naturally occurring mutants with lower susceptibility to vaccine induced cellular immunity. Phillips and co-authors (1991) first described the phenomenon of viral escape from a CTL epitope in 1991; the potential emergence of this phenomenon will need to be investigated in parallel to phase III vaccine trials in the future.

In 2004, there is no HIV vaccine. It is generally believed that a successful HIV vaccine will need to induce both HIV-specific cellular immunity as well as potent, broadly reactive primary isolate neutralizing antibodies. The reality of the research portfolio currently is that this prospect appears to be remote.

HIV THERAPY AND THE EMERGENCE OF RESISTANCE

In the two decades since the first antiretroviral was serendipitously identified, drugs to combat HIV infection have been developed at an increasing rate. These fall into well-defined categories (Table 1), according to which aspect of the virion lifecycle is being inhibited (Figure 2). CART, consisting of at least three antiretroviral drugs, is the current standard of care for

Table 1 *Drugs designed to inhibit HIV-1*

Site of action	Drug class	Drug
Reverse transcriptase	Nucleoside analogues	Zidovudine (AZT/ ZDV)
		Didanosine (ddI)
		Zalcitabine (ddC)
		Stavudine (D4T)
		Lamivudine (3TC)
		Abacavir (ABC)
		Emtricitibine (FTC)
	Nucleotide analogues	Adefovir Dipivoxil[a]
		Tenofovir PMPA
	Nonnucleoside analogues	Nevirapine (NEV)
		Delavirdine (DLV)
		Efavirenz (EFV)
Protease	Protease inhibitors	Saquinavir (hard and soft gel) (SQV)
		Ritonavir (RTN)
		Nelfinavir (NEL)
		Indinavir (IND)
		Amprenavir (AMP)
		Lopinavir
		Tipranavir[a]
		Atazanavir[a]
Integrase	Integrase inhibitors	S-1360[a]
Co-receptors	CCR5 inhibitor	SCH-C[a]
	CXCR4 inhibitor	AMD-3100[a]
Gp41	Fusion inhibitor	Envufutide (T-20)
		T-1249[a]

Drugs that contribute to the majority of CART regimes currently prescribed. Standard CART regimes include two nucleoside analogues in conjunction with either a protease inhibitor or a nonnucleoside analogue.
a) Still in research stages, under trial or not fully licensed at time of writing.

HIV-1-infected patients (Pozniak et al. 2003), and the availability of assays in simple kit form to quantify peripheral virus load has complemented drug development to optimize patient care (Nolte 1999).

Drugs designed to inhibit HIV-1 RT

NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS (NRTI)

The essential action of the NRTI class is to mimic the natural host nucleoside triphosphate molecules (dNTP), which depends on replacing the hydroxyl group at the 3′ position of the deoxyribose sugar ring in the natural dNTPs by an alternative moiety in the drug (Figure 3). For example, the azido group at the 3′ position in Zidovudine (ZDV) (3′-azido-3-deoxythymidine, an analogue of thymidine, also called AZT or Retrovir and produced by GlaxoSmithKline) promotes the drug's chain-termination activity (Figure 3). This compound was initially designed as an anti-tumor agent and was found to inhibit the HIV-1 RT (Mitsuya et al. 1985). It competes in vitro with natural host nucleosides and is incorporated into the lengthening DNA strand by the viral RT, resulting in chain termination.

The NRTIs can be divided into the thymidine analogues: ZDV and Stavudine (2′,3′-didehydro-3′-deoxythymidine) or D4T, and non-thymidine analogues: Didanosine (2′,3′-dideoxyinosine), ddI; Zalcitabine (2′,3′-dideoxycytidine), ddC; Lamivudine ((-)-2′-deoxy-3′-thiothiadine), 3TC; Emtricitibine ((-)B-l-3′-thio-2′-3′-dideoxy-5-fluorocytidine), FTC and Abacavir (IS, 4R)-4-[2-amino-6(cyclopropyl amino)-9H-purin-9-yl]-2-cyclopentene-1-methanol succinate), ABC). Since the former act predominantly in dividing cells and the latter in resting cells, combinations of the two groups are often coprescribed. An early clinical trial, designated the DELTA study (Delta Coordinating Committee 1996) which investigated whether two NRTIs in combination were more effective than AZT alone in delaying disease progression, demonstrated that combining AZT with ddI or ddC conferred a survival advantage over AZT monotherapy and heralded the concept of combination therapy.

Initial treatment with AZT monotherapy resulted in viral rebound and the discovery of a genotypic pattern of resistance, as mutations emerged initially at codons 41 and 215, then at 67, 70, 210, and 219. An alternative pathway leading to AZT resistance and broad cross-class resistance is the 'Q151M complex' (Shirasaka et al. 1995) associated with mutations at codons 62, 75, 77, and 116. These mutations seem to act via interference with the dNTP binding site (Shirasaka et al. 1995). This is seen more commonly when AZT is prescribed with ddI or ddC and confers 320-fold resistance to AZT and cross-resistance to ddI, ddC, D4T, Abacavir, and 3TC.

NUCLEOTIDE REVERSE TRANSCRIPTASE INHIBITORS (NTRTI)

The NtRTI require two intracellular phosphorylation events for activity. Two drugs originally from Gilead Sciences (Adefovir dipivoxil and Tenofovir (bis-POC PMPA)) are already monophosphorylated and, therefore, require only a single monophosphorylation for activation. Adefovir, although not licensed following problems with renal toxicity, had shown potent reductions in viral load after one year of monotherapy and appeared to have a favorable resistance profile compared to the NRTIs. It was also active against herpes simplex virus, cytomegalovirus, and hepatitis B virus (Xiong et al. 1997; Merta et al. 1990). Tenofovir which has similar activity without the toxicity, received FDA approval in the United States in 2001.

Although Adefovir has been withdrawn, it was active against viruses with the RT mutation in codon 184 and with AZT resistance (Miller et al. 1999; Gu et al. 1995).

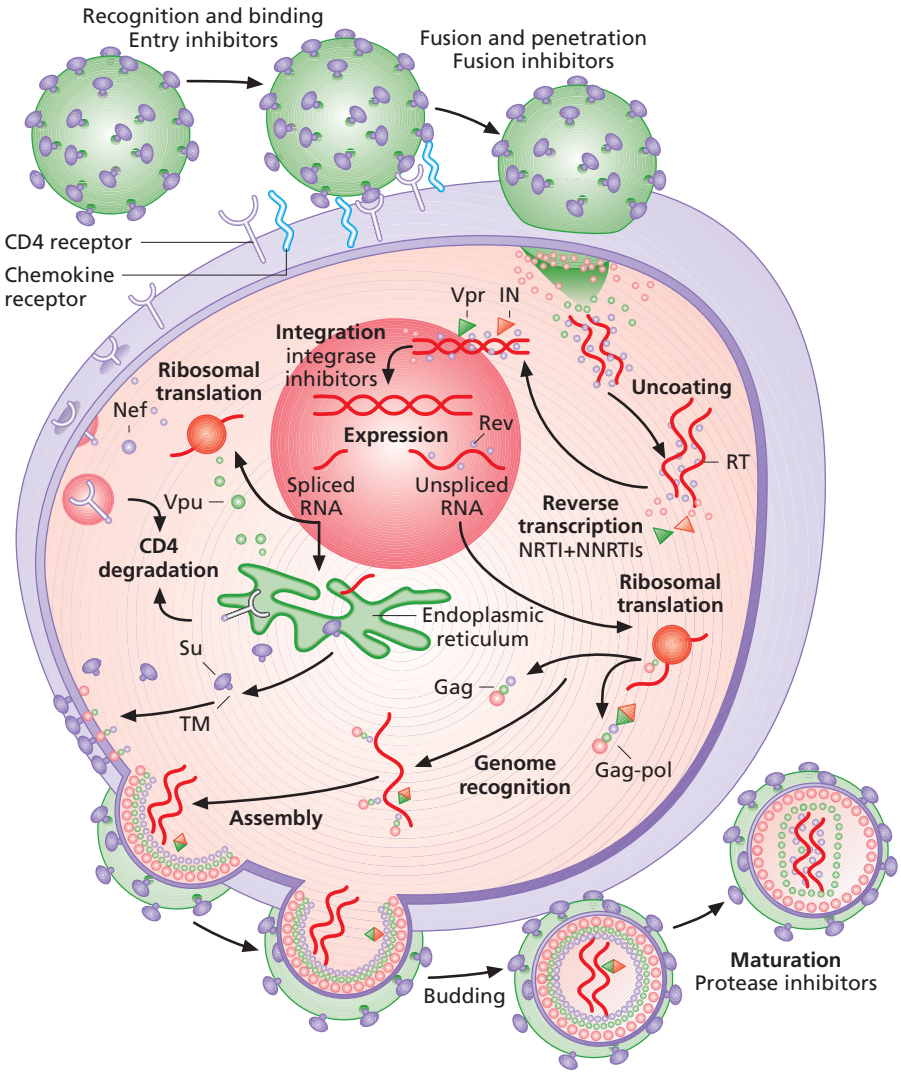

Figure 2 *The HIV-1 life cycle and site of action of antiretroviral drugs. Targets of drugs already approved for use by the FDA are shown in red. Others currently undergoing development and likely to be available for clinical trial in the near future are shown in blue. The HIV-1 core penetrates the host-cell post-entry via receptor-binding and fusion with the plasma membrane. Double-stranded proviral DNA resulting from the action of RT on the viral single-stranded RNA is translocated to the nucleus, where it is integrated into the host chromosomal DNA, courtesy of the viral integrase. Viral RNA is transcribed from the proviral DNA and viral proteins are translated from host cell ribosomes. New virions are assembled at the membrane from which they bud, maturing as they do so under the action of the viral protease. Redrawn from Pomerantz and Horn (2003) with permission.*

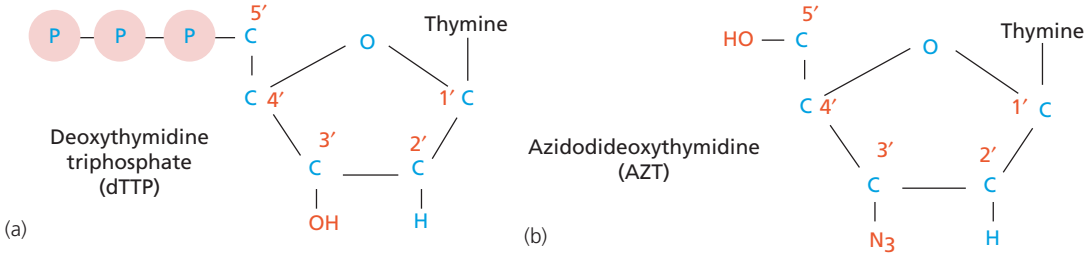

Figure 3 *Structure and mechanism of action of NRTIs. The structure of* **(a)** *the natural dNTP, deoxythymidine triphosphate (dTTP) and* **(b)** *azidodideoxythymidine (AZT, Zidovudine). The important difference is that the hydroxyl group attached to the carbon at position 3 of dTTP, which is vital to the DNA polymerase reaction, has been replaced by an azido group. Hence, when AZT is incorporated into the growing DNA strand, chain termination ensues.*

Mutations at codons 65 and 70 have been associated with resistance to Adefovir in vitro (Gu et al. 1995), and K70E has also been found in vivo (Mulato et al. 1998), although the significance of this is still undetermined. Interestingly, the activity of Adefovir against viruses containing the M184V mutation was 3–4-fold greater than against wild-type virus (Miller et al. 1999). Viruses containing the K65R and L210W mutation have reduced sensitivity to Tenofovir.

NONNUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS (NNRTI)

The NNRTIs include Nevirapine, Efavirenz, Delavirdine, and the thiobenzimidazolone (TIBO) agents. These are noncompetitive inhibitors of RT (Spence et al. 1995) and bind to a specific site associated with codons 100–108 and 181–190 that provide the hydrophobic binding pocket within the polymerase domain of the p66 subunit of RT (Spence et al. 1995). These codons are also sites for key resistance mutations.

Although potent, the NNRTIs induce early resistance (Richman et al. 1994), often associated with mutations near codons 100 to 108 and 181 to 190, the locations of the drug-binding site. The Y181C mutation emerges rapidly in vitro, to cause 100-fold decrease in susceptibility to Nevirapine (Richman et al. 1991) and highly resistant strains have been identified in vivo within eight weeks of therapy (Richman et al. 1994; de Jong et al. 1997). Drug levels which exceed the IC_{50} of the resistant strains can be achieved in vivo using the higher dose of 400 mg, although with a higher incidence of side-effects (Havlir et al. 1995).

The K103N mutation seems to produce classwide resistance, including to newer drugs such as Efavirenz (DMP-266) (De Clercq 1998), although Efavirenz maintains some activity in the presence of the Y181C mutation (Jeffrey et al. 1998). The quinolone/quinoxaline class of NNRTIs, such as Nevirapine, also develop resistance through mutation at codon 190, but at the expense of enzymatic activity (Kleim et al. 1994). The major concern with NNRTIs is that only one mutation is required to induce resistance and, hence, they should be used in combination with other antiretroviral agents.

Drugs designed to inhibit HIV-1 protease

The viral protease acts to cleave and process the precursor proteins encoded by the *gag* and *gag–pol* genes. By inhibiting this posttranslational cleavage, the resultant virions are non-infectious. The RT inhibitors only block HIV-1 replication in acutely infected cells, whereas the protease inhibitors (PI) inhibit virus production from chronically infected cells, since they act at a late stage in the lifecycle (Lambert et al. 1992). The PIs inhibit the protease enzyme by acting as peptidomimetic competitive inhibitors at the enzymatic active site. Therapy with PIs also appears to have a more suppressive effect on HIV-1 replication in lymph nodes than the RTIs (Gunthard et al. 1998a; Wong et al. 1997a).

Resistance and cross-resistance to PIs are well documented and at least 24 mutations have been identified in the 99 amino acid sequence (Figure 4). To provide prolonged efficacy, PIs need to be prescribed as part of a three-drug CART regime. Such regimes significantly reduce mortality and morbidity associated with HIV-1 infection (Palella et al. 1998) and, accordingly, have been given the acronym 'HAART,' for Highly Active Antiretroviral Therapy.

The interpretation of mutations associated with PI resistance is complex, especially with drugs such as Indinavir (Condra et al. 1996), when a large number of codons appear to be involved. Moreover, resistance is only one factor leading to drug failure. Others include the effects of bioavailability (Kupferschmidt et al. 1998; Vella and Floridia 1998; Perry and Noble 1998), cytochrome P450 metabolism (Wacher et al. 1998; Kupferschmidt et al. 1998), intolerance (Deeks et al. 1998; Sepkowitz et al. 1998; d'Arminio et al. 1998), and glycoprotein P transporter proteins (Kim et al. 1998; Wacher et al. 1998). Nevertheless, resistance remains a major cause of drug failure, and the issue of cross-resistance is becoming increasingly important, as failure on one PI may preclude the use of others (Condra et al. 1995).

A promising new class of antiretroviral agents are the 'Fusion inhibitors.' Two agents, T20 and T1249, bind to the HR1 domain of gp41 and disrupt the conformational change in this protein required for viral attachment and entry to the host cell (Kilby et al. 1998b; Lambert et al. 1999). As these drugs are peptides they cannot currently be given orally and, in addition, resistance has already been documented (Kilby et al. 1998b). Agents which bind to the co-receptors CCR5 (Simmons et al. 1997) and CXCR4 (Rusconi et al. 2000) or inhibit the -CD4 interaction (Jacobson et al. 2000) are also in development. For example, data on SCH-C, a CCR5 antagonist, have shown a 0.5 $\log_{10}$ reduction in viral load in a limited number of subjects over 10 days (Reynes et al. 2002). A CXCR4 antagonist termed AMD-3100 reduces viral load by 0.8 $\log_{10}$ RNA copies/ml (Schols et al. 2002), although antiviral potency has been questioned (Hendrix et al. 2002). The novel entry inhibitor BMS-806, is an antagonist of CD4–gp120 interactions and is still in preclinical development (Lin et al. 2002). It is active against multiple HIV-1 subtypes and against viruses displaying CXCR4 and CCR5 tropism.

MECHANISMS OF DRUG RESISTANCE

The infidelity of the retroviral RT results in a high mutation rate when viral genomic RNA is converted to DNA, as discussed. In the absence of complete viral inhibition, as might be associated with poor adherence,

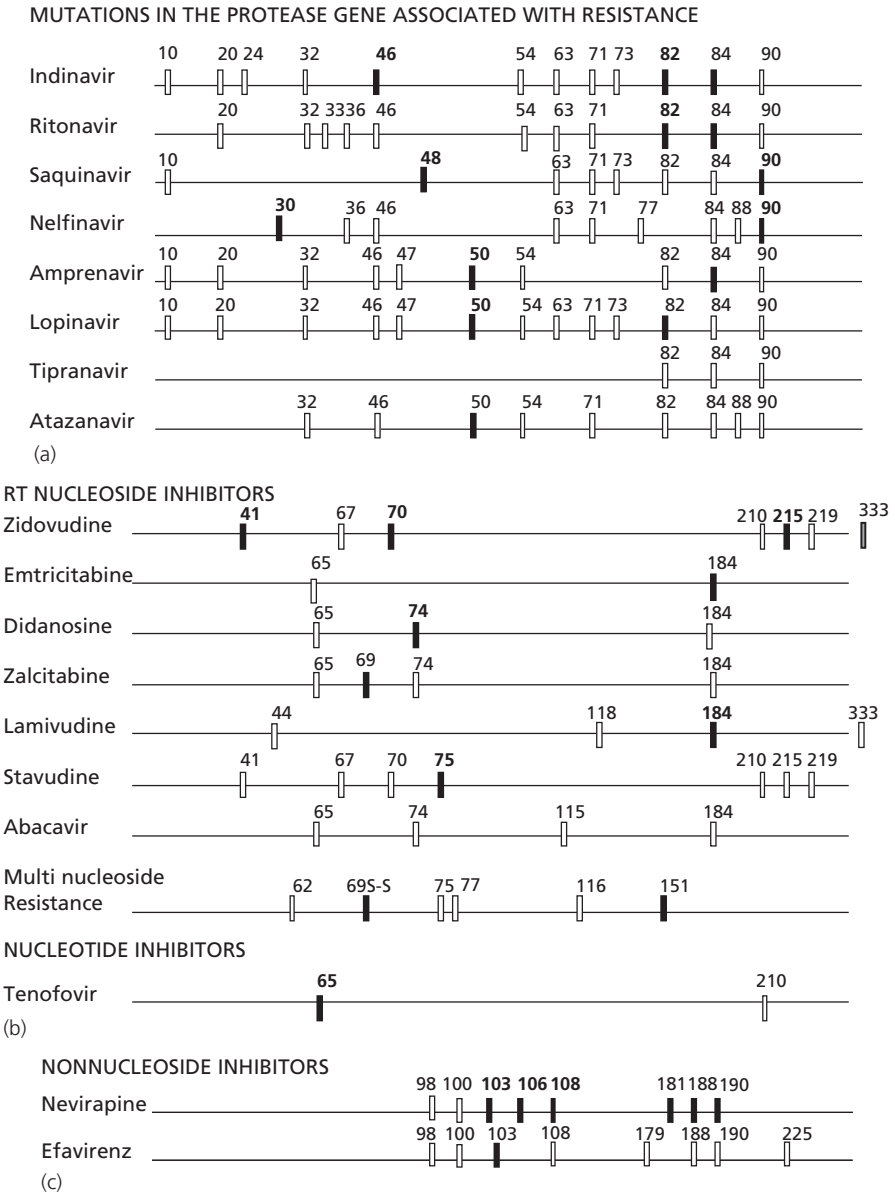

Figure 4 *Major point mutations associated with* **(a)** *PI resistance,* **(b)** *NRTI, and* **(c)** *NNRTI. Filled codons represent key mutations and white codons are secondary mutations.*

increased drug metabolism or drug sanctuary sites, there is increased opportunity for selection of drug-resistant mutants. According to the principles of natural selection, these variants soon become dominant and replicating viral RNA becomes detectable in the plasma. The recurrence of detectable plasma virus on therapy is often described as virological or therapeutic 'failure.' The point mutations in the *pol* gene that are commonly associated with drug resistance are detailed in Figure 4.

Although the genetic basis of HIV-1 drug resistance is well documented, the mechanisms underlying the loss of drug sensitivity are only now being understood. For the NRTI class of antiretroviral agents, there are two possible biochemical explanations for resistance. Either the retroviral RT develops increased ability to discriminate between natural dNTP molecules and inhibitors, or the enzyme acquires the ability to remove the chain-terminating inhibitors from the extending viral DNA in a process called 'pyrophosphorylysis' (Meyer et al. 1998; Boyer et al. 2001).

Certain mutations in HIV-1 RT decrease the activity of the nucleoside analogue by reducing its binding or altering the orientation of its binding so as to be unfavorable for incorporation. An example of such a mutation is the methionine to valine mutation at codon 184 of HIV-1 RT responsible for high-level resistance to 3TC and cross-resistance to other NRTIs (Tisdale et al. 1993). The beta-methyl group of the valine clashes

sterically with the l-oxathiolane ring of 3TC, resulting in mal-positioning of 3TC-triphosphate and a markedly reduced incorporation of 3TC and other NRTIs into the viral cDNA.

The second mechanism, pyrophosphorylysis, is the opposite reaction to reverse transcription, resulting in the removal of chain-terminating inhibitors from the extending viral DNA (Meyer et al. 1998; Boyer et al. 2001). Some AZT resistance mutations enhance the ability of HIV-1 RT to excise AZT-monophosphate from the AZT-terminated cDNA, freeing up the 3′ hydroxyl group (Figure 1) and allowing DNA polymerization to proceed. This excision reaction is catalyzed by ATP, and some AZT resistance mutations (e.g. 210W, 215Y/F) probably increase the binding affinity of ATP to the mutant enzyme. This enhanced excision capability of the mutant enzyme is not specific for AZT-monophosphate-terminated cDNA, and this helps to explain the cross-resistance observed between AZT and some other nucleoside analogues, such as D4T and Abacavir (Lennerstrand et al. 2001). Additionally, the 69SS mutation that confers multidrug resistance to the NRTI class also increases pyrophosphorylysis (Mas et al. 2000). Mutations such as M184V in RT, which confer resistance to 3TC, inhibit pyrophosphorylysis (Gotte et al. 2000). The M184V mutation alters the polymerase active site to interfere specifically with the ATP-mediated excision of AZT-MP from the end of the primer strand and, thereby, partially restores sensitivity to other NRTIs, such as AZT (Boyer et al. 2002).

The 20-year anniversary of the discovery of HIV-1 was celebrated in 2003. Within two decades research has changed the diagnosis of HIV infection in the western world from a certain death sentence to a manageable condition. However, viral latency (Wong et al. 1997b; Finzi et al. 1997), the recognition of tissue compartmentalization of replication which facilitates an evolutionary path independent of that taken by viruses in the periphery (Haggerty and Stevenson 1991; Zhu et al. 1996; Overbaugh et al. 1996; Zhang et al. 1998) and the persistence of low-level replication despite HAART (Dornadula et al. 1999; Dornadula et al. 2001), all conspire to undermine efforts to eradicate HIV-1 from infected hosts. Much remains to be understood of the way in which the virus responds in vivo to protect itself from annihilation, and further elucidation of the mechanism of replication will undoubtedly impact on the development of more novel and effective treatment regimens.

ACKNOWLEDGMENTS

We are thankful to the members of the laboratories at the Heinrich-Pette Institute (HPI), Hamburg, Germany and the Laboratory of Retrovirus Research at the Institute for Clinical and Molecular Virology, University of Erlangen-Nuremburg, and also Stefan Pöhlmann, Victor Wray, and Karin Metzner for comments on the manuscript. U.S. was supported by an Heisenberg grant from the German Research Council (DFG), and by DFG grants SFB-466-A11 and SFB 2003-A1, by grant IE-S08T06 from the German Human Genome Research, and by NIH/NIDDK RO1 grant DK59537-01.

PROPERTIES OF PRIONS

Introduction

Prion diseases, also termed transmissible spongiform encephalopathies (TSE), are inevitably fatal neurodegenerative conditions that affect humans and a wide variety of animals (Aguzzi et al. 2001c). Although prion diseases may present with certain morphological and pathophysiological features that parallel other progressive encephalopathies, such as Alzheimer's and Parkinson's disease (Aguzzi and Haass 2003; Aguzzi and Raeber 1998), they are unique in that they are transmissible. Homogenization of brain tissue from affected individuals and intracerebral inoculation into another individual of the same species will typically reproduce the disease. This important fact was recognized almost six decades ago in the case of scrapie (Cuille and Chelle 1939), a prototypic prion disease that affects sheep and goats.

The agent that elicits TSEs was termed prion by Stanley B. Prusiner, and defined as 'a small proteinaceous infectious particle which is resistant to inactivation by most procedures that modify nucleic acids' (Prusiner 1982). However, within the present chapter the term 'prion' will be used operationally to denote the infectious agent, without implying that it possesses particular chemical or structural characteristics.

Prions certainly differ from all other known infectious pathogens in several respects. First, prions do not appear to contain an informational nucleic acid genome longer than 50 bases that would code for their progeny. Second, the only known component of the prion is a modified protein that is encoded by a cellular gene. Third, the major, and possibly only, component of the prion is the scrapie isoform of the prion protein (PrP^{Sc} or PrP-res), which is a disease-associated conformer of the cellular isoform PrP^{C} (also termed PrP-sen).

A fundamental event in prion diseases is a conformational change that occurs during the conversion of PrP^{C} into PrP^{Sc}. PrP^{C} has been identified in all mammals and birds examined to date, as well as in the frog *Xenopus laevis* (Strumbo et al. 2001), and in fish (Oidtmann et al. 2003; Rivera-Milla et al. 2003). PrP^{C} is anchored to the external surface of cells by a glycolipid moiety (Stahl et al. 1987). The function of PrP^{C} is unknown. All attempts to identify post-translational chemical modifications that distinguish PrP^{Sc} from PrP^{C} have been unsuccessful to

date (Stahl et al. 1993). PrP^{C} contains approximately 45 percent α-helix and two very short stretches of β-sheet (Riek et al. 1996). Conversion to PrP^{Sc} creates a protein that contains approximately 30 percent α-helix and 45 percent β-sheet. The mechanism by which PrP^{C} is converted into PrP^{Sc} remains unknown but PrP^{C} seems to bind to PrP^{Sc}, perhaps along with ancillary proteins, to form an intermediate complex during the formation of nascent PrP^{Sc} (Meier et al. 2003). Transgenic (Tg) mouse studies have provided genetic evidence that incoming prions in the inoculum interact preferentially with homotypic PrP^{C} during the propagation of prions (Prusiner et al., 1990; M. Scott et al. 1993).

The human prion diseases are referred to as kuru, Creutzfeldt–Jakob disease (CJD), variant CJD (vCJD), Gerstmann–Sträussler–Scheinker (GSS) disease, and fatal familial insomnia (FFI). The most common prion diseases of animals are scrapie of sheep and goats, bovine spongiform encephalopathy (BSE) or 'mad cow' disease, and chronic wasting disease (CWD) of deer and elk (Table 1). Kuru was the first of the human prion diseases to be transmitted to experimental animals, and it has often been suggested that kuru spread among the Fore people of Papua New Guinea by ritual cannibalism (Gajdusek et al. 1966; Gajdusek 1977). The experimental and presumed human-to-human transmission of kuru led to the belief that prion diseases are infectious disorders caused by unusual viruses similar to those causing scrapie in sheep and goats. Yet a paradox was presented by the occurrence of CJD in families, first reported more than 70 years ago (Kirschbaum 1924; Meggendorfer 1930), which appeared to be a genetic disease. The significance of familial CJD remained largely unappreciated until mutations in the protein coding region of the PrP gene on the short arm of chromosome 20 were discovered (Sparkes et al. 1986; Hsiao et al. 1989). The earlier finding that brain extracts from patients who had died of familial prion diseases inoculated into experimental animals often transmit disease posed a conundrum that was resolved with the genetic linkage of these diseases to mutations of the *PRNP* gene that encodes PrP^{C} (Masters et al. 1981a; Prusiner 1989a; Tateishi et al. 1992a). To date, all cases of familial prion disease were shown to cosegregate with *PRNP* missense or, in one case, nonsense mutations.

Table 1 *Human prion diseases*

Disease	Etiology
Kuru	Infection
Creutzfeldt–Jakob disease:	
Iatrogenic	Infection
Sporadic	Unknown
Familial	*PRNP* mutation
Variant	Presumed BSE infection
Gerstmann–Sträussler–Scheinker disease	*PRNP* mutation
Fatal familial insomnia	*PRNP* mutation

The most common form of prion disease in humans is sporadic CJD (sCJD). Its cause is unknown. Many attempts to show that the sporadic prion diseases are caused by infection have been unsuccessful (Malmgren et al. 1979; Brown et al. 1987; Harries Jones et al. 1988; Cousens et al., 1990). The discovery that inherited prion diseases are caused by germline mutation of the PrP gene raised the possibility that sporadic forms of these diseases might result from a somatic mutation (Prusiner 1989a). Alternatively, since PrP^{Sc} is formed from the cellular isoform of the prion protein, PrP^{C}, by a post-translational process (Borchelt et al. 1990), sporadic prion diseases may result from the spontaneous conversion of PrP^{C} into PrP^{Sc}.

CJD was reported to have a worldwide incidence of one case per 10^{6} inhabitants annually (Masters and Richardson 1978). However, in countries that carry out active surveillance programs, reported CJD incidence is often higher (Aguzzi et al. 2000a), and in Switzerland it has reached $3.0/10^{6}$/year (Glatzel et al. 2002, 2003b), suggesting that many cases may go undetected. Less than 1 percent of CJD cases are infectious, and most of those seem to be iatrogenic. Between 10 and 15 percent of cases of prion disease are inherited, whilst the remaining cases are sporadic. Kuru was once the most common cause of death among New Guinea women in the Fore region of the Highlands (Gajdusek and Zigas 1957, 1959; Gajdusek et al. 1966) but has virtually disappeared with the cessation of ritualistic cannibalism (Alpers 1987; Mead et al. 2003). Most patients with CJD present primarily with dementia, but approximately 10 percent exhibit cerebellar dysfunction as the initial sign. People with either kuru or GSS usually present with ataxia, whereas those with FFI manifest insomnia and autonomic dysfunction (Hsiao and Prusiner 1990; Brown 1992; Medori et al. 1992b).

PrP^{CJD} has been found in the brains of most patients who died of prion disease. The term PrP^{CJD} is sometimes used when referring to the abnormal isoform of PrP in human brain. In this chapter, PrP^{Sc} is used interchangeably with PrP^{CJD}. PrP^{Sc} is always used after human CJD prions have been passaged into an experimental animal, because the nascent PrP^{Sc} molecules are produced from host PrP^{C} and the PrP^{CJD} in the inoculum serves only to initiate the process. In the brains of some patients with inherited prion diseases, as well as transgenic mice expressing mouse (Mo) PrP with the human GSS point mutation (Pro→Leu), detection of PrP^{Sc} by western blotting has been problematic despite clinical and neuropathological hallmarks of neurodegeneration (Hsiao et al. 1990, 1994), but histological techniques such as histoblotting (Taraboulos et al. 1992a) have often revealed protease-resistant PrP.

Experimental transmission of neurodegeneration from the brains of patients with inherited prion diseases to

inoculated rodents has been less frequent than with sporadic cases (Tateishi et al. 1992a). Whether this distinction between transmissible and nontransmissible inherited prion diseases will persist is unclear. Transgenic mice expressing a chimeric Hu/Mo PrP gene are highly susceptible to human prions from sporadic and iatrogenic CJD (iCJD) cases (Telling et al. 1994), and – somewhat unexpectedly – transgenic mice expressing a full-length bovine *Prnp* transgene appear to be the best model for transmission of human prions to date (Scott et al. 1999). There is hope that suitable transgenic mice may eventually make the use of apes and monkeys for the study of human prion diseases unnecessary. To date, this is not yet possible for several reasons:

- the molecular determinants that determine species barriers are not fully understood, and may encompass species-specific host factors additionally to PrP
- the peripheral pathophysiology of prion diseases may differ considerably between mice and humans.

Scrapie is the most common natural prion disease of animals. An investigation into the etiology of scrapie followed the vaccination of sheep for louping ill virus with formalin-treated extracts of ovine lymphoid tissue unknowingly contaminated with scrapie prions (Gordon 1946). Two years later, more than 1 500 sheep developed scrapie from this vaccine. In the late 1990s a similar incident led to widespread scrapie infection of Italian sheep herds. Although the transmissibility of experimental scrapie became well established, the spread of natural scrapie within and among flocks of sheep remained puzzling. Parry argued that host genes were responsible for the development of scrapie in sheep. He was convinced that natural scrapie is a genetic disease which could be eradicated by proper breeding protocols (Parry 1962; Parry and Livett 1973). He considered its transmission by inoculation to be of importance primarily for laboratory studies and communicable infection of little consequence in nature. Other investigators viewed natural scrapie as an infectious disease and argued that host genetics only modulates susceptibility to an endemic infectious agent (Dickinson et al. 1965).

Prion-infested offal is thought to be responsible for the epidemic of BSE (Wilesmith et al. 1992b). Prions in the offal from scrapie-infected sheep, or perhaps from rare cows affected by hypothetical 'sporadic BSE,' seem to have survived the rendering process that produced meat and bone meal (MBM). Whether the 'Ur-BSE prion' originated from sheep, or was autochtonous to cows, is a question that may not be solvable, and is of mainly academic and legal significance.

The MBM was fed to cattle as a nutritional supplement. After BSE was recognized, MBM produced from domestic animal offal was banned from further use. Since 1986, when BSE was first recognized, >180 000 cattle have died of BSE. More than 130 persons have developed a 'new variant' of CJD (Chazot et al., 1996; http://www.doh.gov.uk/cjd/stats/aug02.htm, 2002; Will et al. 1996), which is likely to represent transmission of BSE to humans (Bruce et al. 1997; Collinge et al. 1996; Hill et al. 1997a).

As we learn about the molecular and genetic characteristics of prion proteins, our understanding of prions and their place in biology will undoubtedly undergo considerable change. Indeed, the discovery of PrP, the identification of pathogenic *PRNP* gene mutations, the differences in the structures of PrP^{C} and PrP^{Sc}, as well as studies of the process by which prions move from the site of infection to the brain, have already forced us to think about these diseases from viewpoints that had not been previously considered.

Development of the prion concept

HYPOTHESES ON THE NATURE OF THE SCRAPIE AGENT

The published literature contains a fascinating record of the structural hypotheses for the scrapie agent, proposed to explain the unusual features first of the disease and later those of the infectious agent. Among the earliest hypotheses was the notion that scrapie was a disease of muscle caused by the parasite *Sarcosporidia* (M'Fadyean, 1918; M'Gowan 1914). With the successful transmission of scrapie to animals, the hypothesis that scrapie is caused by a 'filtrable' virus became popular (Cuille and Chelle 1939; Wilson et al. 1950). With the findings of Tikvah Alper and her colleagues that scrapie infectivity resists inactivation by ultraviolet (UV) and ionizing irradiation (Alper et al. 1966, 1967), a myriad of hypotheses on the chemical nature of the scrapie agent emerged, including the quite prescient conjecture that it may consist of a self-replicating protein (Griffith 1967).

BIOASSAYS OF PRION INFECTIVITY

The experimental transmission of scrapie from sheep (Gordon 1946) to mice (Chandler 1961) gave investigators a more convenient laboratory model, which yielded considerable information on the nature of the unusual infectious pathogen that causes scrapie (Alper et al. 1966, 1967, 1978; Gibbons and Hunter 1967; Pattison and Jones 1967; Millson et al. 1971). Yet progress was slow because quantification of infectivity in a single sample required holding 60 mice for at least one year before accurate scoring could be accomplished (Chandler 1961).

Attempts to develop a more economical bioassay by relating the titre to incubation times in mice were unsuccessful (Eklund et al. 1963; Hunter and Millson 1964). However, some investigators used incubation times to characterize different 'strains' of scrapie agent, whilst others determined the kinetics of prion replication in

rodents (Dickinson and Meikle, 1969; Kimberlin and Walker 1978a, 1979). Quantitative bioassays based on incubation times had been applied to the measurement of picorna and other viruses three decades earlier (Gard 1940). After scrapie incubation times were reported to be approximately 50 percent shorter in Syrian hamsters than in mice (Marsh and Kimberlin 1975), studies were undertaken to determine whether the incubation times in hamsters could be related to the titer of the inoculated sample. It was found that there was an excellent inverse correlation between the length of the incubation time and the logarithm of the dose of inoculated prions, and a more rapid and economical bioassay was developed (Prusiner et al. 1980a, 1982b). This improved bioassay for the scrapie agent in Syrian golden hamsters accelerated purification of the infectious particles by a factor of nearly 100. Still, the soaring costs of animal caretaking make it impossible for most institutions to carry out large-scale incubation-time-based prion titration studies. The recent development of a quantitative, highly sensitive cell-based bioassay by Klohn and Weissmann may foster a much-needed quantum leap in prion analytics (Klohn et al. 2003), which could prove crucial for many practical purposes, such as validation of prion decontamination procedures.

THE PRION CONCEPT

Once an effective protocol was developed for preparation of partially purified fractions of scrapie agent from hamster brain, it became possible to demonstrate that the procedures that modify or hydrolyze proteins produce a diminution in scrapie infectivity (Prusiner et al. 1981a, 1982b). At the same time, tests done in search of a scrapie-specific nucleic acid were unable to demonstrate any dependence of infectivity on a polynucleotide (Prusiner 1982; Riesner et al. 1993), in agreement with earlier studies reporting the extreme resistance of infectivity to UV irradiation at 254 nm (Alper et al. 1967).

On the basis of these findings, it seemed unlikely that the infectious pathogen capable of transmitting scrapie was a virus or a viroid. For this reason the term 'prion' was introduced to distinguish the proteinaceous infectious particles that cause scrapie, CJD, GSS, and kuru from both viroids and viruses (Prusiner 1982). Hypotheses for the structure of the infectious prion particle included:

- proteins surrounding a nucleic acid encoding them (a virus)
- proteins associated with a small polynucleotide
- proteins devoid of nucleic acid (Prusiner 1982).

Mechanisms postulated for the replication of infectious prion particles ranged from those used by viruses to the synthesis of polypeptides in the absence of nucleic acid template to post-translational modifications of cellular proteins. Subsequent discoveries have narrowed hypotheses for both prion structure and the mechanism of replication.

Considerable evidence has accumulated over the past decade supporting the prion hypothesis. But while the prion concept is now enjoying considerable acceptance, it should not go unmentioned that several core issues regarding prion replication are still entirely obscure (Chesebro 1998).

Discovery of the prion protein

Once the dependence of prion infectivity on protein was clear, the search for a scrapie-specific protein intensified. Although the insolubility of scrapie infectivity made purification problematic, this property was used by Prusiner along with its relative resistance to degradation by proteases to extend the degree of purification (Prusiner et al. 1980a, 1981b). In subcellular fractions from hamster brain enriched for scrapie infectivity, a protease-resistant polypeptide of 27–30 kDa (later designated $PrP^{27–30}$) was identified, which was absent from controls (Bolton et al. 1982; McKinley et al. 1983). Radioiodination of partially purified fractions revealed a protein unique to preparations from scrapie-infected brains (Bolton et al. 1982; Prusiner et al. 1982a).

Progress in the study of prions was greatly accelerated by the discovery of PrP and determination of its N-terminal sequence (Bolton et al. 1982; Prusiner et al. 1982a, 1984). Purification of $PrP^{27–30}$ to near-homogeneity allowed determination of its NH_2-terminal amino acid sequence. Determination of a single, unique sequence for the NH_2 terminus of $PrP^{27–30}$ permitted the synthesis of an isocoding mixture of oligonucleotides that was subsequently used to identify incomplete PrP cDNA clones from hamster (Oesch et al. 1985) and mouse (Chesebro et al. 1985). cDNA clones encoding the entire open reading frames (ORF) of Syrian hamster (SHa) and Mo PrP were subsequently recovered (Basler et al. 1986; Locht et al. 1986).

The experiments described above established that PrP is encoded by a chromosomal gene, and not by a nucleic acid within the infectious scrapie prion particle (Oesch et al. 1985; Basler et al. 1986). Levels of PrP mRNA remain unchanged throughout the course of scrapie infection – an unexpected observation which led to the identification of the normal PrP gene product, a protein of 33–35 kDa, designated PrP^{C} (Basler et al. 1986; Oesch et al. 1985). PrP^{C} is protease-sensitive and soluble in nondenaturing detergents, whereas $PrP^{27–30}$ is the protease-resistant core of a 33–35 kDa disease-specific protein, designated PrP^{Sc}, which is insoluble in detergents (Meyer et al. 1986).

THE *PRNP* GENE LOCUS

The entire ORF of all known mammalian and avian *Prnp* genes is contained within a single exon (Figure 1) (Basler et al. 1986; Westaway et al. 1987; Hsiao et al. 1989; Gabriel et al. 1992). This feature of the PrP gene eliminates the possibility that PrP^{Sc} arises from alter-

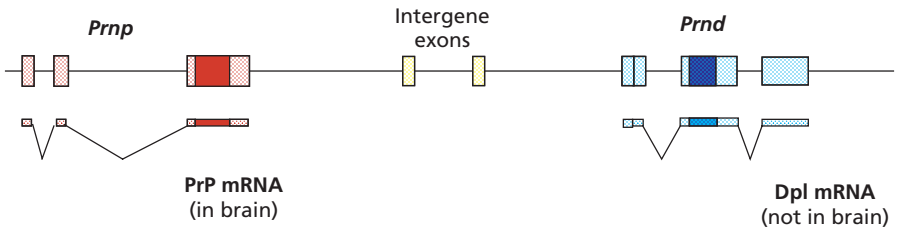

Figure 1 *Structure and organization of the chromosomal* Prnp *and* Prnd *genes. In all mammals examined the entire ORF is contained within a single exon. The 5′-untranslated region of the PrP mRNA is derived from either one or two additional exons (Basler et al. 1986; Puckett et al. 1991; Westaway et al. 1991, 1994a). Only one PrP mRNA has been detected. A prion protein homologue termed Dpl is encoded by the* Prnd *locus. PrP^{Sc} is thought to be derived from PrP^{C} by a post-translational process (Basler et al. 1986; Borchelt et al. 1990, 1992; Caughey et al. 1991b; Taraboulos et al. 1992b). The amino acid sequence of PrP^{Sc} is identical to that predicted from the translated sequence of the DNA encoding the PrP gene (Basler et al. 1986; Stahl et al. 1993), and no unique post-translational chemical modifications have been identified that might distinguish PrP^{Sc} from PrP^{C}. Thus, it seems likely that PrP^{C} undergoes a conformational change as it is converted to PrP^{Sc}. A second gene bearing remarkable structural homologies with* Prnp *was identified approximately 16 kb 3′ of the* Prnp *locus, and was termed* Prnd*. The product of this locus is termed* Doppel*.*

native RNA splicing (Basler et al. 1986; Westaway et al. 1987, 1991), although mechanisms such as RNA editing or protein splicing remain a possibility (Blum et al. 1990; Kane et al. 1990). The two exons of the SHaPrP gene are separated by a 10 kb intron: exon 1 encodes a portion of the 5′-untranslated leader sequence whilst exon 2 encodes the ORF and the 3′-untranslated region (Basler et al. 1986). The murine and ovine PrP genes are composed of three exons; exon 3 is analogous to exon 2 of the hamster (Westaway et al. 1991, 1994a). The promoters of both the SHa and Mo PrP genes contain multiple copies of GC-rich repeats and are devoid of TATA boxes. These GC nonamers represent a motif that may function as a canonical binding site for the transcription factor Sp1.

PrP genes map to the short arm of human chromosome 20 and to the homologous region of mouse chromosome 2 (Sparkes et al. 1986). Hybridization studies demonstrated <0.002 *Prnp* gene sequences per ID_{50} unit in purified prion fractions, strongly suggesting that a nucleic acid encoding PrP^{Sc} cannot possibly constitute a component of the infectious prion particle (Oesch et al. 1985). This is a major feature that distinguishes prions from viruses, including retroviruses that carry cellular oncogenes and from satellite viruses that derive their coat proteins from other viruses previously infecting cells. Although *Prnp* mRNA is constitutively expressed in the brains of adult animals (Chesebro et al. 1985; Oesch et al. 1985), it is highly regulated during development (Manson et al. 1992; Sales et al. 2002). In the septum, levels of PrP mRNA and choline acetyltransferase increased in parallel during development (Mobley et al. 1988). In other brain regions, PrP gene expression occurred at an earlier age.

PrP amyloid

The discovery of $PrP^{27–30}$ in fractions enriched for scrapie infectivity was accompanied by the identification of rod-shaped particles in the same fractions (Prusiner et al. 1982a, 1983). The fine structure of these rod-shaped particles failed to reveal any regular substructure. Indeed, the irregular ultrastructure of the prion rods differentiates them from most viruses, which have regular, distinct structures (Williams 1954), and made them indistinguishable ultrastructurally from many purified amyloids (Cohen et al. 1982). This analogy was extended when the prion rods were found to display the tinctorial properties of amyloids (Prusiner et al. 1983). These findings were followed by the demonstration that amyloid plaques in the brains of humans and other animals with prion diseases contain PrP, as determined by immunoreactivity and amino acid sequencing (Bendheim et al. 1984; DeArmond et al. 1985; Kitamoto et al. 1986; Roberts et al. 1988; Tagliavini et al. 1991).

Solubilization of $PrP^{27–30}$ into liposomes with retention of infectivity (Gabizon et al. 1987) suggests that large PrP polymers are not required for infectivity – although it is well possible that PrP^{Sc} oligomers may constitute nucleation centers pivotal to prion replication (Jarrett and Lansbury 1993; Lansbury 1994). In Tg(SHaPrP) mice inoculated with SHa prions, numerous amyloid plaques were found but none was observed if these mice were inoculated with mouse prions, indicating that amyloid formation is not an obligatory feature of prion diseases (Prusiner et al. 1990; Prusiner and DeArmond 1994). In agreement with these studies, PrP plaques are consistently found in some inherited prion diseases (Ghetti et al. 1989) but absent from others (Hsiao et al. 1991a).

Formation of PrP^{Sc}

Whether PrP^{C} is the substrate for PrP^{Sc} formation, or a restricted subset of PrP molecules are precursors for PrP^{Sc}, or whether reactive transition states exist (Weissmann 1991a), remains to be established. Several experimental results argue that PrP molecules destined to become PrP^{Sc} exit to the cell surface, as does PrP^{C} (Stahl et al. 1987) prior to its conversion into PrP^{Sc}

(Caughey and Raymond 1991; Borchelt et al. 1992; Taraboulos et al. 1992b).

Like other glycophosphatidylinositol (GPI)-anchored proteins, PrP^{C} seems to recirculate via a subcellular compartment bounded by cholesterol-rich, non-acidic, detergent-insoluble membranes denominated 'rafts' (Figure 2) (Keller et al. 1992; Anderson 1993; Shyng et al. 1994; Gorodinsky and Harris 1995; Taraboulos et al. 1995). Within the raft compartment, GPI-anchored PrP^{C} seems to be either converted into PrP^{Sc} or partially degraded (Taraboulos et al. 1995; Meier et al. 2003). After denaturation PrP^{Sc}, like PrP^{C}, can be released from the cell membranes by digestion with phosphatidylinositol-specific phospholipase C, suggesting that PrP^{Sc} is tethered only by the GPI anchor (Borchelt et al. 1993). In scrapie-infected cultured cells, PrP^{Sc} is trimmed at the N terminus to form $PrP^{27–30}$ in an acidic intracellular compartment (Caughey et al. 1991b; Taraboulos et al. 1992b). In contrast to cultured cells, the N-terminal trimming of PrP^{Sc} is minimal in brain, where little $PrP^{27–30}$ is found (McKinley et al. 1991a). Deleting the GPI addition signal resulted in greatly diminished synthesis of PrP^{Sc} (Rogers et al. 1993), and soluble dimeric PrP^{C} inhibits prion replication (Meier et al. 2003). In contrast to PrP^{C}, PrP^{Sc} accumulates primarily within cells, where it is deposited in cytoplasmic vesicles, many of which seem to be secondary lysosomes (Taraboulos et al. 1990b, 1992b; Caughey et al. 1991b; McKinley et al. 1991b; Borchelt et al. 1992). Studies of scrapie-infected brains suggest that PrP^{Sc} accumulates within either lysosomes or late endosomes (Laszlo et al. 1992; Arnold et al. 1995).

Although most of the difference in the mass of $PrP^{27–30}$ predicted from the amino acid sequence and observed after post-translational modification is due to complex-type oligosaccharides (Endo et al. 1989; Haraguchi et al. 1989), these sugar chains are not required for PrP^{Sc} synthesis in scrapie-infected cultured cells, based on experiments with the asparagine-linked glycosylation inhibitor tunicamycin, and site-directed mutagenesis studies (Taraboulos et al. 1990a).

SEARCH FOR A CHEMICAL MODIFICATION OF PRP

The discovery that the entire ORF of the PrP gene is contained within a single exon, first in Syrian hamsters and later in humans and other animals, argued that PrP^{Sc} is not generated by alternative splicing (Basler et al. 1986; Goldmann and Hunter 1988; Hsiao et al. 1989; Goldmann et al. 1991b; Westaway et al. 1994a, 1994b). This prompted a search for a post-translational chemical modification to explain the differences in the properties of these two PrP isoforms (Stahl et al. 1993). PrP^{Sc} was analyzed by mass spectrometry and gas phase sequencing in order to identify any amino acid substitutions or post-translational chemical modifications. The amino acid sequence was the same as

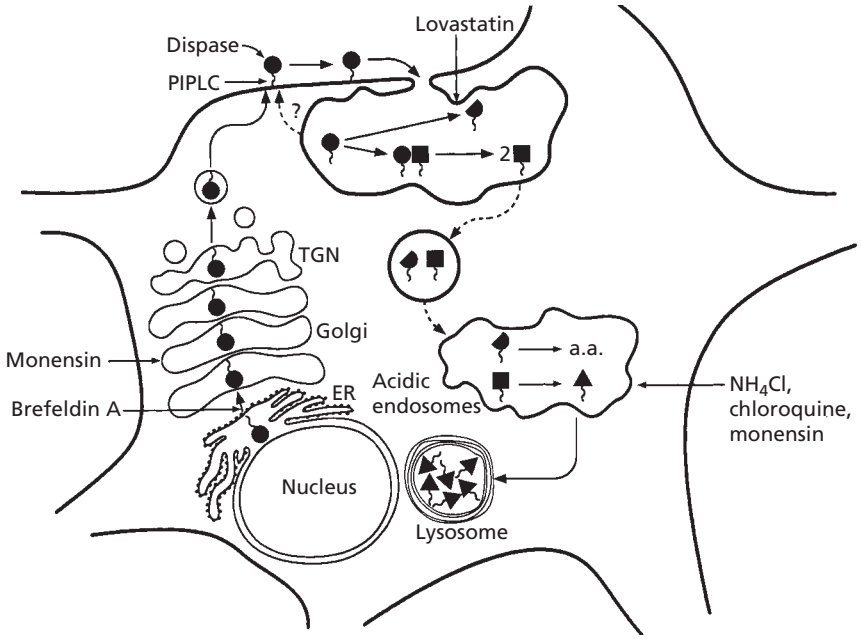

Figure 2 *Pathways of prion protein synthesis and degradation in cultured cells. PrP^{Sc} is denoted by squares; circles denote PrP^{C}. Before becoming protease-resistant, the PrP^{Sc} precursor transits through the plasma membrane and is sensitive to dispase or PIPLC added to the medium. PrP^{Sc} formation probably occurs in a compartment accessible from the plasma membrane, such as caveolae or early endosomes, both of which are non-acidic compartments. The synthesis of nascent PrP^{Sc} seems to require the interaction of PrP^{C} with existing PrP^{Sc}. In cultured cells, but not brain, the N terminus of PrP^{Sc} is trimmed to form $PrP^{27–30}$; PrP^{Sc} then accumulates primarily in secondary lysosomes. The inhibition of PrP^{Sc} synthesis by brefeldin A demonstrates that the endoplasmic reticulum (ER)–Golgi is not competent for its synthesis and that transport of PrP down the secretory pathway is required for the formation of PrP^{Sc}.*

that deduced from the translated ORF of the PrP gene, and no candidates for post-translational chemical modifications that might differentiate PrP^C from PrP^{Sc} were found (Stahl et al. 1993). These findings forced consideration of the possibility that conformation distinguishes the two PrP isoforms.

STRUCTURES OF PURIFIED PRP^C AND PRP^{SC}

Low-resolution structural studies indicated that PrP^C has a high α-helix content (ca. 40 percent) and little β-sheet (3 percent) (Pan et al. 1993). These findings were refined by Wüthrich and colleagues who determined the fine structure of PrP^C by nuclear magnetic resonance spectroscopy (Riek et al. 1996; Hornemann et al. 1997) (Figure 3a), and later also by crystallographic studies (Figure 3b) (Knaus et al. 2001). By contrast, the β-sheet content of PrP^{Sc} is ca. 40 percent and the α-helix ca. 30 percent as measured by Fourier-transformed infrared (FTIR) (Pan et al. 1993) and circular dichroism (CD) spectroscopy (Safar et al. 1993b) (Figure 4). No high-resolution structure is available for PrP^{Sc}, although interesting models have been conjectured on the basis of electron crystallography (Wille et al. 2002). That $PrP^{27–30}$ has a high β-sheet content was inferred from the green-gold birefringence of the prion rods after staining with Congo red (Prusiner et al. 1983). Indeed, $PrP^{27–30}$ polymerized into rod-shaped particles with ultrastructural appearance of amyloid (Figure 5) contains ca. 50 percent β-sheet and ca. 20 percent α-helix (Caughey et al. 1991a; Gasset et al. 1993; Safar et al. 1993a). In contrast to $PrP^{27–30}$ which did polymerize into rod-shaped amyloids, neither purified PrP^C nor PrP^{Sc} formed aggregates detectable by electron microscopy (Figure 5) (McKinley et al. 1991a; Pan et al. 1993).

It is still possible that a hitherto undetected chemical modification of a small fraction of PrP^{Sc} initiates the conversion process into PrP^{Sc}. Limitations of the current analytical techniques for proteins prevent a stringent study of this question, and it is quite possible that PrP^{Sc} consists of inhomogeneous species, only some of which are capable of propagation. Because PrP^{Sc} seems to be the only component of the 'infectious' prion particle, it is likely that this conformational transition is a fundamental event in the propagation of prions. Accordingly, denaturation of $PrP^{27–30}$ under conditions which reduced scrapie infectivity resulted in diminution of β-sheet content (Gasset et al. 1993; Safar et al. 1993b).

CONVERSION OF PRP^C INTO PRP^{SC}

Studies with Tg(SHaPrP) mice have provided genetic information about the process in which PrP^C is converted into PrP^{Sc} through the formation of a PrP^C/PrP^{Sc} complex (Prusiner et al. 1990), even if such complex was not isolated physically. The level of PrP^C expression seems to be directly proportional to the rate of PrP^{Sc} formation and, thus, inversely related to the length of the incubation time. Formation of the PrP^C/PrP^{Sc} complex was facilitated when the amino acid sequences of the two PrP isoforms were the same; SHaPrP differs from MoPrP at 16 positions out of 254. Differences in amino acid sequence delayed prion formation, resulting in a prolongation of the incubation time (Scott et al. 1989).

The protein-only hypothesis posits that the agent is devoid of nucleic acid and consists solely of an abnormal conformer of the cellular prion protein, PrP^C (Figure 6, p. 10).

In vitro conversion of recombinant ^{35}S-labeled PrP^C to a PrP^{Sc}-like protease-resistant moiety was achieved by mixing with a 50-fold excess of PrP^{Sc} (Kocisko et al. 1994). The binding of PrP^C to PrP^{Sc} depends on the same residues (Kocisko et al. 1995) that render Tg(MH2M) mice susceptible to SHa prions (M. Scott et al. 1993) and seems to be strain-dependent (Bessen et al. 1995). However, evidence is still lacking that the converted material acquires infectious properties (Aguzzi and Heikenwalder 2003).

Propagation of prions

Initial transgenetic studies had shown that the 'species barrier' between mice and Syrian hamsters for the transmission of prions can be abolished by expression of a SHaPrP transgene in mice (Scott et al. 1989). Transgenic mice expressing human (Hu) PrP were then constructed. These Tg(HuPrP) mice inoculated with human prions failed to develop CNS dysfunction more frequently than nontransgenic controls (Telling et al. 1994). Faced with this apparent dichotomy, Scott constructed mice expressing a chimeric Hu/Mo PrP transgene designated MHu2M because earlier studies had shown that chimeric Syrian hamster/mouse (SHa/Mo) PrP transgenes supported transmission of either Mo or SHa prions (Scott et al., 1992; M. Scott et al. 1993). The Tg(MHu2M) mice expressing the chimeric transgene were highly susceptible to human prions, suggesting that Tg(HuPrP) mice have difficulty converting $HuPrP^C$ into PrP^{Sc} (Telling et al. 1994). Although MoPrP and HuPrP differ at 28 residues, only nine or perhaps fewer amino acids in the region between codons 96 and 167 feature in the species barrier in the transmission of human prions into mice, as demonstrated by the susceptibility of Tg(MHu2M) mice to human prions.

When Tg(HuPrP) mice were crossed with gene-targeted mice in which the MoPrP gene had been disrupted ($Prnp^{0/0}$) (Büeler et al. 1992), they were rendered susceptible to human prions. These findings suggested that Tg(HuPrP) mice were resistant to human prions because $MoPrP^C$ inhibited the conversion of $HuPrP^C$ into PrP^{Sc}: once $MoPrP^C$ was removed by gene ablation, the inhibition was abolished (Telling et al. 1995). Whereas earlier studies argued that PrP^C forms a complex with PrP^{Sc} during the formation of nascent

PrP^{Sc} (Prusiner et al. 1990), these findings suggested that PrP^{C} also binds to one (or more than one) additional macromolecule during the conversion process. Telling and colleagues called this second macromolecule 'protein X' with the proviso that a second binding site on PrP^{Sc} might also function as protein X. However, 8 years after its initial postulation, no physical evidence for protein X has come forward, and Collinge and colleagues have observed exceptions to the genetic observations that had sparked the invention of protein X. Therefore, at present it is still possible that protein X is indeed a prion replication cofactor, but it is equally possible that it is nonexistent, that it exists but is not a protein, or that multiple host-encoded factors ('proteins X, Y, and Z') distinct from PrP may bind to PrP^{Sc} (Fischer et al. 2000; Maissen et al. 2001) and influence prion replication in vivo through a variety of direct and indirect mechanisms. On the basis of the available spectrum of data, one may speculate that the latter scenario is by far the most likely.

Transgenetics and gene targeting

Ablation of the PrP gene (*Prnp*$^{0/0}$) affected neither development nor behavior of the mice (Büeler et al. 1992; Manson et al. 1994a). In fact, *Prnp*$^{0/0}$ mice have remained healthy for more than 2 years. *Prnp*$^{0/0}$ mice are resistant to prions and do not propagate scrapie infectivity (Büeler et al. 1993; Prusiner et al. 1993; Sailer et al. 1994). *Prnp*$^{0/0}$ mice were sacrificed 5, 60, 120, and 315 days after inoculation with Rocky Mountain Laboratory prions passaged in CD-1 Swiss mice. Except for

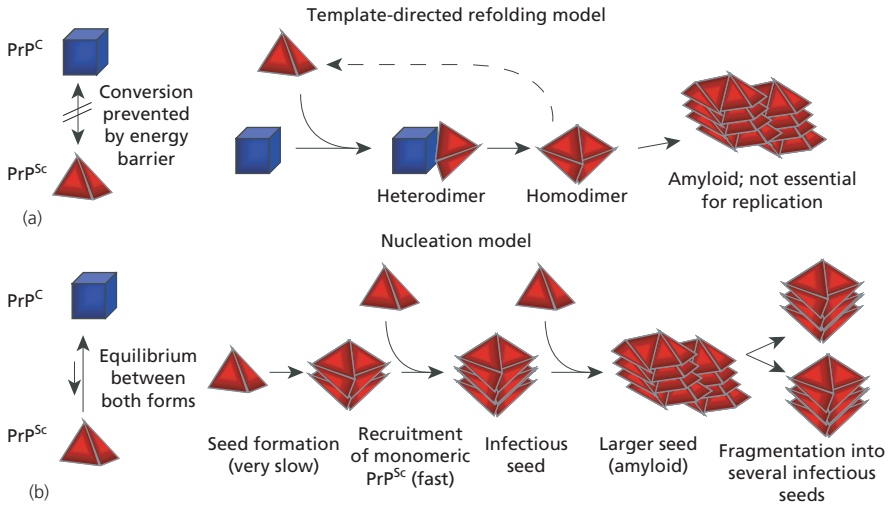

Figure 6 *Models for the conformational conversion of PrP^C into PrP^{Sc}.* **(a)** *The 'refolding' or template-assistance model postulates an interaction between exogenously introduced PrP^{Sc} and endogenous PrP^C, which is induced to transform itself into further PrP^{Sc}. A high-energy barrier may prevent spontaneous conversion of PrP^C into PrP^{Sc}.* **(b)** *The 'seeding' or nucleation-polymerization model proposes that PrP^C and PrP^{Sc} are in a reversible thermodynamic equilibrium. Only if several monomeric PrP^{Sc} molecules are mounted into a highly ordered seed, can further monomeric PrP^{Sc} be recruited and eventually aggregates to amyloid. Within such a crystallike seed, PrP^{Sc} becomes stabilized. Fragmentation of PrP^{Sc} aggregates increases the number of nuclei, which can recruit further PrP^{Sc} and thus results in apparent replication of the agent.*

residual infectivity from the inoculum detected at 5 days after inoculation, no infectivity was detected in the brains of $Prnp^{0/0}$ mice. $Prnp^{0/0}$ mice crossed with Tg(SHaPrP) mice were rendered susceptible to hamster prions but remained resistant to mouse prions (Büeler et al. 1993). Since the absence of PrP^C expression does not provoke disease, it is likely that scrapie and the other prion diseases result not from an inhibition of PrP^C function due to PrP^{Sc} but rather from interference with some as yet undefined cellular process (Hegde et al. 1998, 1999).

Mice heterozygous ($Prnp^{+/0}$) for ablation of the PrP gene had prolonged incubation times when inoculated with mouse prions (Figure 7) (Büeler et al. 1994; Manson et al. 1994b). The $Prnp^{+/0}$ mice developed signs of neurological dysfunction at 400–460 days after inoculation. Therefore, the amount of available PrP^C is rate-limiting for the development of disease – a finding with significant implications for prion therapy. These findings are in agreement with studies on Tg(SHaPrP) mice in which increased SHaPrP expression was accompanied by diminished incubation times (Prusiner et al. 1990), and reinforce the idea that the concentration of PrP^C in brain is rate-limiting for its conversion into PrP^{Sc}.

Because $Prnp^{0/0}$ mice do not express PrP^C, they can be easily immunized to produce α-PrP antibodies. $Prnp^{0/0}$ mice immunized with mouse or hamster prion rods produced α-PrP antisera that bound mouse, SHa, and human PrP (Prusiner et al. 1993; Brandner et al. 1996b). These findings contrast with earlier studies in which α-MoPrP antibodies could not be produced in mice, presumably because the mice had been rendered tolerant by the presence of $MoPrP^C$ (Barry and Prusiner 1986; Kascsak et al. 1987; Rogers et al. 1991). That $Prnp^{0/0}$ mice readily produce α-PrP antibodies is consistent with the hypothesis that the lack of an immune response in prion diseases is due to the fact that PrP^C and PrP^{Sc} share many epitopes. For reasons that are not understood, $Prnp^{0/0}$ mice have not proved useful to produce α-PrP antibodies that specifically recognize CD epitopes present on PrP^{Sc} but absent from PrP^C – although such experiments have now been attempted for more than a decade.

MODELING OF GSS IN TRANSGENIC MICE

The codon 102 point mutation found in GSS patients was introduced into the MoPrP gene and Tg(MoPrP-P101L)H mice were created expressing high (H) levels of the mutant transgene product. Two lines of Tg(MoPrP-P101L)H mice spontaneously developed CNS degeneration, characterized by clinical signs indistinguishable from experimental murine scrapie and neuropathology consisting of widespread spongiform morphology and astrocytic gliosis (Hsiao et al. 1990) and PrP amyloid plaques (Hsiao et al. 1994). Excitingly, transmission of brain homogenate from Tg(MoPrP-P101L)H mice to healthy mice expressing lower levels of the same transgene (denoted Tg196/$Prnp^{0/0}$) induced spongiform encephalopathy (Telling et al. 1996).

In other studies, modifying the expression of mutant and wild-type *Prnp* genes in transgenic mice permitted experimental manipulation of the pathogenesis of both inherited and infectious prion diseases. Although overexpression of the wtPrP-A transgene ca. eightfold was not deleterious to the mice, it did shorten scrapie incubation times to as little as 45 days after inoculation with mouse scrapie prions (Telling et al. 1996).

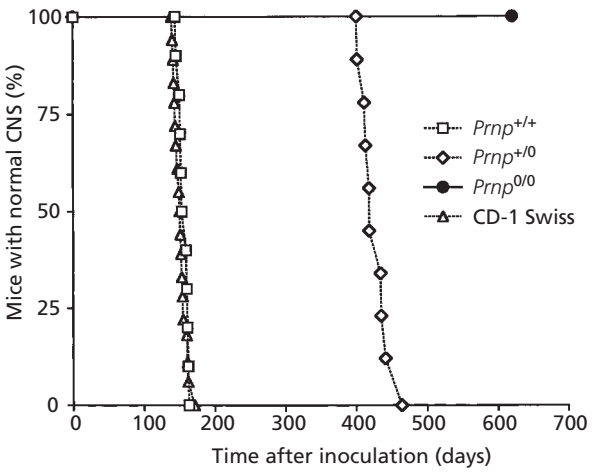

Figure 7 *Incubation times in PrP gene ablated* $Prnp^{+/0}$ and $Prnp^{0/0}$ mice as well as wild-type $Prnp^{+/+}$ and CD-1 mice inoculated with RML mouse prions. The RML prions were heated and irradiated at 254 nm prior to intracerebral inoculation into CD-1 Swiss mice (open triangles), $Prnp^{+/+}$ mice (open squares), $Prnp^{+/0}$ mice (open diamonds) or $Prnp^{0/0}$ mice (solid circle).

Prion diversity

The diversity of scrapie prions was first appreciated in goats inoculated with 'hyper' and 'drowsy' isolates (Pattison and Millson 1961b). Scrapie isolates or 'strains' from goats with a drowsy syndrome transmitted a similar syndrome to inoculated recipients, whereas those from goats with a 'hyper' or ataxic syndrome transmitted an ataxic form of scrapie to recipient goats. Subsequently, studies in mice demonstrated the existence of many scrapie 'strains' in which extracts prepared from the brains of mice inoculated with a particular preparation of prions produced a similar disease in inoculated recipients (Dickinson and Fraser 1979; Bruce and Dickinson 1987; Dickinson and Outram 1988). While the clinical signs of scrapie for different prion isolates in mice tended to be similar, the isolates could be distinguished by the incubation times, the distribution of CNS vacuolation that they produced, and whether or not amyloid plaques formed.

That such isolates could be propagated through multiple passages in mice suggested that the scrapie pathogen has a nucleic acid genome that is copied and passed on to nascent prions (Dickinson et al. 1968; Bruce and Dickinson 1987). But no evidence for scrapie-specific nucleic acid encoding information that specifies the incubation time and the distribution of neuropathological lesions has emerged from considerable efforts using a variety of experimental approaches. In striking contrast, mice expressing PrP transgenes have demonstrated that the level of PrP expression is inversely related to the incubation time (Prusiner et al. 1990). Furthermore, the distribution of CNS vacuolation and attendant gliosis are a consequence of pattern of PrP^{Sc} deposition which can be altered by both PrP genes and non-PrP genes (Prusiner et al. 1990). These observations taken together begin to build an argument for PrP^{Sc} as the informational molecule in which prion 'strain'-specific information is encrypted. Deciphering the mechanism by which PrP^{Sc} carries information for prion diversity and passes it onto the nascent prions is a challenging goal. Whether PrP^{Sc} can adopt multiple conformations, each one of which produces prions exhibiting distinct incubation times and patterns of PrP^{Sc} deposition, remains to be determined (Cohen et al. 1994). Preliminary immunochemical evidence suggests that PrP^{Sc} of different strains may expose different epitopes (Safar et al. 1998), and may display different stability to chaotropic salts (Peretz et al. 2002) – which perhaps may provide indirect evidence for conformational differences, but may also indicate association with different 'third parties' of proteic or other nature.

PRION STRAINS AND VARIATIONS IN PATTERNS OF DISEASE

Scrapie was first transmitted to sheep and goats by intraocular inoculation (Cuille and Chelle 1939) and later by intracerebral, oral, subcutaneous, intramuscular, and intravenous injections of brain extracts from sheep developing scrapie. Incubation periods of 1–3 years were common, and often many of the inoculated animals failed to develop disease (Dickinson and Stamp 1969; Hadlow et al. 1980, 1982). Different breeds of sheep exhibited markedly different susceptibilities to scrapie prions inoculated subcutaneously, suggesting that the genetic background might influence host permissiveness (Gordon 1966).

The lengths of the incubation times have been used to distinguish prion strains inoculated into sheep, goats, mice, and hamsters. Dickinson and his colleagues developed a system for 'strain typing' by which mice with genetically determined short and long incubation times were used in combination with the F1 cross (Dickinson et al. 1968, 1984; Dickinson and Meikle 1971). For example, C57BL mice exhibited short incubation times of ca. 150 days when inoculated with either the ME7 or the Chandler isolates; VM mice inoculated with these same isolates had prolonged incubation times of ca. 300 days. The mouse gene controlling incubation times was labelled *Sinc* and long incubation times were said to be a dominant trait because of prolonged incubation times in F1 mice. Prion strains were categorized into two groups based on their incubation times:

1. those causing disease more rapidly in 'short' incubation time C57BL mice
2. those causing disease more rapidly in 'long' incubation time VM mice.

Noteworthy are the 22A and 87V prion strains that can be passaged in VM mice while maintaining their distinct characteristics.

MOLECULAR BASIS OF PRION STRAINS

The mechanism by which isolate-specific information is carried by prions remains enigmatic; indeed, explaining the molecular basis of prion diversity seems to be a formidable challenge. Some investigators are still contending that scrapie is caused by a viruslike particle containing a scrapie-specific nucleic acid that encodes the information expressed by each isolate (Bruce and Dickinson 1987). To date, no such polynucleotide has been identified, despite using a wide variety of techniques, including measurements of the nucleic acids in purified preparations. An alternative hypothesis has been suggested that PrP^{Sc} alone is capable of transmitting disease but the characteristics of PrP^{Sc} might be modified by a cellular nucleic acid (Weissmann 1991b). This accessory cellular polynucleotide is postulated to induce its own synthesis upon transmission from one host to another, but there is no experimental evidence to support its existence.

Two additional hypotheses not involving a nucleic acid have been offered to explain distinct prion isolates: a non-nucleic acid second component might create prion diversity, or post-translational modification of PrP^{Sc} might be responsible for the different properties of distinct prion isolates (Prusiner 1991). Whether the PrP^{Sc} modification is chemical or only conformational remains to be established, but no candidate chemical modifications have been identified (Stahl et al. 1993). Structural studies of GPI anchors of two SHa isolates have failed to reveal any differences; it is interesting that ca. 40 percent of the anchor glycans have sialic acid residues (Stahl et al. 1992). A portion of the PrP^{C} GPI anchors also have sialic acid residues; PrP is the first protein found to have sialic acid residues attached to GPI anchors.

Multiple prion isolates might be explained by distinct PrP^{Sc} conformers that act as templates for the folding of de novo synthesized PrP^{Sc} molecules during prion 'replication.' Although it is clear that passage history can be responsible for the prolongation of incubation time when prions are passed between mice expressing different PrP allotypes (Carlson et al. 1989) or between species (Prusiner et al. 1990), many scrapie strains show distinct incubation times in the same inbred host (Bruce et al. 1991).

PrP^{Sc} species associated with two hamster-adapted scrapie strains, hyper (HY) and drowsy (DY), proved to display characteristic clinical and histopathological properties as well as distinct biochemical patterns with respect to proteinase K digestion (Bessen and Marsh 1992, 1994) – which may be explainable by the presence of different conformations of PrP^{Sc}. Analogous findings have been made with other prion strains propagated in mice. In addition, PrP^{Sc} of certain strains differ in the ratio of diglycosylated to the monoglycosylated form. Based on the fragment size and the relative abundance of individual bands, three distinct patterns (PrP^{Sc} types 1–3) were defined for sporadic and iCJD cases (Collinge et al. 1996; Parchi et al. 1996, 1999). By contrast, all cases of vCJD displayed a novel pattern, designated type 4 by Collinge, and type IIb by Parchi and Gambetti (Figure 8). Interestingly, brain extracts from BSE-infected cattle as well as BSE-inoculated macaques exhibited a type 4 pattern. Even more intriguingly, transmission of BSE or vCJD to mice produced mouse PrP^{Sc} with a type 4 pattern indistinguishable from the original inoculum (Hill et al. 1997a) – findings that impressively support the hypothesis that vCJD is the human counterpart to BSE. An additional tool, which may eventually serve to characterize prion strains, utilizes the differential affinity of certain antibodies for properly folded and denatured isoforms of PrP, thereby differentiating as many as eight different conformers (Safar et al. 1998). This provides further circumstantial evidence for the assumption that strain specificity is encrypted within the physical structure of PrP.

THE FUNCTION OF THE CELLULAR PRION PROTEIN

Despite considerable efforts, the physiological function of PrP^{C} is still unclear. A proposed role for PrP^{C} in synaptic function (Collinge et al. 1994) has been questioned by other investigators (Lledo et al. 1996) and a possible regulation of circadian rhythm by PrP^{C} has remained more-or-less anecdotal (Tobler et al. 1996). Hence, the only definite phenotype of $Prnp^{0/0}$ mice is their resistance to prion inoculation (Büeler et al. 1993). It seems, however, rather unlikely that a singular protein that is as highly conserved among species as PrP^{C}, from turtles to frogs, fish, and humans, has evolved for the sole reason of bestowing susceptibility to prion diseases.

If the function of PrP^{C} were completely unrelated to prion disease pathogenesis, PrP^{C} may be just one of many proteins whose function awaits clarification. Yet the function of PrP^{C} may very well have something to do, in a subtle way, with prion-induced damage. *Prnp* ablation does not elicit disease, even when induced postnatally (Mallucci et al. 2002): hence prion pathology is unlikely to come about by simple loss of PrP^{C} function. If PrP^{C} transduces a signal (in analogy to many other GPI-linked proteins), or possesses some enzymatic activity, one could speculate that conversion to PrP^{Sc} may alter signal transduction strength, or substrate specificity, thereby conferring a toxic dominant function. In these scenarios, understanding the function of PrP^{C} may be instrumental to deciphering prion pathology, and perhaps even to devising therapeutical approaches.

Is PrP^{C} an enzyme? Glockshuber noted that PrP^{C} has similarities to membrane-anchored signal peptidases (Glockshuber et al. 1998), but his observation has not been substantiated by functional data. PrP^{C} can bind

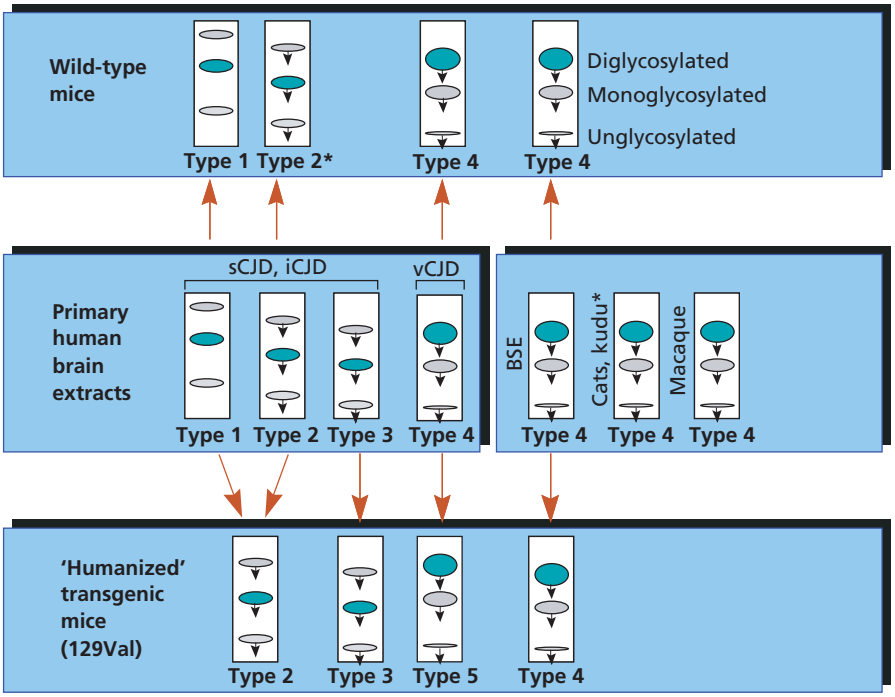

Figure 8 *Patterns of PrP glycosylation. Representation of the three glycosylated PrP^{Sc} moieties (un-, mono-, and diglycosylated PrP^{Sc}) in immunoblots of brain extracts after digest with proteinase K. Different inocula result in specific mobilities of the three PrP bands as well as different predominance of certain bands (middle panel). These characteristic patterns can be retained, or changed to other predictable patterns after passage in wild-type (upper panel) or humanized mice (PrP-deficient mice bearing a human PrP transgene, lower panel). Based on the fragment size and the relative abundance of individual bands, three distinct patterns (PrP^{Sc} types 1–3) were defined for sporadic and iatrogenic CJD cases. By contrast, all cases of vCJD displayed a novel pattern, designated as type 4 pattern.*

copper (Brown et al. 1997; Wadsworth et al. 1999), but reports of increased copper content of neurons lacking PrP^{C} have been questioned by contradictory findings (Waggoner et al. 2000). The speculation that PrP^{C} may be a superoxide dismutase (Brown et al., 1997; D.R. Brown et al. 1999) was perceived as particularly attractive in view of its multiple copper-binding sites. However, PrP^{C} does not make any measurable contribution to dismutase activity in vivo (Hutter et al. 2003; Waggoner et al. 2000). Interestingly, it was recently suggested that amino proximally truncated PrP^{C} may depress endogenous dismutase activity (Sakudo et al. 2003).

Perhaps PrP^{C} and PrP^{Sc} do not possess any intrinsic biological activity, yet they modify the function of other proteins. This supposition has prompted a search for PrP-interacting partners, and there is no dearth of PrP-binding proteins: the antiapoptotic protein Bcl-2 (Kurschner et al. 1995), caveolin (Gorodinsky and Harris 1995; Harmey et al. 1995), the laminin receptor precursor (Rieger et al. 1997), plasminogen (Fischer et al. 2000) and N-CAM (Schmitt-Ulms et al. 2001). None of these interactors, however, have yet revealed a functional pathway in which PrP^{C} would be involved in vivo. It was recently shown that PrP-deficient macrophages do not support bacterial 'swimming internalization' of the gram-negative bacterium, *Brucella abortus* (Watarai et al. 2003) and that PrP^{C} interacts with a *Brucella* heat-shock protein, Hsp60. These intriguing findings raise the question of whether PrP^{C} is a part of a general Hsp60-dependent 'danger-sensing' mechanism (Aguzzi and Hardt 2003).

THE PRION DOPPELGANGER

After the advent of large-scale sequencing efforts and genome projects, it was realized that there is an ORF directly adjacent of *Prnp* that encodes a protein sharing significant homology with PrP^{C} (Moore et al. 1999). The novel gene, *Prnd*, is located 16 kb downstream of *Prnp* in the mouse genome, and encodes a protein of 179 residues, which was termed Dpl ('downstream of the *Prnp* locus' or 'Doppel,' German for 'double') (Moore et al. 1999; Weissmann and Aguzzi 1999; Behrens and Aguzzi 2002). The *Prnd* gene is evolutionarily conserved from humans to sheep and cattle, and shows roughly 25 percent identity with the carboxy-proximal two-thirds of PrP^{C}. Structural studies indicate that Dpl contains three α-helices, like PrP^{C}, and two disulfide bridges between the second and third helices (Lu et al. 2000; Silverman et al. 2000; Mo et al. 2001). Dpl mRNA is expressed at high levels in testis, less in other peripheral organs and, notably, at very low levels in brain of adult wild-type mice. However, significant *Prnd* mRNA transcripts were

detected during embryogenesis and in the brains of newborn mice, arguing for a possible function of Dpl in brain development (Li et al. 2000).

To probe the function of Dpl, the *Prnd* gene was inactivated in embryonic stem (ES) cells (Behrens et al. 2001). Similarly to mice lacking PrP^C, mice devoid of Dpl survive to adulthood and do not show obvious phenotypical alterations, suggesting that Dpl is dispensable for embryogenesis and postnatal development (Behrens et al. 2002). The similarities between PrP^C and Dpl in primary amino acid sequence, structure, and subcellular localization suggest related biological functions: therefore a possible role of PrP^C and Dpl during development may be masked by functional redundancy. To address this question it will be necessary to generate mice lacking *Prnp* as well as *Prnd* and to study whether the lack of both PrP^C and Dpl will result in an exacerbation of the mutant phenotypes. These double-mutant mice may finally reveal the true physiological function of PrP^C and Dpl, and pave the way for the long-awaited understanding of these proteins.

ES cells carrying a homozygous null mutation of the *Prnd* locus, and a normal *Prnp* locus, were found to be capable of giving rise to all neural cell lineages when transplanted into host brains. The Dpl protein resembles an N-terminally truncated PrP^C protein lacking the octamer repeats. But the latter version of PrP^C is actually capable of supporting PrP^{Sc} propagation (Flechsig et al. 2000), suggesting that the Dpl protein may in principle be susceptible to conversion into 'Dpl^{Sc}.' However, presently there is no evidence whether upon scrapie inoculation Dpl can be converted into a misfolded β-strand-rich, protease-resistant conformation. After inoculation with scrapie prions, Dpl-deficient neural grafts showed spongiosis, gliosis, and unimpaired accumulation of PrP^{Sc} and infectivity similar to wild-type neuroectodermal grafts (Behrens et al. 2001). Therefore in neural grafts *Prnd* deficiency does not prevent prion pathogenesis. It is important to note, however, that this experimental approach does not rule out a role for Dpl in peripheral prion pathogenesis and in PrP^{Sc} transport to the brain. The latter possibility is worth studying, because *Prnd* is expressed in the spleen, a major peripheral reservoir of PrP^{Sc} and prion infectivity (Li et al. 2000).

Four polymorphisms in human *Prnd* were detected, but no strong association was found between any of these polymorphisms and human prion diseases (Mead et al., 2000; Peoc'h et al., 2000). These findings further argue against an important function of Dpl in neurons during prion disease, at least in genetically determined forms of these diseases.

Phenotypes of *Prnp*-deficient mice

Although this was not realized for several years, a Dpl-associated phenotype had been accidentally produced in knock-out mice lacking PrP^C. In the course of the 1990s, several mouse lines with targeted disruptions of *Prnp* were independently generated in various laboratories. All mutant mouse lines lacked significant portions of the *Prnp* ORF and did not produce PrP^C protein, but showed two strikingly different phenotypes. Zrch $Prnp^{0/0}$ and Edbg $Prnp^{-/-}$ (termed after the city of origin) showed only minor defects (Büeler et al. 1992; Collinge and Palmer 1994; Manson et al. 1994a; Tobler et al. 1996) whereas Ngsk $Prnp^{-/-}$, Zürich II and Rcm0 mice develop cerebellar Purkinje cell degeneration causing ataxia with advancing age (Sakaguchi et al. 1996; Moore et al. 1999; Rossi et al. 2001). This conundrum was solved when David Westaway and colleagues realized that in the brain of ataxic, but not of healthy *Prnp*-mutant mice, *Prnd* mRNA was up-regulated (Moore et al. 1999; Li et al. 2000). An intergenic splicing event places the Dpl locus under the control of the *Prnp* promoter, probably due to the deletion of the *Prnp* intron 2 sequence including its splicing acceptor (Moore et al. 1999). This intergenic splicing event could be detected at very low levels also in wild-type mice, but was greatly enhanced by the absence of the intron 2 splice acceptor (Moore et al. 1999). Whereas the *Prnp* promoter is strongly expressed in neuronal cells, the *Prnd* promoter is not (Moore et al. 1999; Li et al. 2000; Rossi et al. 2001) and therefore *Prnd* expression from the *Prnp* promoter results in overproduction of Dpl in the brain (Moore et al. 1999; Li et al. 2000; Rossi et al. 2001). Further experiments have demonstrated an inverse correlation between the mRNA levels of *Prnd* and the onset of ataxia. Disease progression was accelerated by increasing *Prnd* levels, supporting the notion that ectopic Dpl expression, but not functional loss of PrP^C, may be responsible for neuronal degeneration in ataxic *Prnp*-deficient mice (Rossi et al. 2001).

The function of the Doppel protein

Behrens and colleagues inactivated the *Prnd* gene. However, they have not been able to generate any progeny from intercrosses of $Prnd^{-/-}$ mice. Female $Prnd^{-/-}$ mice, when crossed to $Prnd^{-/-}$ or $Prnd^{+/-}$ mice, yielded litter sizes similar to those of wild-type. By contrast, male $Prnd^{-/-}$ mice were infertile. Their sexual activity was similar to that of controls, as shown by a normal number of copulation plugs. However, the number of spermatozoa in the cauda epididymis of $Prnd^{-/-}$ males was reduced, and motility of mutant sperm was decreased. Therefore, sterility of Dpl-mutant males is not due to behavioral abnormalities, but may be due to a spermatogenesis defect. Indeed, $Prnd^{-/-}$ sperm heads were severely malformed and lacked a discernible well-developed acrosome (Figure 9). As the acrosome is essential for sperm/egg interaction, this defect could explain the sterility of *Prnd*-deficient males.

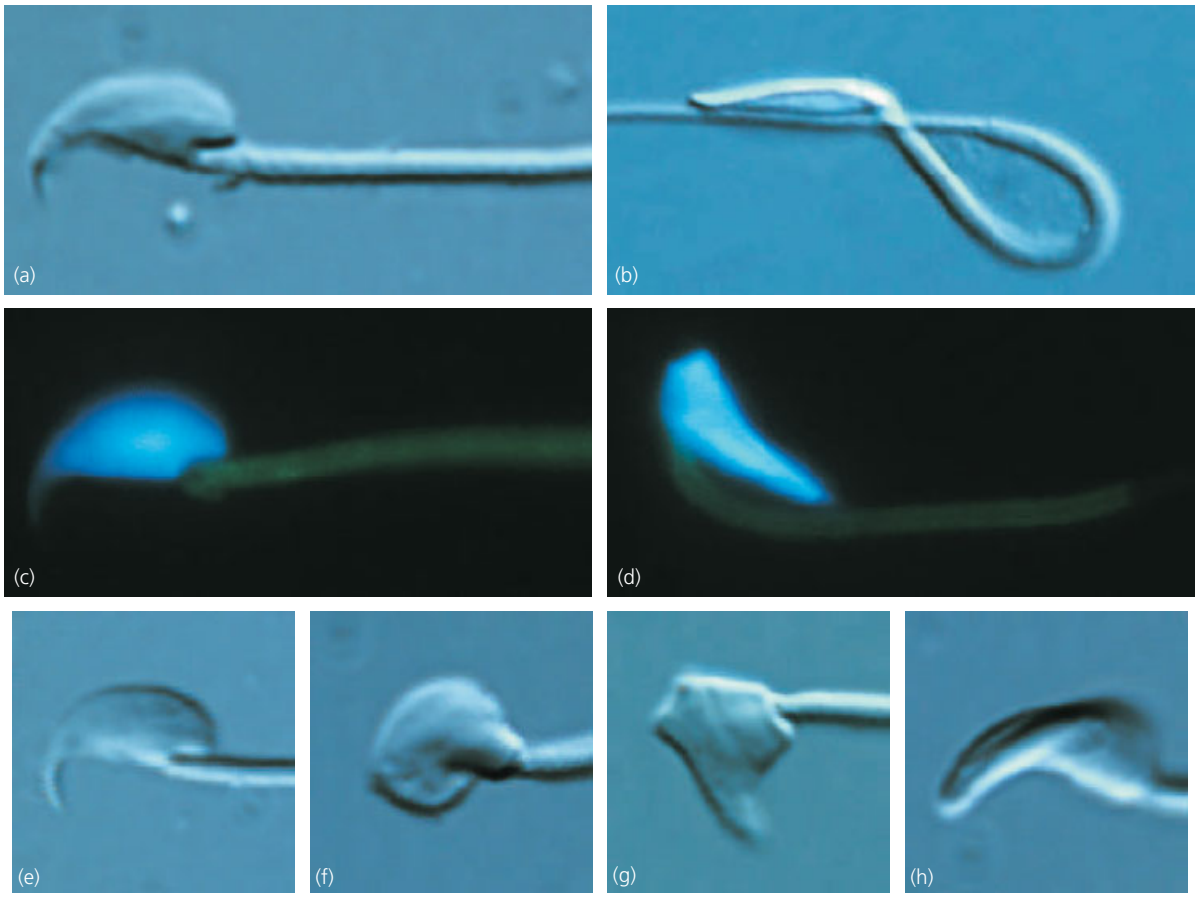

Figure 9 *Morphology of sperms in mice lacking the Doppel gene. Spermatozoa from Dpl-deficient mice are often heavily malformed. (a, b) Photographs of bright field images of spermatozoa isolated from wild-type* **(a)** *and* $Prnd^{-/-}$ *mice* **(b)**. **(c, d)** *Spermatozoa isolated from* $Prnd^{+/+}$ **(c)** *and* $Prnd^{-/-}$ *mice* **(d)** *were stained with mitotracker to detect mitochondria (in green) and with the DNA stain Hoechst (in blue). (***e, h** *Photographs of bright-field images of sperm heads from* $Prnd^{+/+}$ **(e)** *and* $Prnd^{-/-}$ *mice* **(f–h)**

In vitro fertilization (IVF) experiments confirmed that spermatozoa isolated from $Prnd^{-/-}$ males were unable to fertilize wild-type oocytes. Spermatozoa of $Prnd^{-/-}$ males never penetrated the zona pellucida. However, if the zona pellucida was partially dissected and IVF was performed with sperm suspension from $Prnd^{-/-}$ males, fertility was partially rescued. These data indicate that $Prnd^{-/-}$ spermatozoa are capable of oocyte fertilization, albeit at a lower frequency than controls, but that they cannot overcome the barrier imposed by the zona pellucida (Figure 10).

A significant amount of PrP^{C} is expressed in mature spermatozoa. The PrP protein found in testes was truncated in its carboxy terminus in the vicinity of residue 200 (Shaked et al. 1999). A protective role for PrP against copper toxicity has been proposed: sperm cells originating from *Prnp*-ablated mice were found to be more susceptible to high copper concentrations than wild-type sperm. However, male $Prnp^{0/0}$ knockout mice are not sterile and produce normal litter sizes. PrP expressed in testes is clearly not capable of compensating for the absence of Dpl, suggesting nonredundant functions for the two proteins. However, Dpl may mask a minor function of PrP^{C} in testes development or spermiogenesis; therefore, it will be very interesting to explore whether males lacking both PrP^{C} and Dpl might display a more severe defect than $Prnd^{-/-}$ single mutant mice. Also, it will be interesting to determine whether testicular expression of amino terminally truncated PrP^{C} restores the fertility of Dpl-deficient mice: if so, this would finally provide a long-sought experimental window into structure–function relationships affecting the physiology of PrP^{C}.

At present the molecular mechanism by which Dpl regulates acrosome development is unclear. Dpl may be present on the acrosomic vesicles through its GPI-anchor, and possibly participate in acrosome morphogenesis. Alternatively, Dpl may regulate acrosome function in a more indirect way. We have also observed that sperm isolated from $Prnd^{-/-}$ mice is greatly impaired in sperm/egg interaction and that $Prnd^{-/-}$ spermatozoa fail to trigger the acrosomal reaction. Oligosaccharides have been implicated in sperm binding

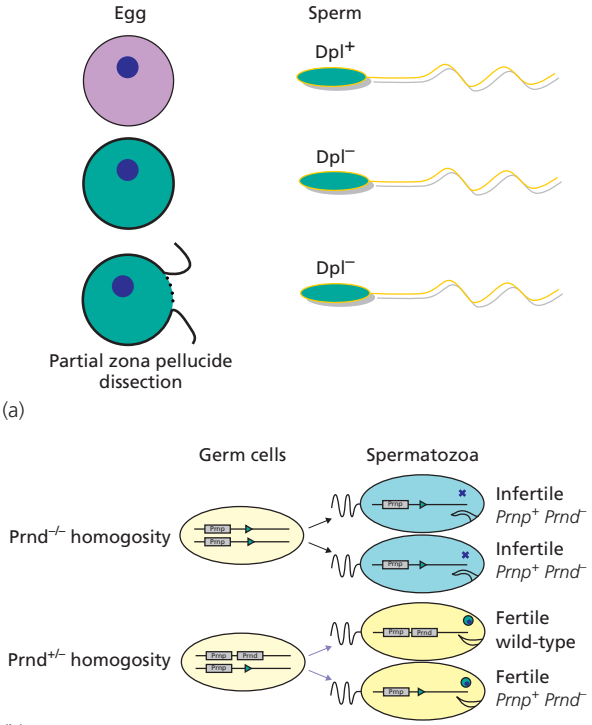

Figure 10 *A possible model for the function of the Doppel protein in fertilization.* **(a)** *Male sterility in mice that lack the Doppel protein appears to come about because Doppel-deficient sperms are incapable of fertilizing eggs. The process that appears to be disturbed relates to the acrosomal reaction and to the penetration of the zona pellucida. In fact, mechanical dissection of the zona pellucida restores, at least in part, fertility.* **(b)** *Interestingly, haploid spermatozoa lacking the Doppel gene (*Prnd^{-}*) are perfectly fertile when generated in the context of a heterozygous* Prnd$^{+/-}$ *mouse. Instead,* Prnd^{-} *sperms are infertile when generated in a* Prnd$^{-/-}$ *mouse. This may be because sperms spend much of the maturation time in the form of syncytia, with maturing cells connected to each other by cytoplasmic bridges. This may allow sufficient amounts of Doppel protein to be transferred from* Prnd^{+} *to* Prnd^{-} *spermatids, and rescue fertility in trans.*

and signaling for the acrosome reaction, but the composition and structure of the essential carbohydrate moieties remain controversial (Wassarman et al. 2001). Dpl is a highly glycosylated protein located at the outside of the plasma membrane (Moore et al. 1999; Silverman et al. 2000); therefore, it is possible that Dpl present on the sperm plasma membrane is directly involved in sperm/egg interaction. With regard to the keen interest in the development of new methods of contraception (in particular those targeting the male), the phenotype of *Prnd*$^{-/-}$ mutant mice suggests that inhibition of Dpl function may provide a novel target for contraceptive intervention (Behrens and Aguzzi 2002).

In this context, it is interesting to mention that the laboratory of David Melton in Edinburgh has reported a slightly different phenotype of Dpl-deficient mice (communicated by D. Paisley and D. Melton). In contrast to the mice generated in Zurich, Doppel-deficient homozygous males in Edinburgh appear to be able to fertilize eggs. In a series of IVFs, the Melton laboratory has reported that progression to the early cleavage divisions occurred, but was soon thereafter followed by death of the embryos at the preimplantation stage. Instead, there were no obvious malformations of sperms. Whether this discrepancy is related to a divergent genetic background of the mice utilized, whether it points to slightly different targeting strategies, or finally, whether it might uncover yet another surprising phenomenon in the genetics of prion-related genes, is – at the time of writing – wholly unclear.

CLINICAL AND PATHOLOGICAL ASPECTS OF PRION DISEASES

Scrapie

EXPERIMENTAL SCRAPIE

For decades, studies of experimental scrapie were performed exclusively with sheep and goats, which required incubation periods of 1–3 years. A crucial methodological advance in experimental studies of scrapie was created by the demonstration that scrapie could be transmitted to mice (Chandler 1961, 1963) which could be used for endpoint titrations of particular samples. In addition, pathogenesis experiments were performed directed at elucidating factors governing incubation times and neuropathological lesions (Eklund et al. 1967; Dickinson et al. 1968).

NATURAL SCRAPIE IN SHEEP AND GOATS

Even though scrapie was recognized as a distinct disorder of sheep with respect to its clinical manifestations as early as 1738, the disease remained an enigma, even with respect to its pathology, for more than two centuries (Parry 1983). Some veterinarians thought that scrapie was a disease of muscle caused by parasites, whilst others thought that it was a dystrophic process (M'Gowan 1914). An investigation into the etiology of scrapie followed the vaccination of sheep for louping-ill virus with formalin-treated extracts of ovine lymphoid tissue unknowingly contaminated with scrapie prions (Gordon 1946). Two years later, more than 1 500 sheep developed scrapie from this vaccine.

Scrapie of sheep and goats share with CWD of deer and elk a unique property among prion diseases: they seem to be readily communicable within flocks. Although the transmissibility of scrapie seems to be well established, the mechanism of the natural spread of scrapie among sheep is puzzling. The placenta has been implicated as one source of prions, accounting for the horizontal spread of scrapie within flocks (Pattison and Millson 1961a; Pattison 1964; Pattison et al. 1972;

Onodera et al. 1993). Whether this view is correct remains to be established. In Iceland, scrapie-infected flocks of sheep were destroyed and the pastures left vacant for several years; however, reintroduction of sheep from flocks known to be free of scrapie for many years eventually resulted in scrapie (Palsson 1979). The source of the scrapie prions that attacked the sheep from flocks without a history of scrapie is unknown. Transmission through mites has been advocated (Wisniewski et al. 1996), but its significance on the field remains somewhat anecdotal.

GENETICS OF SHEEP

Parry argued that host genes were responsible for the development of scrapie in sheep. He was convinced that natural scrapie is a genetic disease which could be eradicated by proper breeding protocols (Parry 1962, 1983). He considered its transmission by inoculation to be of importance primarily for laboratory studies and communicable infection of little consequence in nature. Other investigators viewed natural scrapie as an infectious disease, and argued that host genetics only modulates susceptibility to an endemic infectious agent (Dickinson et al. 1965). The incubation time gene for experimental scrapie in Cheviot sheep, called *Sip*, is said to be linked to a PrP gene (Hunter et al. 1989); however, the null hypothesis of nonlinkage has yet to be tested and this is important, especially in view of earlier studies which argue that susceptibility of sheep to scrapie is governed by a recessive gene (Parry 1962, 1983).

Polymorphisms at codons 136 and 171 of the PrP gene in sheep that produce amino acid substitutions have been studied with respect to the occurrence of scrapie in sheep (Clouscard et al. 1995). In Romanov and Ile-de-France breeds of sheep, a polymorphism in the PrP ORF was found at codon 136 (A→V) which correlates with scrapie (Laplanche et al. 1993b). Sheep homozygous or heterozygous for Val at codon 136 were susceptible to scrapie whereas those that were homozygous for Ala were resistant. Unexpectedly, only one of 74 scrapied autochthonous sheep had a Val at codon 136; these sheep were from three breeds denoted Lacaune, Manech, and Presalpes (Laplanche et al. 1993a).

In Suffolk sheep, a polymorphism in the PrP ORF was found at codon 171 (Q→R) (Goldmann et al. 1990a, 1990b). Studies of natural scrapie in the USA have shown that ca. 85 percent of the afflicted sheep are of the Suffolk breed. Only those Suffolk sheep homozygous for Gln (Q) at codon 171 had scrapie, although healthy controls with QQ, QR, and RR genotypes were found (Westaway et al. 1994b). These results argue that susceptibility in Suffolk sheep is governed by the PrP codon 171 polymorphism. Whether the PrP codon 171 or 136 polymorphisms in Cheviot sheep have the same profound influence on susceptibility to scrapie as has been found for codon 171 in Suffolks is unknown (Goldmann et al. 1991a; Hunter et al. 1991).

Bovine spongiform encephalopathy

EPIDEMIC OF MAD COW DISEASE

In 1986, an epidemic of a previously unknown disease appeared in cattle in Great Britain (Wells et al. 1987): bovine spongiform encephalopathy (BSE) or 'mad cow' disease. BSE was shown to be a prion disease by demonstrating protease-resistant PrP in brains of ill cattle (Hope et al. 1988; Prusiner et al. 1993). Based mainly on epidemiological evidence, it has been proposed that BSE represents a massive common-source epidemic which has caused more than 180 000 cases to date (Weissmann and Aguzzi 1997). In Britain, cattle, particularly dairy cows, were routinely fed MBM as a nutritional supplement (Wilesmith et al. 1988, 1992a, b; Wilesmith and Wells 1991). The MBM was prepared by rendering the offal of sheep and cattle using a process that involved steam treatment and hydrocarbon solvent extraction. The extraction process produced a protein and fat-rich fractions; the protein or greaves fraction contained about 1 percent fat from which the MBM was prepared. In the late 1970s, the price of tallow prepared from the fat fraction fell, making it no longer profitable to use hydrocarbons in the rendering process. The resulting MBM contained about 14 percent fat: perhaps the high lipid content protected scrapie prions in the sheep offal from being completely inactivated by steam.

Since 1988, the practice of using dietary protein supplements for domestic animals derived from rendered sheep or cattle offal has been forbidden in the UK. Curiously, almost half of the BSE cases have occurred in herds where only a single affected animal has been found; several cases of BSE in a single herd are infrequent (Wilesmith et al. 1988; Dealler and Lacey 1990; Wilesmith and Wells 1991; Weissmann and Aguzzi 1997). In 1992, the BSE epidemic reached a peak, with over 35 000 cattle afflicted (Figure 11). In 1993, fewer than 32 000 cattle were diagnosed with BSE and in 1994 the number was approximately 22 000. In 2003, BSE had become a rare disease in British and European cattle, but regrettably (and quite unexplicably), it still had not completely disappeared.

TRANSMISSION OF BSE TO EXPERIMENTAL ANIMALS

Brain extracts from BSE cattle have transmitted disease to mice, cattle, sheep, and pigs after intracerebral inoculation (Fraser et al. 1988; Dawson et al. 1990a, b; Bruce et al. 1993). Transmissions to mice and sheep suggest that cattle preferentially propagate a single 'strain' of prions: seven BSE brains all produced similar incubation times as measured in each of three strains of inbred mice (Bruce et al. 1993). However, this notion was

recently challenged on the basis of transgenetic studies (Asante et al. 2002). Incontrovertible evidence for the existence of several BSE strains, in the opinion of the author, has yet to be provided.

Of particular importance to the BSE epidemic is the recent transmission of BSE to the nonhuman primate marmoset after intracerebral inoculation followed by a prolonged incubation period (Baker et al. 1993). The potential parallels with kuru of humans, confined to the Fore region of New Guinea (Gajdusek et al. 1966; Gajdusek 1977), are worthy of consideration. Once the most common cause of death among women and children in that region, kuru has almost disappeared with the cessation of ritualistic cannibalism (Alpers 1987). Although it seems likely that kuru was transmitted orally, as proposed for BSE among cattle, some investigators argue that other routes of transmission were important because oral transmission of kuru prions to apes and monkeys has been difficult to demonstrate (Gajdusek 1977; Gibbs et al. 1980).

ORAL TRANSMISSION OF PRIONS

Besides BSE, four other animal diseases seem to have arisen from ingestion of prions. It has been suggested that an outbreak of transmissible mink encephalopathy in 1985 arose from the use for feed of a cow with a sporadic case of BSE (Will et al. 1996). The source of prions in CWD of mule, deer and elk is unclear (Williams and Young 1980, 1982). The prion-contaminated MBM thought to be the cause of BSE is also most likely the cause of feline spongiform encephalopathy (FSE) and exotic ungulate encephalopathy. FSE has been found in domestic cats throughout Europe, as well as in a puma and a cheetah (Willoughby et al. 1992). Three cases of FSE in domestic cats have been transmitted to laboratory mice and PrP^{Sc} has been identified in their brains by immunoblotting (Pearson et al. 1992). Whether FSE may have transmitted to a human (Zanusso et al. 1998) remains anectodal and unproven. Prion disease has been found in the brains of the nyala, greater kudu, eland, gembok, and Arabian oryx in British zoos; all of these animals are exotic ungulates. Of eight greater kudu born into a herd maintained in a London zoo since 1987, five have developed prion disease. Except for the first case, none of the other four kudu was exposed to feeds containing ruminant-derived MBM (Kirkwood et al. 1993). Brain extracts prepared from a nyala and a greater kudu have been transmitted to mice (Kirkwood et al. 1990; Cunningham et al. 1993). PrP of the greater kudu differs from the bovine protein at four residues; Arabian oryx PrP differs from the sheep PrP at only one residue (Poidinger et al. 1993).

Chronic wasting disease of deer and elk

As the only prion disease of wildlife, CWD was initially reported in 1980 as a TSE in captive research deer in Colorado and Wyoming – the disease origin still remains completely obscure (Williams and Young 1980). Since 1980, free-ranging mule deer (*Odocoileus hemionus*), white-tailed deer (*Odocoileus virginanus)*, and Rocky Mountain elk (*Cervus elaphus nelsoni*) have been detected in the same region of Colorado and Wyoming (Spraker et al. 1997), but recently increased surveillance efforts across the USA and Canada have startlingly revealed CWD in adjacent states (Nebraska, New Mexico, and Utah) but also distant (Wisconsin, Illinois, Canada) from this original endemic region. Additionally, game-ranched elk have not escaped the disease, with CWD being first detected in 1997. The staggeringly high transmission apparent in captive deer (up to 90 percent infected in one facility, (Williams and Young 1992)) and in free-ranging deer (up to 15 percent, (Miller et al. 2000)), occurs by unknown mechanisms, but it is likely to be a horizontal route; saliva or feces could potentially harbor infectious prions and contaminate grazing areas.

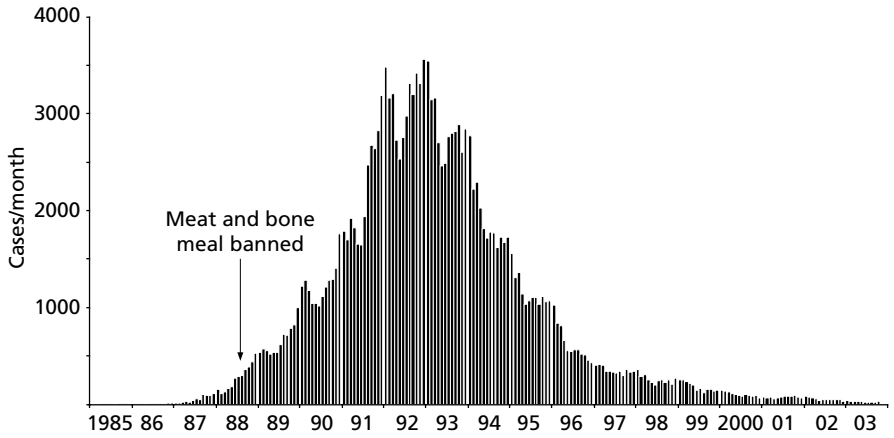

Figure 11 *Annual incidence of bovine spongiform encephalopathy in Great Britain. All cases were confirmed clinically and neuropathologically. (Statistics compiled by John Wilesmith, Central Veterinary Laboratory at Weybridge, United Kingdom)*

Clinical signs of CWD are remarkably subtle and nonspecific, characterized by lethargy, weight loss, flaccid hypotonic facial muscles, polydipsia/polyuria, excessive salivation, and behavioral changes, such as loss of fear of humans (Williams and Young 1980). Of the TSEs, histological brain lesions are most similar to BSE and scrapie, and include large single or septate intraneuronal vacuoles prominent in the parasympathetic vagal nucleus of the medulla oblongata, and also evident in the thalamus, hypothalamus, pons, midbrain, and olfactory cortex (Williams and Young 1993; Spraker et al. 1997). Similar to scrapie, PrP^{CWD} is abundant in secondary lymphoid tissues, and can be detected in tonsil, Peyer's patches, and ileocecal lymph node by immunohistochemistry as early as 12 weeks after experimental oral CWD inoculation (Sigurdson et al. 1999).

The capacity for CWD transmission to other species is clearly an area of great concern. Unfortunately, very little is known about the risk for other wildlife species, domestic ruminants, or humans contracting the disease. Cattle have been inoculated intracerebrally with CWD, and by 2 years post-inoculation, three of 13 had developed a TSE (Hamir et al. 2001). No cattle which have been orally inoculated have shown clinical signs of a TSE at 63 months post-inoculation (M.W. Miller and E.S. Williams, unpublished findings). Thus, cattle appear to be highly resistant to CWD by a natural route of exposure. The ability of PrP^{CWD} to convert human PrP^{c} in vitro was determined to be inefficient, but similar to the efficiency of PrP^{BSE} or ovine PrP^{Sc} to convert human PrP^{c} (Raymond et al. 2000).

Human prion diseases

The human prion diseases are manifest as infectious, inherited, and sporadic disorders, and are often referred to as kuru, sCJD, familial CJD, vCJD, GSS syndrome, and FFI, depending upon the clinical, genetic, and neuropathological findings (Table 1).

DIAGNOSIS OF HUMAN PRION DISEASES

Human prion disease should be considered in any patient who develops a progressive subacute or chronic decline in cognitive or motor function. Typically adults between 40 and 70 (or more) years of age, patients often exhibit clinical features helpful in providing a premorbid diagnosis of prion disease, particularly sCJD (Roos et al. 1973; Brown et al. 1986a). There is as yet no specific diagnostic test for prion disease in the cerebrospinal fluid: the concentration of the proteins 14-3-3 (Hsich et al. 1996), S-100, and neuron-specific enolase is often increased, but these represent general markers of neuronal breakdown and do not allow for definite diagnosis of prion encephalopathy. A definitive diagnosis of human prion disease, which is invariably fatal, can often be made from the examination of brain tissue. Since 1992, knowledge of the molecular genetics of prion diseases has made it possible, using peripheral tissues, to diagnose inherited prion disease in living patients by sequencing the prion alleles.

A broad spectrum of neuropathological features in human prion diseases precludes a precise neuropathological definition. The classic neuropathological features of human prion disease include spongiform degeneration, gliosis, and neuronal loss in the absence of any significant inflammatory reaction (Budka et al. 1995). When present, amyloid plaques that stain with α-PrP antibodies are diagnostic.

The presence of protease-resistant PrP (PrP^{Sc} or PrP^{CJD}) in the infectious and sporadic forms, and in most of the inherited forms of these diseases, implicates prions in their pathogenesis. The absence of PrP^{CJD} in a biopsy specimen may simply reflect regional variations in the concentration of the protein (Serban et al. 1990). In some patients with inherited prion disease, PrP^{Sc} is barely detectable or undetectable (Little et al. 1986; Brown et al. 1992b; Manetto et al. 1992; Medori et al. 1992b); this situation seems to be mimicked in transgenic mice that express a mutant PrP gene and spontaneously develop neurological illness indistinguishable from experimental murine scrapie (Hsiao et al. 1990, 1994).

In humans and transgenic mice that have no detectable protease-resistant PrP but express mutant PrP, neurodegeneration may, at least in part, be caused by abnormal metabolism of mutant PrP (Hegde et al. 1998, 1999). Because molecular genetic analyses of PrP genes in patients with unusual dementing illnesses are readily performed, the diagnosis of inherited prion disease can often be established where there was little or no neuropathology (Collinge et al. 1990), atypical neurodegenerative disease (Collinge et al. 1990) or misdiagnosed neurodegenerative disease (Heston et al. 1966; Azzarelli et al. 1985), including Alzheimer's disease.

Since the prion is defined as the transmissible agent causing spongiform encephalopathies, horizontal transmission of neurodegeneration to experimental hosts should be considered the 'gold standard' of prion disease. However, transmission of inherited prion diseases from humans to experimental animals is frequently negative when using rodents, despite the presence of a pathogenic mutation in the *PRNP* gene (Tateishi et al. 1992b). New lines of transgenic mice with enhanced susceptibility to human or animal prions (Telling et al. 1994; Weissmann et al. 1998) are starting to enable transmission studies that were not practical in apes and monkeys (Brown et al. 1994b).

Stanley Prusiner advocates that the hallmark common to all prion diseases, whether sporadic, dominantly inherited or acquired by infection, is that they involve the aberrant metabolism of the prion protein (Prusiner 1991). The author of this chapter, however, contends that nontransmissible diseases involving aberrant states

of PrP may differ significantly in their pathophysiology from TSE proper, and cautions that their classification can only be provisional given the current state of knowledge. The term 'prion' is used here in an operational meaning: it is not meant to be necessarily identical with PrP^{Sc}, but it simply denotes the infectious agent, whatever this agent exactly consists of (Aguzzi and Weissmann 1997). If one takes this viewpoint, PrP^{Sc} defined originally as the protease-resistant moiety associated with prion disease would be a mere surrogate marker for the prion. Even if this position may seem all too negativistic in view of the wealth of compelling evidence in favor of the protein-only hypothesis, we still do not understand the molecular details of prion replication.

Because protease resistance and infectivity of PrP^{Sc} may not necessarily be congruent, it is desirable to expand the range of reagents that will interact specifically with disease-associated prion protein, but not (or to a lesser degree) with its counterpart, PrP^{C}. One IgM monoclonal antibody termed 15B3 has been described a few years ago to fulfill the above conditions (Korth et al. 1997), but this antibody has not become generally available, and no follow-up studies have been published. Disappointingly, expression of the complementarity-determining regions of 15B3 in the context of a phage, as well as expression of its heavy chain variable region in transgenic mice, failed to reproduce the specificity of PrP^{Sc} binding (Heppner et al. 2001b).

The puzzling phenomenon was described that a prevalent constituent of blood serum, plasminogen, captures efficiently PrP^{Sc} but not PrP^{C} when immobilized onto the surface of magnetic beads (Fischer et al. 2000; Maissen et al. 2001). While the significance of this phenomenon in vivo has yet to be addressed, plasminogen binds to PrP^{Sc} from a variety of species and genotypes (Maissen et al. 2001), and the captured PrP^{Sc} retains the glycotype profile characteristic of the prion strain from which it was isolated (M. Maissen and A. Aguzzi, unpublished data).

In practical terms, however, a definitive diagnosis of human prion disease can be rapidly accomplished if PrP^{Sc} can be detected by western immunoblot analysis of brain homogenates in which samples are subjected to limited proteolysis to remove PrP^{C} before immunostaining (Bockman et al. 1985, 1987; Brown et al. 1986b; Serban et al. 1990). Because of regional variations in PrP^{Sc} concentration, methods using homogenates prepared from small brain regions may give false-negative results. Alternatively, PrP^{Sc} may be detected in situ in cryostat sections bound to nitrocellulose membranes followed by limited proteolysis to remove PrP^{C}, and guanidinium salt treatment to denature PrP^{Sc}, and thus enhance its accessibility to α-PrP antibodies (Taraboulos et al. 1992a). Denaturation of PrP^{Sc} in situ prior to immunostaining has also been accomplished by autoclaving fixed tissue sections (Kitamoto et al. 1992).

In the familial forms of the prion diseases, molecular genetic analyses of PRNP can be diagnostic and can be performed on DNA extracted from blood leukocytes antemortem. Unfortunately, such testing is of little value in the diagnosis of the sporadic or infectious forms of prion disease. Although the first missense PrP mutation was discovered when the two PrP alleles of a patient with GSS were cloned from a genomic library and sequenced (Hsiao et al. 1989), all subsequent novel missense and insertional mutations have been identified in PrP ORFs amplified by polymerase chain reaction (PCR) and sequenced. The 759 base pairs encoding the 253 amino acids of PrP reside in a single exon of the PrP gene, providing an ideal situation for the use of PCR. Amplified PrP ORFs can be screened for known mutations using one of several methods, the most reliable of which is automated sequencing. The list of disease-associated *PRNP* mutations is unlikely to be complete yet, and novel mutations may be found when the PrP ORF is sequenced. It is thinkable, but unproven, that mutations and/or polymorphisms in regulatory and intronic regions may contribute to CJD susceptibility.

When PrP amyloid plaques in brain are present, they are diagnostic for prion disease as noted above. Unfortunately, they are present in only ca. 10 percent of CJD cases but, by definition, in all cases of GSS. The amyloid plaques in CJD are compact (kuru plaques). Those in GSS are either multicentric (diffuse) or compact. The amyloid plaques in prion diseases contain PrP (Kitamoto et al. 1986; Roberts et al. 1986, 1988). The multicentric amyloid plaques that are pathognomonic for GSS may be difficult to distinguish from the neuritic plaques of Alzheimer's disease except by immunohistology (Ghetti et al. 1989; Nochlin et al. 1989; Ikeda et al. 1991). In the GSS kindreds, the diagnosis of Alzheimer's disease was excluded because the amyloid plaques failed to stain with β-amyloid antiserum, but stained with PrP antiserum. In subsequent studies, missense mutations were found in the PrP genes of these kindreds.

In summary, the diagnosis of prion disease may be made in patients on the basis of:

- the presence of PrP^{Sc}
- mutant PrP genotype or
- appropriate immunohistology,

and should not be excluded in patients with atypical neurodegenerative diseases until one, or preferably two, of these examinations have been performed.

Infectious prion diseases

IATROGENIC CREUTZFELDT–JAKOB DISEASE

Accidental transmission of CJD to humans seems to have occurred by corneal transplantation (Duffy et al. 1974), contaminated EEG electrode implantation (Bernoulli et al. 1977), and surgical operations using

contaminated instruments or apparatus (Table 2) (Masters and Richardson 1978; Kondo and Kuroina 1981; Will and Matthews 1982; Davanipour et al. 1984). A cornea unknowingly removed from a donor with CJD was transplanted to an apparently healthy recipient who developed CJD after a prolonged incubation period. Corneas of animals have significant levels of prions (Buyukmihci et al. 1980), making this situation seem quite probable. The same improperly decontaminated EEG electrodes that caused CJD in two young patients with intractable epilepsy caused CJD in a chimpanzee 18 months after their experimental implantation (Bernoulli et al. 1979; Gibbs et al. 1994).

Surgical procedures may have resulted in accidental inoculation of patients with prions during their operations (Gajdusek 1977; Will and Matthews 1982; Brown et al. 1992c), presumably because some instrument or apparatus in the operating theatre became contaminated when a CJD patient underwent surgery. Although the epidemiology of these studies is highly suggestive, no proof for such episodes exists.

Since 1988, 11 cases have been recorded of CJD after implantation of dura mater grafts (Otto 1987; Thadani et al. 1988; Masullo et al. 1989; Nisbet et al. 1989; Miyashita et al. 1991; Willison et al. 1991; Brown et al., 1992c; Martinez Lage et al. 1993). All the grafts were thought to have been acquired from a single manufacturer whose preparative procedures were inadequate to inactivate human prions (Brown et al. 1992c). One case of CJD occurred after repair of an eardrum perforation with a pericardium graft (Tange et al. 1989). Thirty cases of CJD in physicians and healthcare workers have been reported (Berger and David 1993); however, no occupational link has been established (Ridley and Baker 1993). Whether any of these cases represents infectious prion diseases contracted during care of patients with CJD or processing specimens from these patients remains uncertain. It is interesting to note that surgical operations of any kind appear to constitute a mild risk factor for subsequent CJD (Collins et al. 1999).

Table 2 *Transmission of prion diseases among humans (kuru and iatrogenic cases), as compiled from published reports and various national surveillance centers*

Diseases	No. of cases
Kuru (1957–82)	
Adult females	1 739
Adult males	248
Children and adolescents	597
Total	2 584
Iatrogenic Creutzfeldt–Jakob disease	
Electroencephalography electrodes	2
Corneal transplants	2
Human pituitary hormones	143
Dura mater grafts	114
Neurosurgical procedures	5
Total	266

HUMAN GROWTH HORMONE THERAPY

The possibility of transmission of CJD from contaminated human grown hormone (HGH) preparations derived from human pituitaries has been raised by the occurrence of fatal cerebellar disorders with dementia in >80 patients ranging in age from 10 to over 60 years (Brown et al. 1985b; Buchanan et al. 1991; Fradkin et al. 1991; Brown 1992). Although one case of spontaneous CJD in a 20-year-old woman has been reported (Packer et al. 1980; Brown et al. 1985a; Gibbs et al. 1985), CJD in people under 40 years of age is extremely rare. These patients received injections of HGH every 2–4 days for 4–12 years (Gibbs et al., 1985; Koch et al., 1985; Powell Jackson et al. 1985; Tintner et al. 1986; Croxson et al. 1988; Marzewski et al. 1988; New et al. 1988; Anderson et al. 1990; Billette de Villemeur et al. 1991; Macario et al. 1991; Ellis et al., 1992). It is interesting that most of the patients presented with cerebellar syndromes that progressed over periods varying from 6 to 18 months. Some patients became demented during the terminal phases of their illnesses. This clinical course resembles kuru more than ataxic CJD in some respects (Prusiner et al. 1982c). Assuming that these patients developed CJD from injections of prion-contaminated HGH preparations, the possible incubation periods range from 4 to 30 years (Brown et al. 1992c). The longest incubation periods are similar to those (20–30 years) associated with recent cases of kuru (Gajdusek 1977; Prusiner et al. 1982c; Klitzman et al. 1984). Many patients received several common lots of HGH at various times during their prolonged therapies, but no single lot was administered to all the American patients. An aliquot of one lot of HGH has been reported to transmit CNS disease to a squirrel monkey after a prolonged incubation period (Gibbs et al. 1993). How many lots of the HGH might have been contaminated with prions is unknown.

CJD has an annual incidence of 1–1.5/10^6 (Masters and Richardson 1978). Updated numbers can be found at the web site www.eurocjd.ed.ac.uk/euroindex.htm. About 1 percent of the population dies each year and most CJD patients die within one year of developing symptoms. Thus, one per 10^4 dead people may be infected with the CJD agent. Since 10 000 human pituitaries were typically processed in a single HGH preparation, the possibility of hormone preparations contaminated with CJD prions is not remote (Brown et al. 1985b). The concentration of CJD prions within infected human pituitaries is unknown; it is interesting that widespread degenerative changes have been observed in both the hypothalamus and pituitary of sheep with scrapie (Beck et al. 1964). The forebrains from scrapie-infected mice have been added to human pituitary suspensions to determine if prions and HGH co-purify (Lumley Jones

et al. 1979). Bioassays in mice suggest that prions and HGH do not co-purify with currently used protocols (Taylor et al. 1985). Although these results seem reassuring, the relatively low titer of the murine scrapie prions used in these studies may not have provided an adequate test (Brown 1985). The extremely small size and charge heterogeneity exhibited by scrapie (Alper et al. 1966; Prusiner et al. 1978, 1980b, 1983; Bolton et al. 1985) and presumably CJD prions (Bendheim et al. 1985; Bockman et al. 1985) may complicate procedures designed to separate pituitary hormones from these slow infectious pathogens. Fortunately, the advent of recombinant protein production has rendered this problem obsolete – however, it is possible that a number of HGH-treated persons are incubating prions, and may pass it to others and/or develop iCJD in the future.

Molecular genetic studies have revealed that most patients developing iCJD after receiving pituitary-derived HGH are homozygous for either Met or Val at codon 129 of the PrP gene (Collinge et al. 1991; Brown et al. 1994a; Deslys et al. 1994). Homozygosity at the codon 129 polymorphism has also been shown to predispose individuals to sCJD (Palmer et al. 1991). It is interesting that valine homozygosity seems to be over-represented in these HGH cases compared to the general population.

Five cases of CJD have occurred in women receiving human pituitary gonadotropin (Cochius et al. 1990; Cochius et al. 1992; Healy and Evans 1993).

Inherited prion diseases

FAMILIAL PRION DISEASE

The recognition that ca. 10 percent of CJD cases are familial (Kirschbaum 1924; Meggendorfer 1930; Stender 1930; Davison and Rabiner 1940; Jacob et al. 1950; Friede and DeJong 1964; Rosenthal et al. 1976; Masters and Gajdusek 1979; Masters et al. 1981a, b) posed a perplexing problem once it was established that CJD is transmissible (Gibbs et al. 1968, 1969). Equally puzzling was the transmission of GSS to nonhuman primates (Gibbs et al. 1968, 1969; Masters et al. 1981a) and mice (Tateishi et al. 1979), because most cases of GSS are familial (Gerstmann et al. 1936). Like sheep scrapie, the relative contributions of genetic and infectious etiologies in the human prion diseases remained a conundrum until molecular clones of the PrP gene became available to probe the inherited aspects of these disorders.

PRP MUTATIONS AND GENETIC LINKAGE

The discovery of the PrP gene and its linkage to scrapie incubation times in mice (Carlson et al. 1986) raised the possibility that mutation might feature in the hereditary human prion diseases. A proline (P)→leucine (L) mutation at codon 102 was shown to be linked genetically to development of GSS with a logarithm of odds (LOD) score exceeding 3 (Hsiao et al. 1989). This mutation may be due to the deamination of a methylated CpG in a germline PrP gene resulting in the substitution of a thymine (T) for cytosine (C). The P102L mutation has been found in ten different families in nine different countries, including the original GSS family (Doh-ura et al., 1989; Goldgaber et al. 1989; Goldhammer et al. 1993). Amyloid plaques isolated from patients with GSS (P102L) were composed of PrP molecules with an L at residue 102 based on protein sequencing of purified peptides (Kitamoto et al. 1991b). Patients with GSS who have a P→L substitution at PrP codon 105 have also been reported (Kitamoto et al. 1993a).

Some patients with a mutation at codon 117 have a dementing or telencephalic form of GSS (Doh-ura et al., 1989; Hsiao et al. 1991b), whereas others have an ataxic form of the disease (Mastrianni et al. 1995). In both forms of GSS (A117V), PrP amyloid plaques were found as well as spongiform degeneration. The factor or factors that determine the different phenotypes of this disease are unknown.

Patients with PrP mutations at codons 198 and 217 (Hsiao et al. 1992) were once thought to have familial Alzheimer's disease, but are now known to have prion diseases on the basis of PrP immunostaining of amyloid plaques and PrP gene mutations (Farlow et al. 1989; Ghetti et al. 1989; Nochlin et al. 1989; Giaccone et al. 1990). A genetic linkage study of this family produced a LOD score exceeding 6 (Dlouhy et al. 1992). Patients with the codon 198 mutation resulting in a phenylalanine (F)→serine (S) substitution (Hsiao et al. 1992) have numerous neurofibrillary tangles (NFT) that stain with antibodies to tau (τ) protein and have amyloid (Farlow et al. 1989; Ghetti et al. 1989; Nochlin et al. 1989; Giaccone et al. 1990) that are composed largely of a PrP fragment extending from residues 58 to 150 (Tagliavini et al. 1991). Because the F198S mutation is not contained within the major PrP peptide of the amyloid plaques, patients heterozygous at codon 129 were chosen to determine whether this peptide is derived from the mutant protein. Like the results of studies with GSS (P102L) (Kitamoto et al. 1991b) and GSS (Y145Stop) (Kitamoto et al. 1993b), protein sequencing revealed that the PrP peptides are derived exclusively from the mutant protein (Tagliavini et al. 1994). Similar results were found with PrP peptides from a patient of Swedish ancestry with the codon 217 mutation resulting in a glutamine (Q)→arginine (R) substitution (Hsiao et al. 1992). The neuropathology of patients with the codon 217 mutation was similar to that of patients with the codon 198 mutation (Ikeda et al. 1991).

One patient with a prolonged neurological illness spanning almost two decades who had PrP amyloid plaques and NFTs had an amber mutation of the PrP gene resulting in a stop codon at residue 145 (Kitamoto et al. 1993b; Kitamoto and Tateishi 1994). Staining of the plaques with α-PrP peptide antisera suggested that they might be composed

exclusively of the truncated PrP molecules. That a PrP peptide ending at residue 145 polymerizes into amyloid filaments is to be expected since an earlier study noted above showed that the major PrP peptide in plaques from patients with the F198S mutation was an 11 kDa PrP peptide beginning at codon 58 and ending at ca. 150 (Tagliavini et al. 1991). A synthetic PrP peptide containing residues 90–145 was found to adopt an α-helical or β-sheet structure depending on the solvent as determined by two-dimensional magnetic resonance imaging, FTIR spectroscopy and fiber diffraction (Nguyen et al. 1995; Zhang et al. 1995).

An insert of 144 bp at codon 53 containing six octarepeats has been described in patients with CJD from four families all residing in southern England (Owen et al. 1989, 1990b, 1991; Crow et al. 1990; Collinge et al. 1992; Poulter et al. 1992). This mutation must have arisen through a complex series of events, because the human PrP gene contains only five octarepeats, indicating that a single recombination event could not have created the insert. Genealogical investigations have revealed that all four families are related, arguing for a single founder born more than two centuries ago (Crow et al. 1990). The LOD score for this extended pedigree exceeds 11. Studies from several laboratories have demonstrated that two, four, five, six, seven, eight, or nine octarepeats in addition to the normal five are present in individuals with inherited CJD (Owen et al. 1989, 1990b, 1992; Goldfarb et al. 1991a; Brown 1993), whereas deletion of one octarepeat has been identified without the neurological disease (Laplanche et al., 1990; Vnencak Jones and Phillips 1992; Palmer et al., 1993).

For many years the unusually high incidence of CJD among Israeli Jews of Libyan origin was thought to be due to the consumption of lightly cooked sheep brain or eyeballs (Herzberg et al. 1974; Kahana et al. 1974, 1991). In reality, some Libyan and Tunisian Jews in families with CJD have a PrP gene point mutation at codon 200 resulting in a glutamate (E)→lysine (K) substitution (Goldfarb et al. 1990b; Hsiao et al. 1991a). One patient was homozygous for the E200K mutation but her clinical presentation was similar to that of heterozygotes (Hsiao et al. 1991a), arguing that familial prion diseases are true autosomal dominant disorders. The E200K mutation has also been found in Slovaks originating from Orava in north central Czechoslovakia (Goldfarb et al. 1990c), in a cluster of familial cases in Chile (Goldfarb et al. 1991b), and in a large German family living in the USA (Bertoni et al. 1992). It is likely that the E200K mutation has arisen independently multiple times through the deamidation of a methylated CpG as described above the codon 102 mutation (Hsiao et al. 1989, 1991a). In support of this hypothesis are records of Libyan and Tunisian Jews, indicating that they are descendants of Jews who settled on the island of Jerba off the southern coast of Tunisia around 500 BC and not from Sephardim (Udovitch and Valensi 1984).

Many families with CJD have been found to have a point mutation at codon 178, resulting in an aspartate (D)→asparagine (N) substitution (Fink et al. 1991; Goldfarb et al. 1991c, 1992a; Haltia et al. 1991; Brown et al. 1992a). In these patients as well as those with the E200K mutation, PrP amyloid plaques are rare; the neuropathological changes generally consist of widespread spongiform degeneration. A prion disease called fatal familial insomnia (FFI) was described in three Italian families with the D178N mutation (Lugaresi et al. 1986; Medori et al. 1992a). The neuropathology in these patients with FFI is restricted to selected nuclei of the thalamus. It is unclear whether all patients with the D178N mutation or only a subset present with sleep disturbances. It has been proposed that the allele with the D178N mutation encodes a methionine (M) at position 129 in FFI whereas a valine (V) is encoded at position 129 in familial CJD (Goldfarb et al. 1992b). The discovery that FFI is an inherited prion disease clearly widens the clinical spectrum of these disorders and raises the possibility that many other degenerative diseases of unknown etiology may be caused by prions (Johnson 1992; Medori et al. 1992b). The D178N mutation has been linked to the development of prion disease with a LOD score exceeding 5 (Petersen et al. 1992). Studies of PrP^{Sc} in FFI and familial CJD caused by the D178N mutation reveal that, after limited proteolysis, the molecular mass of the FFI PrP^{Sc} is ca. 2 kDa smaller (Monari et al. 1994). Whether this difference in protease resistance reflects distinct conformations of PrP^{Sc} that give rise to the different clinical and neuropathological manifestations of these inherited prion diseases remains to be established.

A valine (V)→isoleucine (I) mutation at PrP codon 210 produces CJD with classic symptoms and signs (Pocchiari et al. 1993; Ripoll et al. 1993). The V210I mutation is thought to be incompletely penetrant, like the E200K mutation was previously thought to be (Chapman et al. 1994; Spudich et al. 1995). It seems likely that, if a sufficiently large number of people with the V210I mutation could be analyzed, complete penetrance that is age-dependent would be found.

Other point mutations at codons 208 and, possibly, 232 also segregate with inherited prion diseases (Kitamoto et al. 1993c; Kitamoto and Tateishi 1994; Mastrianni et al. 1995). The codon 208 mutation results in the substitution of arginine (R) for histidine (H). A patient with this mutation presented with a progressive dementia and widespread myoclonus was subsequently observed. The diagnosis of CJD was confirmed at autopsy. Patients with the codon 232 mutation present with dementia; this mutation is particularly notable, because it lies within the C-terminal signal sequence that is removed from PrP when the GPI anchor is attached (Stahl et al. 1992). Table 3 summarizes all mutations within the human *PRNP* gene that were found to cosegregate with inherited prion disease.

Table 3 *Synopsis of all* PRNP *mutations and polymorphism, and their association with inherited prion diseases*

Presentation	Mutation in *PRNP*
Creutzfeldt–Jakob phenotype	D178N-129V, V180I, V180I-M232R, T183A, T188A, E196K, E200K, V203I, R208H, V210I, E211Q, M232R, 96 bpi, 120 bpi, 144 bpi, 168 bpi, 48 bpd
Gerstmann–Sträussler–Scheinker phenotype	P102L, P105L, A117V, G131V, F198S, D202N, Q212P, Q217R, M232T, 192 bpi
Fatal familial insomnia phenotype	D178N-129M
Vascular amyloid depositions	Y145STOP
Proven but unclassified prion disease	H187R, 216 bpi
Neuropsychiatric disorder, no proven prion disease	I138M, G142S, Q160s, T188K, T188R, M232R, P238S, 24 bpi, 48 bpi,
Polymorphisms, established influence on phenotype	M129V
Polymorphisms, suggested influence on phenotype	N171S, E219K
Silent polymorphisms	P68P, A117A, G124G, V161V, N173N, H177H, T188T, D202D, Q212Q, R228R, S230S

The wild-type human PrP gene contains five octarepeats [P(Q/H)GGG(G/–) WGQ] from codons 51–91. Deletion of a single octarepeat at codon 81 or 82 is not associated with prion disease (Laplanche et al. 1990; Puckett et al. 1991; Vnencak Jones and Phillips 1992); whether this deletion alters the phenotypic characteristics of a prion disease is unknown. There are common polymorphisms at codons 117 (Ala→Ala) and 129 (Met→Val); homozygosity for Met or Val at codon 129 seems to increase susceptibility to sCJD (Palmer et al. 1991). Octarepeat inserts of 16, 32, 40, 48, 56, 64, and 72 amino acids at codons 67, 75, or 83 are designated as bpi (base pair insertion). Point mutations are designated by the wild-type amino acid preceding the codon number and the mutant residue follows, e.g. P102L. These point mutations segregate with the inherited prion diseases and significant genetic linkage (underlined mutations) has been demonstrated where sufficient specimens from family members are available. The single letter codes for amino acids is as follows: A, Ala; D, Asp; E, Glu; F, Phe; I, Ile; K, Lys; L, Leu; M, Met; N, Asn; P, Pro; Q, Gln; R, Arg; S, Ser; T, Thr; V, Val; and Y, Tyr.

Along with the demonstration that PrP-deficient mice are resistant to prion infections, the linkage of *PRNP* mutations with hereditary prion disease provide a very solid piece of evidence in favor of Prusiner's protein-only hypothesis.

Variant Creutzfeldt–Jakob disease

The most recently recognized form of CJD in humans, new variant CJD (vCJD), was first described in 1996 and has been linked to BSE (Will and Zeidler 1996). vCJD represents a distinct clinicopathological entity that is characterized at onset by psychiatric abnormalities, sensory symptoms, and ataxia, and eventually leads to dementia along with other features usually observed in sCJD. What distinguishes vCJD from sporadic cases is that the age of patients is abnormally low (vCJD, 19–39 years; sCJD, 55–70 years) and duration of the illness is rather long (vCJD, 7.5–22 months; sCJD, 2.5–6.5 months). Moreover, vCJD displays a distinct pathology within the brain characterized by abundant 'florid plaques,' decorated by a daisy-like pattern of vacuolation. Most cases of vCJD have been observed in the United Kingdom (Will et al. 2000). For several years, it has been thought that prions are distributed much more broadly within the body of vCJD victims than of sCJD patients (Wadsworth et al. 2001). However, this view has recently been challenged by the finding of PrP^{Sc} in muscle and spleen of sCJD patients (Glatzel et al. 2003a).

What is the evidence that the agent causing vCJD may be identical with that of BSE when transmitted to humans? None of the arguments to date is conclusive, yet each – and particularly when they are all considered together – is tantalizing. Much effort has gone into characterizing the 'strain properties' of the agent that affects cows and humans. Because the molecular substrate that underlies the nature of prion strains (which are heritable phenotypic traits that can be reproduced upon serial passage through experimental animals) is not known, strain-typing of prions has to rely on surrogate markers.

Two such markers have been particularly useful. One is the distribution of neuronal vacuoles in the brains of affected animals: for example, whereas some strains target the cortical cerebral ribbon, others mainly affect the midbrain (Fraser and Dickinson 1967). The BSE prion strain attacks the dorsal medulla and the superior colliculus (a part of the optical pathway) virulently and consistently (Bruce et al. 1997). Worryingly, BSE prions (extracted from the brains of affected cows) and vCJD prions derived from the brains of British patients produce the same lesional patterns when transmitted to panels of susceptible mice (Aguzzi 1996; Aguzzi and Weissmann 1996; Bruce et al. 1997).

The second marker for strain typing of prions comes from analyzing the biochemical properties of disease-associated PrP recovered from the brains of cattle and humans. Different steric conformations of PrP (which, according to the most popular hypothesis, account for the phenotypic strain properties) expose different sites to the action of proteolytic enzymes. These sites, in turn, can be identified by the different molecular masses of the resulting fragments. When used in conjunction with the ratio of diglycosylated to monoglycosylated PrP –

another parameter that seems to correlate with strain properties – these traits were again found to be indistinguishable between BSE and human vCJD prions (Collinge et al. 1996; Hill et al. 1997a). A third line of argument relating BSE and human vCJD concerns epidemiology of the disease. To date, the total number of definite or probable cases of vCJD is 136 in the UK (Table 4), but only a few cases in other countries including Ireland, France (Chazot et al. 1996), and Italy. Assuming that the quality of the epidemiologic surveillance is similar in these countries and in the rest of Europe (which has not reported cases of vCJD), the unavoidable conclusion is that the incidence of vCJD correlates with the prevalence of BSE.

One of the most powerful arguments is the study of pathogenesis in primates. In a classical experiment, Lasmezas and colleagues inoculated brain extracts from BSE-affected cows into cynomolgus macaques. After about 3 years, all inoculated primates (two adults and one infant) developed spongiform encephalopathy. The histopathological appearance of the disease was identical to that of vCJD and included characteristic 'florid plaques,' which have been recognized in every case of vCJD (Lasmezas et al. 1996b). These are spherical conglomerates of fibrillary birefringent material that stains positive with 'amyloidotropic' dyes such as Congo red. Characteristically, vCJD plaques are surrounded by a rim of microvacuolated brain tissue – a feature which they share with the deposits in sheep scrapie, but that is not seen in classical CJD, nor in any other human spongiform encephalopathy.

Impressive as all of these arguments may seem, however, each is phenomenological rather than causal. Distribution of histopathological lesions, as well as morphology of plaque deposits, is downstream of the molecular events responsible for prion strain specificity. Measurements of the 'glycotype ratio' may be more directly related to the essence of strains, but there is still no way to tell whether they might simply be surrogate markers. It would be desirable to measure the conformation of disease-associated PrP more directly. Some inroads have been made with a method that exploits the relative affinities of anti-PrP^C antibodies (Aguzzi 1998; Safar et al. 1998), but, to our knowledge, this possibility is restricted to differentiation of mouse and hamster PrPs, and has not yet been applied to investigating BSE and vCJD.

Given that a large fraction of the European population may have been exposed to BSE prions, yet only a minute minority developed vCJD, there can be hardly any doubt that additional genetic modifiers exist, other than *PRNP* polymorphisms. It was originally claimed that specific allelotypes of the major histocompatibility complex may represent such modifiers (Jackson et al. 2001), but this was not confirmed by later studies (Pepys et al. 2003).

So what will the numbers of vCJD victims be in the future? Terrible as the disease has been for patients, we

Table 4 *The Department of Health's latest information about the numbers of known cases of Creutzfeldt–Jakob disease*

Referral of suspect CJD			Deaths of definite and probable CJD					
Year	Referrals	Year	Sporadic	Iatrogenic	Familial	GSS	vCJD[a]	Total deaths
1990	53	1990	28	5	0	0	–	33
1991	75	1991	32	1	3	0	–	36
1992	96	1992	45	2	5	1	–	53
1993	78	1993	37	4	3	2	–	46
1994	118	1994	53	1	4	3	–	61
1995	87	1995	35	4	2	3	3	47
1996	134	1996	40	4	2	4	10	60
1997	161	1997	60	6	4	1	10	81
1998	154	1998	63	3	4	1	18	89
1999	170	1999	62	6	2	0	15	85
2000	178	2000	49	1	2	1	28	81
2001	179	2001	56	3	2	2	20	83
2002	163	2002	72	0	4	1	17	94
2003[a]	107	2003[a]	35	4	1	0	15	55
Total	1 753	Total deaths	667	44	38	19	136	904

The Department of Health is issuing the latest information about the numbers of known cases of Creutzfeldt–Jakob disease. This includes cases of variant Creutzfeldt–Jakob disease (vCJD) – the form of the disease thought to be linked to BSE (as of September 2003). For updated information, see the following link: www.doh.gov.uk/cjd/cjd_stat.htm

Referrals: a simple count of all the cases which have been referred to the National CJD Surveillance Unit for further investigation. About half the cases referred in the past have turned out not to be CJD. Cases are notified to the Unit from neurologists, neuropathologists, neurophysiologists, general physicians, psychiatrists, EEG departments, etc.

Deaths: all columns show the number of deaths that have occurred in definite and probable cases of all types of CJD and GSS in the year shown.

Definite cases: the diagnosis was pathologically confirmed, in most cases by postmortem examination of brain tissue.

Probable vCJD cases: those who fulfill the 'probable' criteria and are either still alive, or have died and await postmortem pathological confirmation.

a) As at 1st September 2003.

have not yet seen a large-scale epidemic. Although many mathematical models have been generated (Ghani et al. 1998, 2000), the number of cases is still too small to predict future developments with any certainty. Since the year 2001, the incidence of vCJD in the UK appears to be stabilizing and may actually be even falling (Figure 12). One may argue that it is too early to draw any far-reaching conclusions, but each month passing without any dramatic rise in the number of cases increases the hope that perhaps the total number of vCJD victims will be limited (Valleron et al. 2001).

POSSIBLE TRANSMISSION OF ADDITIONAL PRION EPIZOOTICS TO HUMANS

There is no example of zoonotic transmission of prions from sheep and goat to humans: many epidemiologic studies have failed to implicate scrapie prions from sheep as a cause of CJD (Malmgren et al. 1979; Harries Jones et al. 1988; Cousens et al. 1990). However, there is uncertainty surrounding the danger of transmission to humans represented by CWD. Actually, even transmissibility of BSE to humans relies on circumstantial evidence. Epidemiology and biochemistry favor the link between BSE and vCJD, but are not really conclusive. The Koch postulates (which would unambiguously assign an infectious agent to a disease) have never been fulfilled, and experimental inoculation of humans was never performed. Also, accidental exposure to BSE infectivity of a sizable collective at a precisely defined time point has never occurred, or did not result in disease. For these reasons, speculations that variant Creutzfeldt–Jakob disease may not be due to BSE have never completely subsided.

Likewise, we do not know whether scrapie is just a veterinary problem that only affects sheep and goats, or whether it can cross species barriers and affect humans. Finally, it is unknown whether BSE, upon transmission to sheep, remains as dangerous for humans as cow-derived BSE, or whether it becomes attenuated and acquires the (allegedly) innocuous properties of bona fide sheep scrapie.

Another question relates to the possibility of chronic subclinical disease or a permanent 'carrier' status in cows as well as in humans. Evidence that such a carrier status may be produced by the passage of the infectious agent across species was first reported by Race and Chesebro (Aguzzi and Weissmann 1998; Race and Chesebro 1998), and has been confirmed by others (Hill et al. 2000) – at least for the passage between hamsters and mice. Immune deficiency can also lead to a similar situation in which prions replicate silently in the body, even when there is no species barrier (Frigg et al. 1999). So the problem of animal TSEs could be more widespread than is assumed, and may call for drastic measures in farming. Moreover, people carrying the infectious agent may transmit it horizontally (Aguzzi 2000), and the risks associated with this possibility can be met only if we know more about how the agent is transmitted and how prions reach the brain from peripheral sites.

PrP gene polymorphisms

POLYMORPHISMS AT CODONS 129 AND 219

At PrP codon 129, an amino acid polymorphism for M→V has been identified (Owen et al. 1990a). This polymorphism seems able to influence prion disease

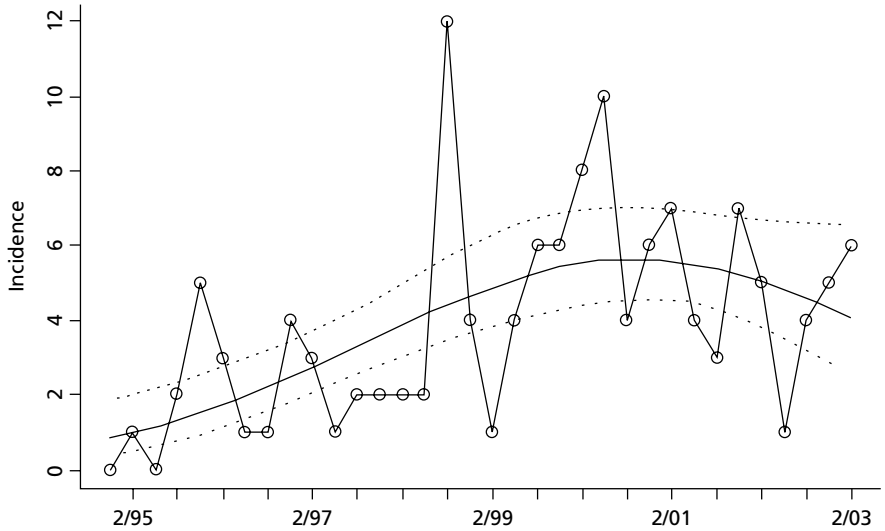

Figure 12 *The course of the vCJD epidemic in the UK. Observed numbers of vCJD deaths in the UK by a quarter (empty circles), and fitted quadratic trend (curved line) with 95 percent confidence interval for the trend (dotted line). The fitted trend shows a good fit to the data with a significant quadtratic term (P=0.002), which would indicate a departure from a constant exponential increase. This model estimates that the current quarterly incidence of deaths is 3.9 and shows that the epidemic reached a peak for deaths in about December 2000 (January 2000 to May 2003 with 95 percent confidence intervals). Regular updates are published by Mr N.J. Andrews (Communicable Disease Surveillance Centre, UK) at the web site: www.cjd.ed.ac.uk/vcjdq.htm*

expression, not only in inherited forms but also in iatrogenic and sporadic forms of prion disease. A second polymorphism resulting in an amino acid substitution at codon 219 (E→K) has been reported in the Japanese population, in which the K allele occurs with a frequency of 6 percent (Kitamoto and Tateishi 1994).

DOES HOMOZYGOSITY AT CODON 129 PREDISPOSE TO CJD?

Studies of caucasian patients with sporadic CJD have shown that most are homozygous for M or V at codon 129 (Palmer et al. 1991). This contrasts with the general population, in which frequencies for the codon 129 polymorphism in caucasians are 12 percent V/V, 37 percent M/M and 51 percent M/V (Collinge et al. 1991). By contrast, the frequency of the V allele in the Japanese population is much lower (Doh-ura et al. 1991; Miyazono et al. 1992) and heterozygosity at codon 129 (M/V) is more frequent (18 percent) in CJD patients than the general population, in whom the polymorphism frequencies are 0 percent V/V, 92 percent M/M and 8 percent M/V (Tateishi and Kitamoto 1993).

Although no specific mutations have been identified in the PrP gene of patients with sCJD (Goldfarb et al. 1990a), homozygosity at codon 129 in sCJD (Hardy 1991; Palmer et al. 1991) is consistent with the results of transgenic mouse studies. The finding that homozygosity at codon 129 predisposes to CJD supports a model of prion production that favors interactions between PrP molecules that are homologous in the H1 and H2 regions (Telling et al. 1995). However, there appears to be considerable evolutionary pressure for maintaining the prion gene. Protective polymorphisms in the human prion gene were heavily selected for, possibly because of evolutionary pressure from cannibalism-propagated prions (Mead et al. 2003). But if prion diseases were so frequent to skew the distribution of *Prnp* alleles, why were $Prnp^{-/-}$ individuals not selected for? This argues for an important, hitherto unidentified function of the cellular prion protein (Aguzzi and Hardt 2003).

BRAIN DAMAGE IN PRION DISEASES

An interesting question regards the molecular mechanism underlying neuropathological changes, in particular cell death, resulting from prion disease. Depletion of PrP^C is an unlikely cause, in view of the finding that abrogation of PrP does not cause scrapie-like neuropathological changes (Büeler et al. 1992), even when elicited postnatally (Mallucci et al. 2002). It is more likely that toxicity of PrP^{Sc} through some PrP^C-dependent process is responsible for neuronal dysfunction and death (Brandner et al. 1998, 1996a).

To address the question of neurotoxicity, brain tissue of $Prnp^{0/0}$ mice was exposed to a continuous source of PrP^{Sc}. Telencephalic tissue from transgenic mice overexpressing PrP (Fischer et al. 1996) was transplanted into the forebrain of $Prnp^{0/0}$ mice and the 'pseudochimeric' brains were inoculated with scrapie prions. All grafted and scrapie-inoculated mice remained free of scrapie symptoms for at least 70 weeks; this exceeded at least sevenfold the survival time of scrapie-infected donor mice (Brandner et al. 1996a). Therefore, the presence of a continuous source of PrP^{Sc} and of scrapie prions does not exert any clinically detectable adverse effects on a mouse devoid of PrP^C. On the other hand, the grafts develop characteristic histopathological features of scrapie after inoculation. The course of the disease in the graft is very similar to that observed in the brain of scrapie-inoculated wild-type mice (Brandner et al. 1998). Since grafts had extensive contact with the recipient brain, prions could navigate between the two compartments, as shown by the fact that inoculation of wild-type animals engrafted with PrP-expressing neuroectodermal tissue resulted in scrapie pathology in both graft and host tissue. Nonetheless, histopathological changes never extended into host tissue, even at the latest stages (>450 days), although PrP^{Sc} was detected in both grafts and recipient brain, and immunohistochemistry revealed PrP deposits in the hippocampus, and occasionally in the parietal cortex, of all animals (Brandner et al. 1996a). Thus, prions moved from the grafts to some regions of the PrP-deficient host brain without causing pathological changes or clinical disease. The distribution of PrP^{Sc} in the white matter tracts of the host brain suggests diffusion within the extracellular space (Jeffrey et al. 1994) rather than axonal transport.

These findings suggest that the expression of PrP^C by an infected cell, rather than the extracellular deposition of PrP^{Sc}, is one of the critical prerequisites for the development of scrapie pathology. Perhaps PrP^{Sc} is inherently nontoxic and PrP^{Sc} plaques found in spongiform encephalopathies are an epiphenomenon rather than a cause of neuronal damage. This hypothesis appears to be supported by the recent data (Ma and Lindquist 2002; Ma et al. 2002), indicating that exaggerated retrograde transport of the prion protein from the endoplasmatic reticulum into the cytosol, or functionally equivalent inhibition of proteasome function, might induce a self-propagating, extremely cytotoxic cellular form, which may ultimately be responsible for neuronal damage. These results are very novel and exciting, but they have been challenged (Roucou et al. 2003) and it is not clear whether they are universally valid (Drisaldi et al. 2003). Therefore it will be important to validate them by investigating whether the aggregated self-propagating material can also be transmitted between individual animals in a classic transmission experiment.

One may therefore propose that availability of PrP^C for some intracellular process elicited by the infectious agent, perhaps the formation of a toxic form of PrP (termed PrP* and discussed in Weissmann 1991a) other than PrP^{Sc} is responsible for spongiosis, gliosis, and neuronal death. This would be in agreement with the

fact that in several instances, and especially in fatal familial insomnia, localized spongiform pathology is detectable although very little PrP^{Sc} is present (Aguzzi and Weissmann 1997).

PERIPHERAL PRION PATHOGENESIS

The fastest and most efficient method for inducing spongiform encephalopathy in the laboratory is intracerebral inoculation of brain homogenate. Inoculation of 1 000 000 ID_{50} infectious units (defined as the amount of infectivity that will induce TSE with 50 percent likelihood in a given host) will yield disease in approximately 6 months; a remarkably strict inverse relationship can be observed between the logarithm of the inoculated dose and the incubation time (Prusiner et al., 1982b, Figure 13).

The above situation does not correspond to what typically happens in the field. There, acquisition of prion infectivity through any of several peripheral routes is the rule. However, prion diseases can also be initiated by feeding (Wells et al. 1987; Kimberlin and Wilesmith 1994; Anderson et al. 1996), by intravenous and intraperitoneal injection (Kimberlin and Walker 1978b) as well as from the eye by conjunctival instillation (J.R. Scott et al. 1993), corneal grafts (Duffy et al. 1974) and intraocular injection (Fraser 1982). Two routes of infection have suggested for a long time that immune cells might be of importance for this phase of prion pathogenesis: oral challenge and administration by scarification (Aguzzi 2003). Therefore, these routes are discussed in some detail in the following paragraphs.

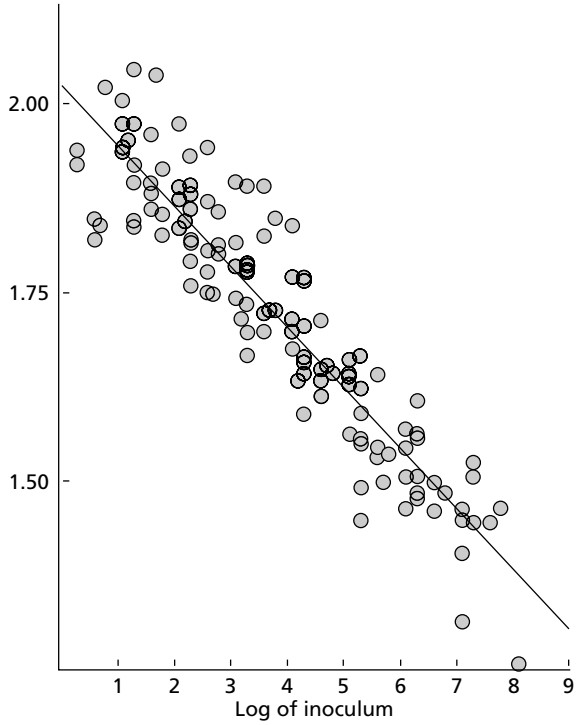

Figure 13 *Prion bioassay by the incubation time method. This figure is reproduced from an important study by Prusiner and colleagues that demonstrates an inverse logarithmic relationship between size of infectious inoculum and latency period of scrapie in experimental animals (Prusiner et al. 1982b). The relationship is so precise that incubation time can actually be used to back-calculate the prion titer of a test article, e.g. for inactivation studies. Measurement of prion titers by the incubation time method has become a standard procedure which can be used for both wild-type and transgenic animals.*

The pathway of orally administered prions

Upon oral challenge, an early rise in prion infectivity can be observed in the distal ileum of infected organisms. This is true for several animal species, but was most extensively investigated in the sheep (Wells et al. 1994; Vankeulen et al. 1996). There, Peyer's patches acquire strong immunopositivity for the prion protein. Immunohistochemical stains with antibodies to the prion protein typically reveal a robust signal in primary B-cell follicles and germinal centers, which roughly colocalizes with the complement receptor, CD35, in a wide variety of secondary lymphoid organs including appendix and tonsils (Hill et al. 1997b). Although conventional light microscopy does not allow differentiating between PrP^{C} and PrP^{Sc}, western blot analysis has not left any doubt about the fact that Peyer's patches do accumulate the disease-associated form of the prion protein.

The latter is true also in the mouse model of scrapie, which is being used as a convenient experimental paradigm by many laboratories including ours. Administration of mouse-adapted scrapie prions (Rocky Mountain Laboratory (RML) strain, originally derived from the Chandler sheep scrapie isolate) induces a surge in intestinal prion infectivity as early as a few days after inoculation (Prinz et al. 2003c). All of the above evidence conjures the suggestion that Peyer's patches may represent a portal of entry for orally administered prions on their journey from the luminal aspect of the gastroenteric tube to the central nervous system. However, the question as to whether the same applies for BSE-affected cattle has been answered less unambiguously.

In a monumental study of BSE pathogenesis in cattle carried out at the UK Veterinary Laboratory Agency, cows of various ages were fed with 100 g, 10 g, 1 g, or 100 mg of brain homogenate derived from BSE-sick cows (Bradley 2000). A large variety of tissues was taken at various points in time, homogenized, and transmitted intracerebrally to indicator organisms in order to assess their prion content. This study was designed to be performed over a time frame of more than a decade and is still under way at the time of writing: it has uncovered a transient surge in infectivity in the distal ileum of cows at approximately 6 months post-infection. Infectivity then subsides, but it appears to return to the terminal ileum at the end stages of disease, perhaps by means of

some sort of retrograde transport (Wells et al. 1998). Although this was not formally confirmed, it appears likely that Peyer's patches are the sites of prion accumulation in the gastrointestinal tract of cattle challenged orally with prions.

Oral prion susceptibility correlates with number but not structure of Peyer's patches

Recruitment of activated B lymphocytes to Peyer's patches requires $\alpha_4\beta_7$ integrin as an essential homing receptor: Peyer's patches of mice that lack β_7 integrin are normal in number, but are atrophic and almost entirely devoid of B cells (Wagner et al. 1996). Therefore, it seemed interesting to investigate the susceptibility to orally administered prions of $\beta_7^{-/-}$ mice. Surprisingly, minimal infectious dose and disease incubation after oral exposure to logarithmic dilutions of prion inoculum were similar in $\beta_7^{-/-}$ and wild-type mice (Prinz et al. 2003c). Despite their atrophy, Peyer's patches of both $\beta_7^{-/-}$ and wild-type mice contained 3–4 $\log LD_{50}$/g prion infectivity at 125 or more days after challenge.

Why does reduced mucosal lymphocyte trafficking not impair, as expected, the susceptibility to orally initiated prion disease? One possible reason may relate to the fact that, despite marked reduction of B cells, M cells were still present in $\beta_7^{-/-}$ mice. In contrast, mice deficient in both tumor necrosis factor (TNF) and lymphotoxin (LT)-α (TNF-$\alpha^{-/-}$ × LT-$\alpha^{-/-}$) or in lymphocytes (RAG-$1^{-/-}$, μMT), in which numbers of Peyer's patches are reduced in number, were highly resistant to oral challenge, and their intestines were virtually devoid of prion infectivity at all times after challenge. Therefore, lymphoreticular requirements for enteric and for intraperitoneal uptake of prions differ from each other and that susceptibility to prion infection following oral challenge correlates with the number of Peyer's patches, but is independent of the number of intestinal mucosa-associated lymphocytes (Prinz et al. 2003c).

Transepithelial enteric passage of prions: a role for membranous epithelial cells (M cells)?

The requirements for transepithelial passage of prions are of obvious interest to prion pathogenesis. Membranous epithelial cells (M cells) are key sites of antigen sampling for the mucosal-associated lymphoid system (MALT) and have been recognized as major ports of entry for enteric pathogens in the gut via transepithelial transport (Neutra et al. 1996). Interestingly, maturation of M cells is dependent on signals transmitted by intraepithelial B cells. The group of Jean-Pierre Kraehenbuhl (Lausanne) has developed efficient in vitro systems, in which epithelial cells can be instructed to undergo differentiation to cells that resemble M cells by morphological and functional–physiological criteria. Therefore, it became feasible to investigate whether M cells are a plausible site of prion entry in a coculture model (Kerneis et al. 1997). Colon carcinoma cells (line CaCo-2) were seeded on the upper face of transwell filters and cultured until confluency was reached. Next, B-lymphoblastoid cells Raji B cells were added onto the lower side of the filters. Lymphoid cells migrated through the pores of the filter and settled within the epithelial monolayer (Figure 14), inducing differentiation of some CaCo-2 cells into M cells. Successful conversion was monitored by measuring transport of fluorescein-conjugated latex beads in cocultures that exhibited a high transepithelial resistance and were therefore tight. Active transepithelial transport of beads, but not passive leakage, was blocked at 4°C. Scrapie prions were administered to the apical compartment of cocultures that combined integrity and active transport of beads. After 24 hours, infectivity was determined within the basolateral compartment by bioassay with *tga20* mice, which overexpress a *Prnp* transgene and develop scrapie rapidly after infection (Fischer et al. 1996). Upon challenge with 5 $\log LD_{50}$ scrapie prions, prions were consistently recovered in the basolateral compartment of co-cultures containing M cells, suggesting transepithelial prion transport (Figure 14). Even at low prion doses (3 $\log LD_{50}$), infectivity was found in at least one M cell-containing co-culture. By contrast, there was hardly any prion transport in CaCo-2 cultures without M cells (Heppner et al. 2001a).

These findings indicate that M cell differentiation is necessary and sufficient for active transepithelial prion transport in vitro. M cell-dependent uptake of foreign antigens or particles is known to be followed by rapid transcytosis directly to the intraepithelial pocket, where key players of the immune system, e.g. macrophages, dendritic cells, and lymphocytes (Neutra et al. 1996), are located. Therefore, prions may exploit M cell-dependent transcytosis to gain access to the immune system (Aguzzi and Heppner 2000). While these findings suggest that M cells are a plausible candidate for the mucosal portal of prion infection, it still remains to be established whether the pathway delineated above does, indeed, represent the first portal of entry of orally administered prions into the body. This will necessitate in vivo experimentation, for example by ablation of M cells through suicide transgenetic strategies, or by M cell-specific expression of *Prnp* transgenes.

Uptake of prion through the skin

Even less well understood, yet possibly much more efficient than oral administration of prions, is challenge by scarification. Application of one droplet of scrapie inoculum to skin abrasions and subsequent delivery of

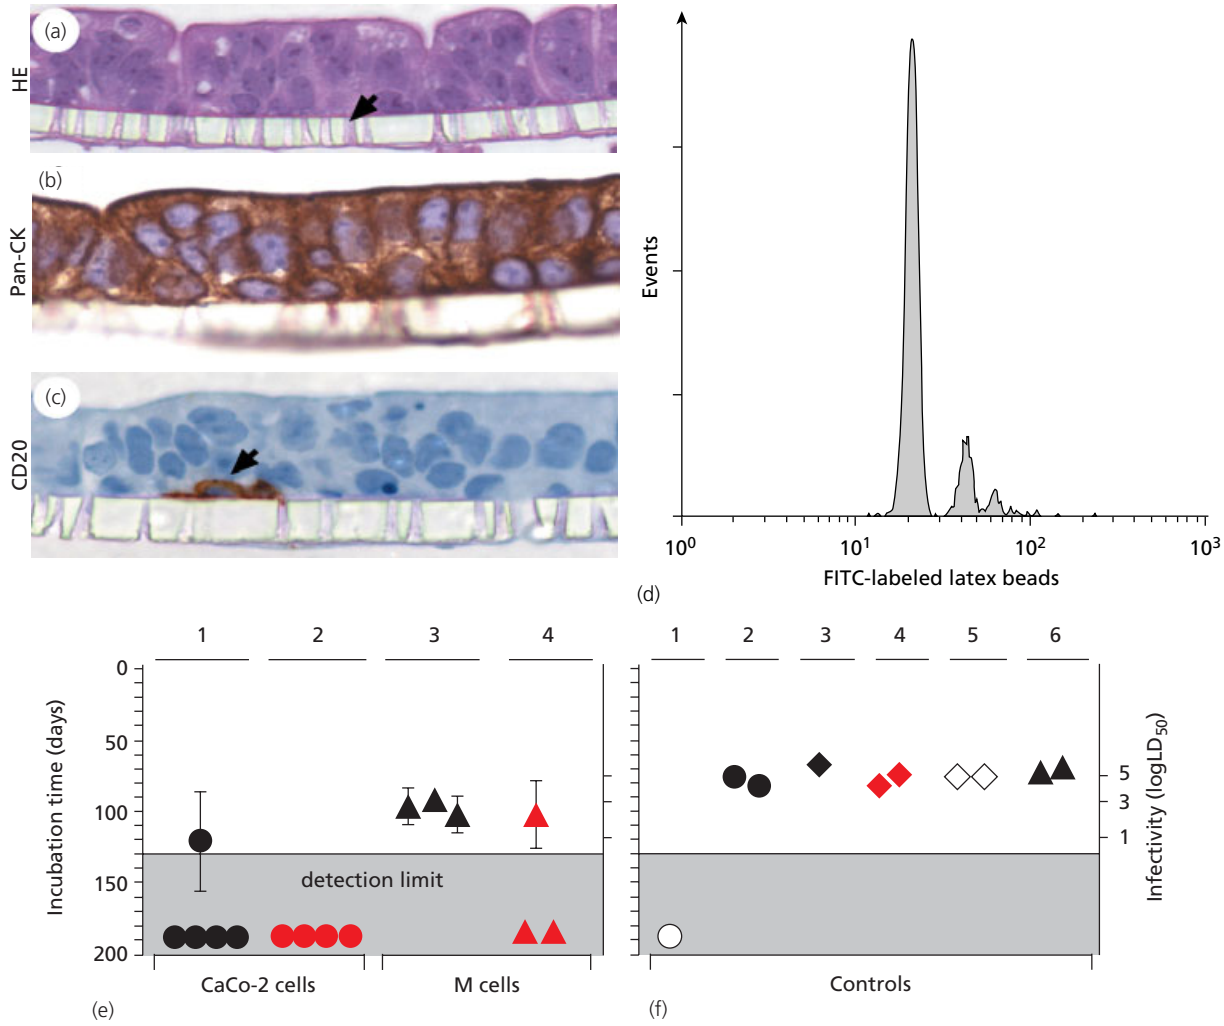

Figure 14 *Transepithelial transport of prions via M-cells. Filter membranes with 3 μm pores were overlaid with epithelial cells (colon carcinoma, line CaCo-2). Human B-lymphoblastoid Raji cells were then cultured on the back side of the membrane.* **(a)** *Morphology of co-cultures on filters, visualized by hematoxylin and eosin (HE) stains.* **(b)** *Immunohistochemical stain for cytokeratins (pan-CK) visualizing human CaCo-2 epithelial cells and* **(c)** *for the B-cell marker CD20, displaying B cells that have successfully migrated through the pores of the filter (arrow).* **(d)** *Flow cytometric analysis demonstrating active (i.e. temperature-dependent) transport of FITC-conjugated latex beads from the apical to the basolateral chamber compartment upon integration of B cells within pouches of the epithelial CaCo-2 cell layer, and differentiation of M cells. Intactness of co-cultures was assessed by measuring transepithelial resistance at 37°C, which was typically >200 Ωcm^2. The presence of additional peaks corresponds to aggregates of several latex beads.* **(e)** *Recovery of prion infectivity upon challenge with different prion inocula [5 (black) or 3 (red) logLD_{50} input infectious units] was only visible in co-cultures containing M cells (triangles, lanes 3, 4). No prion transport was observed in CaCo-2 cultures (circles, lanes 1, 2) without M cells, except in one case in which traces of infectivity were present. Controls: mock inoculum (lane 1), CaCo-2 culture (Ca) after slight mechanical manipulation resulting in a transepithelial resistance <50 Ωcm^2 (lane 2). Prion infectivity dilutions as indicated before (positive control, lanes 3, 4) and after incubating with either CaCo-2 (lane 5) or M cell containing (M) cultures (lane 6). Each symbol represents the mean incubation time in days (ordinate) of four* tga20 *indicator mice until terminal disease.*

sweeping strokes until blood is leaking has been shown to be a highly efficacious method of inducing prion disease (Carp 1982; Taylor et al. 1996). It is thinkable that dendritic cells in the skin may become loaded with the infectious agent by this method, and in fact recent work has implicated dendritic cells as potential vectors of prions in oral (Huang et al. 2002) and in hematogenous spread (Aucouturier et al. 2001) of the agent. It is equally possible (and perhaps more probable), however, that scarification induces direct neural entry of prions into skin nerve terminals. The latter hypothesis has not yet been studied in much detail, but it would help explain the remarkable speed with which central nervous system pathogenesis follows inoculation by this route: dermal inoculation of scarified mice yields typical latency periods of the disease that are similar to those obtained by intracerebral inoculation. The possibility of direct neural spread of the agent has been brought up also by a series of elegant experiments in the laboratories of Oldstone and Chesebro: transgenic mice that

lack the endogenous prion gene but express a *Prnp* transgene exclusively in nervous tissue (under transcriptional control of the neuron-specific enolase regulatory elements) can be efficiently infected by the oral route despite lack of prion protein expression in lymphoid organs (Race et al. 1995). Of course, these experiments do not exclude that dendritic or other mobile cells may participate in neuroinvasion even if they do not express endogenous PrP^{C}. Rapid neuroinvasion was reported following intralingual inoculation, and may also exploit a direct intraneural pathway (Bartz et al. 2003).

LYMPHOCYTES AND PRION PATHOGENESIS

More than a decade ago the normal prion protein was found to be consistently expressed, albeit at moderate levels, in circulating lymphocytes (Cashman et al. 1990). Subsequently, it was clearly shown in a wealth of experimental paradigms that innate or acquired deficiency of lymphocytes would impair peripheral prion pathogenesis, whereas no aspects of pathogenesis were affected by the presence or absence of lymphocytes upon direct transmission of prions to the central nervous system (Kitamoto et al. 1991a; Lasmezas et al. 1996a). Klein and colleagues pinpointed the lymphocyte requirement to B cells (Aguzzi 1997; Klein et al. 1997): at first sight this was very surprising, since there had been no suggestions that any aspect of humoral immunity would be involved in prion diseases. In the same study, it was shown that T-cell deficiency brought about by ablation of the T-cell receptor (TCR)-α chain did not affect prion pathogenesis (Table 5).

TCR-α-deficient mice, however, still contain TCR-γδ T lymphocytes. Although the latter represent a subpopulation of T cells, the experiments described did not allow excluding a role for TCR-γδ T lymphocytes. Therefore, we challenged also TCR-β/δ-deficient mice with prions. Incubation times after intracerebral and intraperitoneal inoculation of limiting or saturating doses of prions, however, elicited disease in these mice with the same kinetics as in wild-type mice (M. Klein and A. Aguzzi, unpublished data). Also, accumulation of PrP^{Sc} and development of histopathological changes in the brain were indistinguishable in these two strains of mice. We therefore conclude that the complete absence of T cells has no measurable impact on prion diseases. Therefore, it is unlikely that the T-cell infiltrates which have been reported to occur in the central nervous system during the course of prion infections (Betmouni et al. 1996; Betmouni and Perry 1999; Perry et al. 2002) represent more than an epiphenomenon.

In 1996–97, when the results of the studies described above were being collected, there was no precise mechanistic model for the role of B cells in prion pathogenesis. It had become rather clear, on the other hand, that lymphocytes alone could not account for the entirety of prion pathogenesis, and an additional sessile compartment had to be involved: adoptive transfer of $Prnp^{+/+}$ bone marrow to $Prnp^{0/0}$ recipient mice did not suffice to restore infectability of *Prnp*-expressing brain grafts, indicating that neuroinvasion was still defective (Blättler et al. 1997).

In an immediately subsequent series of bone marrow transfer experiments, it emerged that peripheral prion pathogenesis required the physical presence of B cells, yet intraperitoneal infection occurred efficiently even in B-cell-deficient hosts that had been transferred with B cell from *Prnp* knock-out mice (Klein et al. 1998).

Table 5 *Susceptibility of various strains of immunodeficient mice to intracerebrally or intraperitoneally administered prions (Klein et al. 1997)*

		Intracerebral route		Intraperitoneal route	
Defect	**Genotype**	**Scrapie**	**Time to terminal disease**	**Scrapie**	**Time to terminal disease**
T	$CD4^{0/0}$	7/7	159±11	8/8	191±1

We measured the latency of scrapie (days from inoculation to terminal disease) upon delivery of a standard prion inoculum. All mice developed spongiform encephalopathy after intracerebral inoculation. By contrast, all mice that carried a defect in B-cell differentiation stayed healthy after intraperitoneal inoculation of RML scrapie prions. Intriguingly, in this and in several subsequent studies, $TNFRI^{-/-}$ developed disease with the same kinetics as wild-type mice, although there are no morphologically detectable follicular dendritic cells in the spleens of $TNFRI^{-/-}$ mice.

Therefore, the presence of B cells – but not expression of the cellular prion protein by these cells – is indispensable for pathogenesis upon intraperitoneal infection in the mouse scrapie model (Aguzzi et al. 2001a).

The above results have been reproduced and confirmed several times over the years by many laboratories in various experimental paradigms: the requirement for B cells in particular appears to be very stringent in most instances investigated. However, it has emerged that not all strains of prions induce identical patterns of peripheral pathogenesis, even when propagated in the same, isogenic strain of host organism. One quite intriguing exception to the B-cell requirement appears to have been recently identified: Manuelidis and colleagues have reported efficient peripheral infection of B-cell-deficient mice with a mouse-adapted strain of human CJD prions (Shlomchik et al. 2001). Despite its somewhat selective interpretation of previously published reports, this study is interesting in that it identifies the unique situation of a prion strain that induces a highly anomalous peripheral pathogenesis.

Straining the lymphocytes

Another interesting discrepancy that remains to be addressed concerns the actual nature of the cells that replicate and accumulate prions in lymphoid organs. In the RML paradigm, four series of rigorously controlled experiments over 5 years (Aguzzi et al. 2000b; Kaeser et al. 2001; Klein et al. 2001; Prinz et al. 2002) unambiguously reproduced the original observation by Thomas Blättler and colleagues that transfer of wild-type ($Prnp^{+/+}$) bone marrow cells (or fetal liver cells) to PrP-deficient ($Prnp^{0/0}$) mice restored accumulation and replication of prions in spleen (Blättler et al. 1997). By contrast, Karen Brown and colleagues reported a diametrically opposite outcome of similar experiments when mice were inoculated with prions of the ME7 strain (K.L. Brown et al. 1999). Since trivial experimental artifacts appear to have been excluded, it is enticing to speculate that this discrepancy may identify yet another significant difference in the cellular tropism of different prion strains.

It is important to note that the Blättler results do not necessarily indicate that lymphocytes are the primary splenic repository of prions: in fact, other experiments suggest that this is quite unlikely. Instead, bone marrow transplantation may

- transfer an ill-defined population with the capability to replenish splenic stroma and to replicate prions, or
- less probably, donor-derived PrP^C expressing hematopoietic cells may confer prion replication capability to recipient stroma by virtue of 'GPI painting,' i.e. the post-translational cell-to-cell transfer of glycophosphoinositol linked extracellular membrane proteins (Kooyman et al. 1998).

Some evidence might be accrued for either possibility: stromal splenic follicular dendritic cells have been described by some authors to possibly derive from hematopoietic precursors, particularly when donors and recipients were young (Szakal et al. 1995; Kapasi et al. 1998). Conversely, instances have been described in which transfer of GPI-linked proteins occurs in vivo with surprisingly high efficiency (Kooyman et al. 1995). Most recently, GPI painting has been described specifically for the cellular prion protein (Liu et al. 2002).

While it has been known for a long time that specific strains of prions may preferentially affect specific subsets of neurons, the Blättler/Brown paradox may uncover an analogous phenomenon in peripheral prion pathogenesis. The latter question may be much more important than it may appear at face value, and its clarification may warrant the investment of significant resources, since the molecular and cellular basis of peripheral tropism of prion strains is likely to be directly linked to the potential danger of BSE in sheep (Bruce et al. 2002; Glatzel and Aguzzi 2001; Kao et al. 2002), as well the potential presence of vCJD prions in human blood (Aguzzi 2000).

PRION HIDEOUTS IN LYMPHOID ORGANS

As mentioned above, prion infectivity rises very rapidly (in a matter of days) in the spleen of intraperitoneally infected mice. Although B lymphocytes are crucial for neuroinvasion, a series of prion titrations in *Prnp*-expressing and *Prnp*-ablated mice, as well as reciprocal bone marrow chimeras thereof, has virtually ruled out the hypothesis that the bulk of infectivity might be contained in lymphocytes. Instead, all evidence points to the fact that most splenic prion infectivity resides in a 'stromal' fraction. Therefore, lymphocytes may be important for trafficking prions within lymphoid organs, but they do not appear to represent a major hideout for the infectious agent. Follicular dendritic cells (FDC) are a prime candidate prion reservoir, since they express large amounts of cellular prion protein, and PrP accumulations tend to co-localize with FDCs in light and electron microscopical analyses of prion-infected spleens. More recently, elegant immunoelectron microscopic studies have evidenced that strong PrP immunoreactivity is situated in the immediate neighborhood of iccosomes (Jeffrey et al. 2000).

A definitive assessment of the contribution of FDCs to prion pathogenesis continues to be problematic since the histogenesis and the molecular characteristics of these cells are ill-defined. In particular, there is a dearth of molecular markers for FDCs. FDCs express S-100 proteins, as well as the complement receptors 2 (CD35) and 4 (identical to the marker FDC-M2). All of these markers, however, are also expressed by additional cell types, even within lymphoid organs (Bofill et al. 2000). The FDC-M1 marker recognized by hybridoma clone 4C11 appears to be more

specific, but it stains also tingeable body macrophages, which are most likely of hematopoietic origin. In addition, the antigen recognized by 4C11 has not been molecularly characterized.

Identification of FDC-specific genes would be extremely important and useful to this effect, since it would allow for transgenic studies of FDC histogenesis using fluorescent marker proteins. Other studies on the immediate wish list that would depend on FDC-specific transcription might include:

- transgenetic expression of *Prnp*-restricted to FDCs
- lineage ablation experiments by expressing conditional suicide genes – such as diphtheria toxin receptor or herpes simplex virus thymidine kinase – in FDCs.

Gene deletion experiments in mice have shown that signaling by both TNF and lymphotoxins is required for FDC development (Fu et al. 1997; Koni et al. 1997; Endres et al. 1999). Membrane-bound LT-α/β (LT-α_1/β_2 or LT-α_2/β_1) heterotrimers signal through the LT-β receptor (LT-βR) (Ware et al. 1995), thereby activating a signaling pathway required for the development and maintenance of secondary lymphoid organs (Mackay et al. 1997; Matsumoto et al. 1997). Membrane LT-α/β heterotrimers are mainly expressed by activated lymphocytes (Browning et al. 1993, 1995). Maintenance of preexisting FDCs in a differentiated state requires continuous interaction with B lymphocytes expressing surface LT-α/β (Gonzalez et al. 1998). Inhibition of the LT-α/β pathway in mice by treatment with LT-βR-immunoglobulin fusion protein (LT-βR-IgFcγ) (Crowe et al. 1994) leads to the disappearance of mature, functional FDCs (defined as cells that express markers such as FDC-M1, FDC-M2, or CD35) within one day, both in spleen and in lymph nodes (Mackay et al. 1997; Mackay and Browning 1998). Prolonged administration of LT-βR-IgFcγ leads to disruption of B-cell follicles.

All of the above prompted a study of the effect of selective ablation of functional FDCs on the pathogenesis of scrapie in mice. FDC depletion was maintained by weekly administration of LT-βR-IgFcγ for 8 weeks. Histological examination of spleen sections revealed that FDC networks had disappeared 1 week after treatment (Figure 15), as expected (Montrasio et al. 2000).

In mice, following peripheral inoculation, infectivity in the spleen rises within days and reaches a plateau after a few weeks (Bruce 1985; Büeler et al. 1993; Rubenstein et al. 1991). Even after intracerebral inoculation, spleens of C57BL/6 animals contain infectivity already 4 days post-infection (Büeler et al. 1993). However, western blot analysis (Figure 16) revealed that 8 weeks after inoculation spleens of control mice showed strong bands of protease-resistant PrP, whereas mice injected weekly with LT-βR-IgFcγ, starting either 1 week before or 1 week after inoculation, showed no detectable signal (less than one-fiftieth of the controls).

Prion infectivity in three spleens for each time point was assayed by intracerebral inoculation into indicator mice (Fischer et al. 1996). In spleens of mice treated with LT-βR-IgFcγ 1 week before intraperitoneal inoculation,

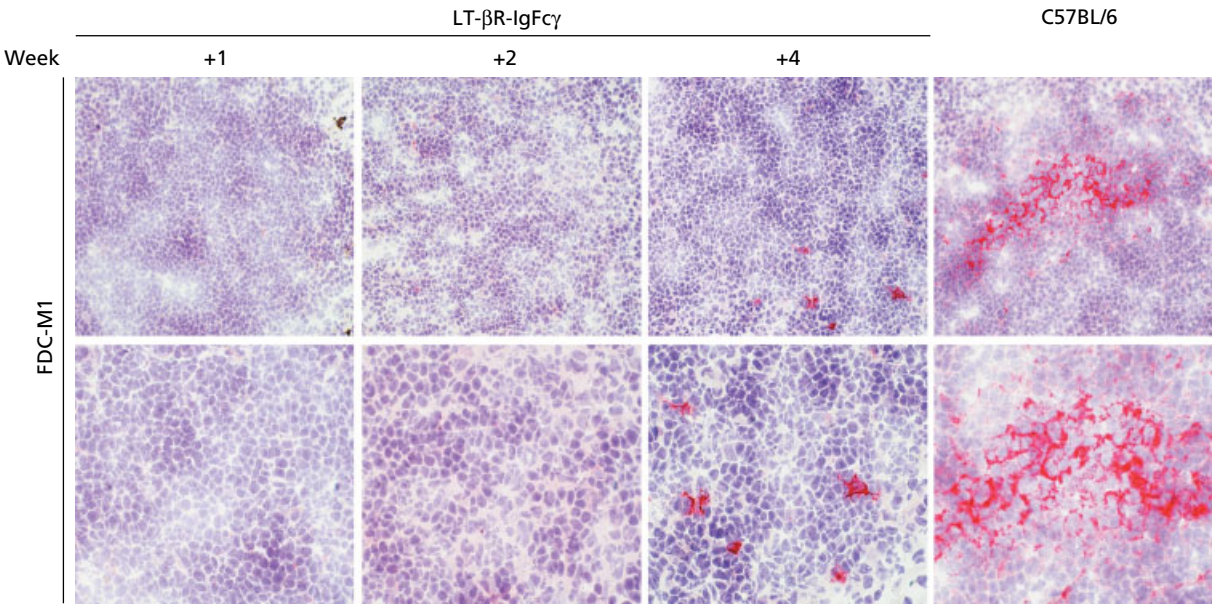

Figure 15 *Depletion of follicular dendritic cells by pharmacological inhibition of lymphotoxin signaling. Time course of FDC depletion in spleen of LT-βR-IgFcγ-treated mice. Left to right: spleen histology at 1 week, 2 weeks, and 4 weeks after administration of lymphotoxin antagonist. Right hand column shows administration of human immunoglobulin for control. Frozen sections of treated (left) and control mice (right) immunostained with follicular dendritic cell specific antibody FDC-M1 at different times points after injection of LT-βR-IgFcγ (original magnifications: upper row 8×25; lower row 8×63). Germinal centers FDC networks were depleted 1 week after treatment as described (Mackay and Browning 1998; Montrasio et al. 2000). Some FDC-M1 positive cells, which may represent residual FDCs or tingeable body macrophages, were still detectable in the spleens of treated mice.*

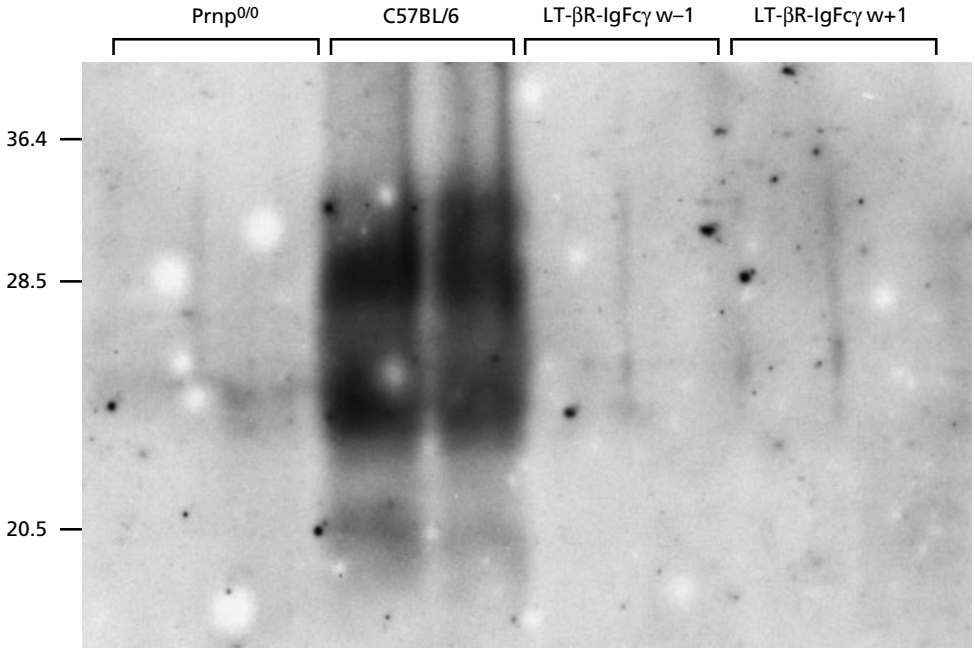

Figure 16 *Inhibition of lymphotoxin signalling blocks prion replication in lymphoid organs. Accumulation of PrP^{Sc} in spleens of LT-βR-IgFcγ-treated mice 8 weeks after inoculation. Immunoblot analysis of spleen extracts (200 μg total protein) from LT-βR-IgFcγ-treated and control mice sacrificed 8 weeks after inoculation. All spleen samples were treated with proteinase K. Mice analyzed (left to right):* $Prnp^{0/0}$*; untreated, LT-βR-IgFcγ-treated C57BL/6 mice either 1 week before (LT-βR-IgFcγ w−1) or after (LT-βR-IgFcγ w+1) prion inoculation. Spleens of two mice for each group were analyzed. Immunoreactive PrP was detected using a rabbit antiserum against mouse-derived PrP (1B3) (Farquhar et al. 1994) and enhanced chemiluminescence. The position of the molecular mass standards (in kDa) is indicated on the left side of the fluorogram. The three diagnostic bands of PrP^{Sc} are only recognized in untreated mice. LT-βR-IgFcγ treatment led to complete disappearance of the signal (reduction >50-fold).*

no infectivity could be detected after 3 or 8 weeks (<1.0 $logID_{50\backslash p}$units/ml 10 percent homogenate). Traces of infectivity, possibly representing residual inoculum, were present in the 1-week samples. In mice treated with LT-βR-IgFcγ 1 week after inoculation, the titers were about 2.2 and 4.1 $logID_{50}$ units/ml 10 percent homogenate at 3 weeks and at borderline detectability at 8 weeks after infection, suggesting that some prion accumulation took place in the first weeks after inoculation but was reversed under treatment with LT-βR-IgFcγ by 8 weeks. Spleens of scrapie-inoculated control mice treated with unspecific pooled human immunoglobulins (huIgG) 1 week after inoculation had 4.5 and 5.5 $logID_{50}$ units/ml 10 percent homogenate 8 weeks after intraperitoneal inoculation.

To assess whether prolonged depletion of mature FDCs would perturb the progression of the disease, C57BL/6 mice were subjected to weekly administration of the fusion protein up to 8 weeks post-inoculation and observed for more than 340 days. Mice receiving LT-βR-IgFcγ starting 1 week after inoculation developed the disease with about 25 days delay as compared to control mice. Whenever FDC depletion was initiated 1 week before inoculation, the effect on incubation time was even more pronounced: Two out of three mice developed scrapie symptoms 60 days later than huIgG-treated controls and one mouse survived >340 days (Montrasio et al. 2000). Double-color immunofluorescence analysis of spleen sections of terminally sick animals revealed that the FDC networks were reconstituted after interruption of LT-βR-IgFcγ administration at 8 weeks and that PrP^{C} and/or PrP^{Sc} colocalized with FDCs. Immunoblot analysis showed that PrP^{Sc} accumulation was restored upon reappearance of FDCs in the spleens of terminal sick LT-βR-IgFcγ-treated mice.

These results show that follicular dendritic cells are essential for the deposition of PrP^{Sc} and generation of infectivity in the spleen and suggest that they participate in the process of neuroinvasion. Therefore, the requirement for B cells for these processes might be explained by their essential role in the maturation of FDCs. PrP knock-out mice expressing PrP transgenes only in B cells do not sustain prion replication in the spleen or elsewhere, suggesting that prions associated with splenic B cells (Raeber et al. 1999a) may be acquired from FDCs. Finally, these results suggest that strategies aimed at depleting FDCs might be envisaged for post-exposure prophylaxis (Aguzzi and Collinge 1997) of prion infections initiated at extracerebral sites. The distance between follicular dendritic cells and sympathetic nerve terminals in lymphoid organs appears to control the velocity of neuroinvasion, since juxtaposition of FDCs and sympathetic nerve terminals increases the velocity of neuroinvasion (Prinz et al. 2003a).

THE CELLULAR BASIS OF PRION LYMPHOTROPISM

As discussed above, inhibition of the LT-β signaling pathway with a soluble receptor depletes FDCs (Mackay and Browning 1998) and abolishes prion replication in spleens, thereby prolonging the latency of scrapie after intraperitoneal challenge (Montrasio et al. 2000). This suggests that B-cell-deficient μMT mice (Kitamura et al. 1991) may be resistant to intraperitoneal prion inoculation (Klein et al. 1997) because of impaired FDC maturation (Klein et al. 1998; Montrasio et al. 2000). However, additional experimentation appears to indicate that PrP^C-expressing hematopoietic cells are required in addition to FDCs for efficient lymphoreticular prion propagation (Blättler et al. 1997; Kaeser et al. 2001). This apparent discrepancy called for additional studies of the molecular requirements for prion replication competence in lymphoid stroma. Therefore peripheral prion pathogenesis was studied in mice lacking TNF-α, LTα/β, or their receptors. After intracerebral inoculation, all treated mice developed clinical symptoms of scrapie with incubation times, attack rates, and histopathological characteristics similar to those of wild-type mice, indicating that TNF/LT signaling is not relevant to cerebral prion pathogenesis. Upon intraperitoneal prion challenge, mice defective in LT signaling (LT-$\alpha^{-/-}$, LT$\beta^{-/-}$, LT-β$R^{-/-}$, or LT-$\alpha^{-/-}$TNF-$\alpha^{-/-}$) proved virtually non-infectible with $\leqslant 5$ $\log LD_{50}$ scrapie infectivity, and establishment of subclinical disease (Frigg et al. 1999) was prevented. By contrast, $TNFR1^{-/-}$ mice were almost fully susceptible to all inoculum sizes, and TNF-$\alpha^{-/-}$ mice showed dose-dependent susceptibility. $TNFR2^{-/-}$ mice had intact FDCs and germinal centers, and were fully susceptible to scrapie. Unexpectedly, all examined lymph nodes of $TNFR1^{-/-}$ and TNF-$\alpha^{-/-}$ mice had consistently high infectivity titers (Prinz et al. 2002). Even inguinal lymph nodes, which are distant from the injection site and do not drain the peritoneum, contained infectivity titers equal to all other lymph nodes. Therefore, TNF deficiency prevents lymphoreticular prion accumulation in spleen but not in lymph nodes.

Why is susceptibility to peripheral prion challenge preserved in the absence of TNFR1 or TNF-$\alpha^{-/-}$, while deletion of LT signaling components confers high resistance to peripheral prion infection? After all, each of these defects (except $TNFR2^{-/-}$) abolishes FDCs. For one thing, prion pathogenesis in the lymphoreticular system appears to be compartmentalized, with lymph nodes (rather than spleen) being important reservoirs of prion infectivity during disease. Second, prion replication appears to take place in lymph nodes even in the absence of mature FDCs.

Bone marrow chimeric mice were generated in order to determine whether hematopoietic components are involved in prion propagation in $TNFR1^{-/-}$ lymph nodes. In $Prnp^{0/0}$ mice grafted with $TNFR1^{-/-}$ hematopoietic cells, high infectivity loads were detectable in lymph nodes but not spleens, indicating that TNFR1-deficient, PrP^C-expressing hematopoietic cells may support prion propagation within lymph nodes (Prinz et al. 2002). These findings are in line with previous studies, which showed that chimeras of PrP-deficient hosts with PrP-expressing hematopoietic cells can accumulate prions chronically (Blättler et al. 1997; Kaeser et al. 2001). The PrP signal colocalized with a subset of macrophages in $TNFR1^{-/-}$ lymph nodes. Since marginal zone macrophages are in close contact to FDCs and also interact with marginal zone B cells, this cell type is certainly a candidate supporter in prion uptake and replication. On the other hand, it has been reported that in short-time infection experiments depletion of macrophages appears to enhance the amount of recoverable infectivity, implying that macrophages may degrade prions rather than transport them (Beringue et al. 2000). The finding that a cell type other than mature FDCs is involved in prion replication and accumulation within lymph nodes may be relevant to the development of post-exposure prophylaxis strategies.

SYMPATHETIC NERVES: A NEUROIMMUNE LINK?

In the last several years, a model has emerged that predicts prion neuroinvasion to consist of two distinct phases (Aguzzi et al. 2001c). The details of the first phase are discussed above: widespread colonization of lymphoreticular organs is achieved by mechanisms that depend on B lymphocytes (Klein et al. 1997, 1998), follicular dendritic cells (Montrasio et al. 2000), and complement factors (Klein et al. 2001). The second phase has long been suspected to involve peripheral nerves, and possibly the autonomic nervous system, and may depend on expression of PrP^C by these nerves (Glatzel and Aguzzi 2000). Glatzel and colleagues have been attempting to test the requirement for expression of PrP^C in peripheral nerves for several years, and have developed a gene transfer protocol to spinal ganglia aimed at resolving this question (Glatzel et al. 2000); however, they were never able to recover infectivity in spinal cords of $Prnp^{0/0}$ mice whose spinal nerves had been transduced by *Prnp*-expressing adenoviruses (M. Glatzel and A. Aguzzi, unpublished results). Also, fast axonal transport does not appear to be involved in prion neuroinvasion, since mice that are severely impaired in this transport mechanism experience prion pathogenesis with kinetics similar to that of wild-type mice (Künzi et al. 2002).

There is substantial evidence suggesting that prion transfer from the lymphoid system to the CNS occurs along peripheral nerves in a PrP^C-dependent fashion

(Blättler et al. 1997; Glatzel and Aguzzi 2000; Race et al. 2000). Studies focusing on the temporal and spatial dynamics of neuroinvasion have suggested that the autonomic nervous system might be responsible for transport from lymphoid organs to the CNS (Clarke and Kimberlin 1984; Cole and Kimberlin 1985; Beekes et al. 1998; McBride and Beekes 1999).

The innervation pattern of lymphoid organs is mainly sympathetic (Felten and Felten 1988). Glatzel and colleagues have shown that denervation by injection of the drug 6-hydroxydopamine (6-OHDA), as well as 'immunosympathectomy' by injection of antibodies against nerve growth factor (NGF) leads to a rather dramatic decrease in the density of sympathetic innervation of lymphoid organs (Figure 17), and significantly delayed the development of scrapie (Glatzel et al. 2001) (Figure 18). Sympathectomy appears to delay the transport of prions from lymphatic organs to the thoracic spinal cord, which is the entry site of sympathetic nerves to the CNS. Transgenic mice overexpressing NGF under control of the K14 promoter, whose spleens are hyperinnervated, developed scrapie significantly earlier than nontransgenic control mice. No alteration in lymphocyte subpopulations was detected in spleens at any time point investigated. In particular, no significant differences in content of FDCs were detected between treated and untreated mice, which negates the possibility that the observed protection may be due to modulation of FDC microanatomy.

While the sympathetic nervous system may represent a major component of the second phase of prion neuroinvasion, many details remain to be elucidated. It is not known whether prions can be transferred directly from FDCs to sympathetic endings, or whether additional cell types are involved. The latter possibility is particularly enticing, since FDCs have not been shown to entertain physical contact with sympathetic nervous system terminals.

Moreover, it is unclear how prions are actually transported within peripheral nerves. Axonal and non-axonal transport mechanisms may be involved, and non-neuronal cells (such as Schwann cells) may play a role. Within the framework of the protein-only hypothesis, one may hypothesize a 'domino' mechanism, by which incoming PrP^{Sc} converts resident PrP^{C} on the axolemmal surface, thereby propagating spatially the infection. While speculative, this model is attractive since it may accommodate the finding that the velocity of neural prion spread is extremely slow (Kimberlin et al. 1983) and may not follow the canonical mechanisms of fast axonal transport. Indeed, recent studies may favor a non-axonal transport mechanism that results in periaxonal deposition of PrP^{Sc} (Hainfellner and Budka 1999; Glatzel and Aguzzi 2000).

The fact that denervated mice eventually developed scrapie may be due to an alternative, low-efficiency route of entry that may become uncovered by the absence of sympathetic fibers, or because of incomplete sympathectomy. Entry through the vagal nerve has been proposed in studies of the dynamics of vacuolation

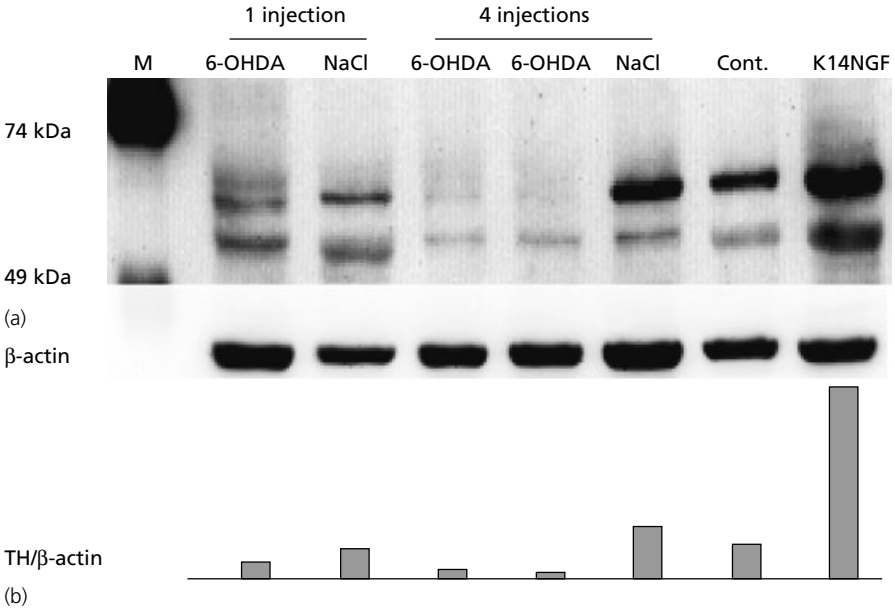

Figure 17 *The sympathetic innervation of the spleen can be ablated by 6-hydroxydopamine (6-OHDA).* **(a)** *The density of sympathetic innervation correlates with the concentration of tyrosine hydroxylase, which was measured by western blot analysis in spleens of adult 6-OHDA-treated mice, K14NGF transgenic mice, and controls. The two main tyrosine hydroxylase bands are visible at ca. 55 kDa. While there is a certain increase in sympathetic innervation with age, it is obvious that 6-OHDA treatment depletes, and the K14NGF transgene increases sympathetic innervation.* **(b)** *Quantification of tyrosine hydroxylase content by chemiluminescence scanning. The bars represent the ratio between signal intensity of the tyrosine hydroxylase band and that of the corresponding β-actin bands (arbitrary units).*

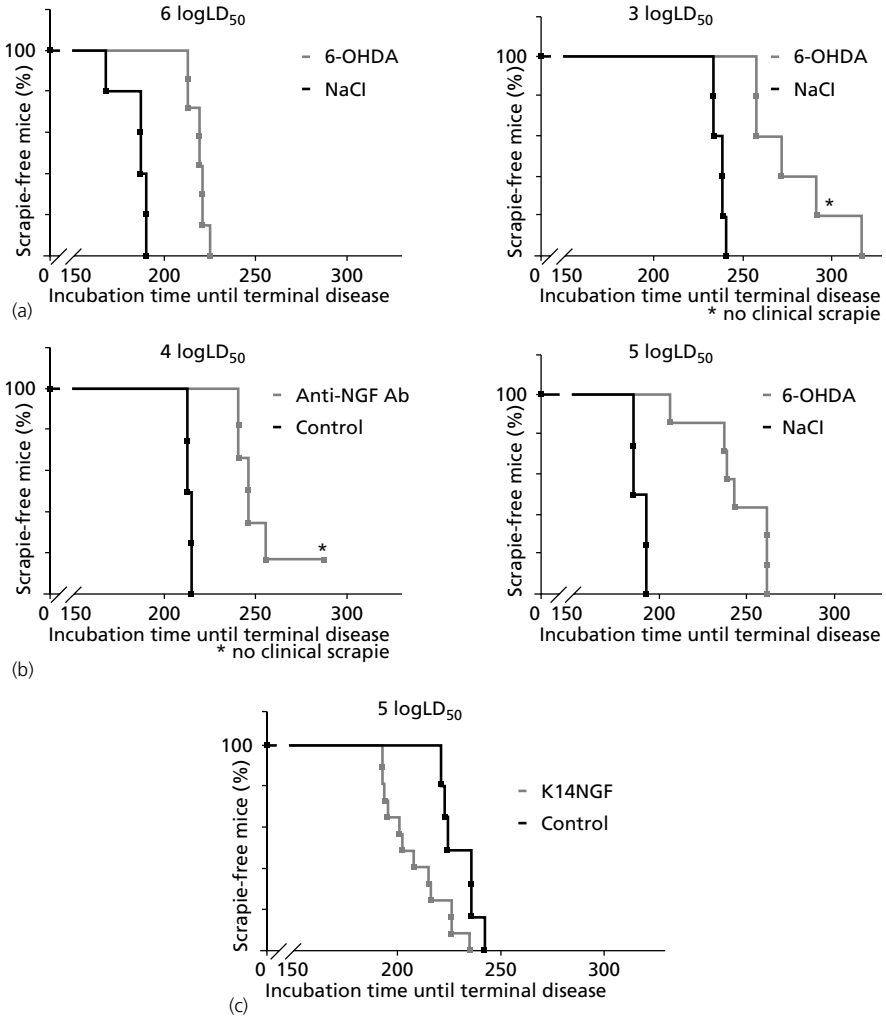

Figure 18 *Modulation of sympathetic nerve density in lymphoid organs affects the efficiency of peripheral prion pathogenesis. Survival plots displaying the incubation time (days) until development of terminal scrapie in C57BL/6 mice inoculated intraperitoneally with prions* **(a–c)** *and of* tga20 *indicator mice inoculated intracerebrally with spinal cord and spleen samples* **(d)**. *Mice injected with 6-OHDA in their adulthood* **(a)**, *as well as mice injected neonatally with anti-NGF antibodies or with 6-OHDA* **(b)** *developed terminal scrapie significantly later than their respective controls. Instead K14NGFmice, which have hyperinnervated spleens, developed terminal scrapie earlier than matched wild-type siblings of the same genetic background* **(c)**. *The size of inoculum is expressed in infectious units (logLD_{50}).*

following oral and intraperitoneal challenge with prions (Baldauf et al. 1997; Beekes et al. 1998). There was no evidence for transport along the vagal nerve in sympathectomized mice, since vagal nuclei were affected similarly to other regions of the brainstem unrelated to the vagal system. This supports the hypothesis that delayed neuroinvasion in denervated mice may occur because of residual innervation of lymphoreticular organs.

The surprising finding that infectious titers in hyperinnervated spleens are at least two logs higher and show enhanced PrP^{Sc} accumulations compared to control mice suggests that sympathetic nerves, besides being involved in the transport of prions, may also accumulate and replicate prions in lymphatic organs (Clarke and Kimberlin 1984). Obviously, this finding has implications related to the permanence and possibly eradication of prions in subclinically infected hosts.

Spread of prions within the central nervous system

Ocular administration of prions has proved particularly useful to study neural spread of the agent, since the retina is a part of the central nervous system and intraocular injection does not produce direct physical trauma to the brain, which may disrupt the blood–brain barrier and impair other aspects of brain physiology. The assumption that spread of prions occurs axonally rests mainly on the demonstration of diachronic spongiform changes along the retinal pathway following intraocular infection (Fraser 1982).

To investigate whether spread of prions within the CNS is dependent on PrP^{C} expression in the visual pathway, PrP-producing neural grafts were used as sensitive indicators of the presence of prion infectivity in

the brain of an otherwise PrP-less host. Following inoculation with prions into the eye of grafted *Prnp*$^{0/0}$ mice, none of the grafts showed signs of scrapie. Therefore, it was concluded that infectivity administered to the eye of PrP-deficient hosts cannot induce scrapie in a PrP-expressing brain graft (Brandner et al. 1996b).

Engraftment of *Prnp*$^{0/0}$ mice with PrP^{C}-producing tissue might lead to an immune response to PrP which, in turn, was shown to be in principle capable of neutralizing infectivity (Heppner et al. 2001b). In order to definitively rule out the possibility that prion transport was disabled by a neutralizing immune response, *Prnp*$^{0/0}$ mice were rendered tolerant by expressing PrP^{C} under the control of the *lck* promoter. These mice overexpress PrP on T lymphocytes, but are resistant to scrapie and do not replicate prions in brain, spleen, and thymus after intraperitoneal inoculation with scrapie prions (Raeber et al. 1999b). Engraftment of these mice with PrP-overexpressing neuroectoderm did not lead to the development of antibodies to PrP after intracerebral or intraocular inoculation, presumably due to clonal deletion of PrP-immunoreactive T lymphocytes. As before, intraocular inoculation with prions did not provoke scrapie in the graft, supporting the conclusion that lack of PrP^{C}, rather than immune response to PrP, prevented prion spread (Brandner et al. 1996b). Therefore, PrP^{C} appears to be necessary for the spread of prions along the retinal projections and within the intact CNS.

These results indicate that intracerebral spread of prions is based on a PrP^{C} -paved chain of cells, perhaps because they are capable of supporting prion replication. When such a chain is interrupted by interposed cells that lack PrP^{C}, as in the case described here, no propagation of prions to the target tissue can occur. Perhaps prions require PrP^{C} for propagation across synapses: PrP^{C} is present in the synaptic region (Fournier et al. 1995) and certain synaptic properties are altered in *Prnp*$^{0/0}$ mice (Collinge et al. 1994; Whittington et al. 1995). Perhaps transport of prions within (or on the surface of) neuronal processes is PrP^{C}-dependent. Within the framework of the protein-only hypothesis (Griffith 1967; Prusiner 1989b), these findings may be accommodated by a 'domino-stone' model in which spreading of scrapie prions in the CNS occurs per continuitatem through conversion of PrP^{C} by adjacent PrP^{Sc} (Aguzzi 1997).

INNATE IMMUNITY AND ANTIPRION DEFENSE

Macrophages and Toll-like receptors

Cells of the monocyte/macrophage lineage typically represent the first line of defense against an extremely broad variety of pathogens. In the case of prions, it might be conceivable that macrophages protect against prions. However, it would be equally conceivable that macrophages, by virtue of their phagocytic properties and of their intrinsic mobility, may function as Trojan horses that transport prion infectivity between sites of replication within the body. This interesting question has not yet been fully resolved.

In a short-term prion infection paradigm, Beringue and colleagues administered dichloromethylene disphosphonate encapsulated into liposomes to mice: this eliminates for a short period of time all spleen macrophages. Accumulation of newly synthesized PrP^{Sc} was accelerated, suggesting that macrophages participate in the clearance of prions, rather than being involved in PrP^{Sc} synthesis (Beringue et al. 2000).

On the basis of the results presented above, Beringue and colleagues have suggested that activation or targeting of macrophages may represent a therapeutic pathway to explore in TSE infection. This suggestion was taken up by Sethi and Kretzschmar, who recently reported that activation of Toll-like receptors (TLR), which function as general stimulators of innate immunity by driving expression of various sets of the immune regulatory molecules, can effect post-exposure prophylaxis in an experimental model of intraperitoneal scrapie infection (Sethi et al. 2002). In this experimental paradigm, administration of prions intraperitoneally elicited disease after approximately 180 days, whereas the administration of CpG oligodeoxynucleotides 7 hours after prion inoculation and daily for 20 days led to disease-free intervals of 'more than 330 days' – although it appears that all inoculated mice died of scrapie shortly thereafter (communicated by H. Kretzschmar at the TSE conference in Edinburgh in September, 2002).

This finding is very surprising, since most available evidence indicates that general activation of the immune system would typically sensitize mice to prions, rather than protect them. The mechanism by which activation of TLRs can result in post-exposure prophylaxis is wholly unclear at present, particularly in view of the fact that mice lacking MyD88 (Adachi et al. 1998), which is an essential mediator of TLR signaling, develop prion disease with exactly the same sensitivity and kinetics as wild-type mice (Prinz et al. 2003b). Moreover, repeated administration of CpG oligonucleotides (ODN) was shown to produce a profound depletion of follicular dendritic cells, which are prominent peripheral prion reservoirs (Heikenwälder et al. 2004). This finding suggests that the alleged protective effect of CpG-ODN administration relies on indiscriminate destruction of immune organs rather than any specific anti-prion effect.

The complement system

Another prominent component at the crossroads between innate and adaptive immunity is represented by the

complement system. Opsonization by complement system components also appears to be relevant to prion pathogenesis: mice genetically engineered to lack complement factors (Klein et al. 2001), or mice depleted of the C3 complement component by administration of cobra venom (Mabbott et al. 2001), exhibit a remarkable resistance to peripheral prion inoculation. This phenomenon may, once again, be related to the pathophysiology of FDCs, which typically function as antigen traps. Trapping mechanisms essentially consist of capture of immune complexes by Fcγ receptors, and binding of opsonized antigens (linked covalently to C3d and C4b complement adducts) to the CD21/CD35 complement receptors.

Capture mediated by Fcγ receptors does not appear to be very important in prion disease: for one thing, knockout mice lacking Fcγ receptors (Takai et al. 1994, 1996; Hazenbos et al. 1996; Park et al. 1998) are just as susceptible to intraperitoneally administered scrapie as wild-type mice. Furthermore, introduction into μMT mice of a generic immunoglobulin μ chain fully restored prion neuroinvasion irrespective of whether this heavy chain allowed for secretion of immunoglobulins, or only for production of membrane-bound immunoglobulins. We therefore conclude that circulating immunoglobulins are certainly not crucial to prion replication in lymphoid organs and to neuroinvasion.

A second mechanism exploited by FDCs for antigen trapping involves covalent linking of proteolytic fragments of the complement components C3 and C4 (Szakal and Hanna 1968; Carroll 1998). The CD21/CD35 complement receptors on FDCs bind C3b, iC3b, C3d, and C4b through short consensus repeats in their extracellular domain. Ablation of C3, or of its receptor CD21/CD35, as well as C1q (alone or combined with BF/C2$^{-/-}$), delayed neuroinvasion significantly after intraperitoneal inoculation when a limiting dose of prions was administered. These effects suggest that opsonization of the infectious agent may enhance its accessibility to germinal centers by facilitating docking to FDCs.

Very large prion inocula (>10^6 infectious units) appear to override the requirement for a functional complement receptor in prion pathogenesis. This is similar to systemic viral infections and coreceptor-dependent retention within the follicular compartment, whose necessity can be overridden by very high affinity antigens (Fischer et al. 1998) or adjuvants (Wu et al. 2000). Additional retention mechanisms for prions may therefore exist in FDCs, which are not complement-dependent, or which may depend on hitherto unidentified complement receptors.

ADAPTIVE IMMUNITY AND PRE-EXPOSURE PROPHYLAXIS AGAINST PRIONS

For many conventional viral agents, vaccination is the most effective method of infection control. But is it at all possible to induce protective immunity in vivo against prions? Prions are extremely sturdy and their resistance against sterilization is proverbial. Preincubation with anti-PrP antisera was reported to reduce the prion titer of infectious hamster brain homogenates by up to 2 log units (Gabizon et al. 1988) and an anti-PrP antibody was found to inhibit formation of PrP^{Sc} in a cell-free system (Horiuchi and Caughey 1999). Also, antibodies (Klein et al. 2001) and F(ab) fragments raised against certain domains of PrP (Peretz et al. 2001) can suppress prion replication in cultured cells. However, it is difficult to induce humoral immune responses against PrP^{C} and PrP^{Sc}. This is most likely due to tolerance of the mammalian immune system to PrP^{C}, which is an endogenous protein expressed rather ubiquitously. Ablation of the *Prnp* gene (Büeler et al. 1992), which encodes PrP^{C}, renders mice highly susceptible to immunization with prions (Brandner et al. 1996b), and many of the best available monoclonal antibodies to the prion protein have been generated in *Prnp*$^{0/0}$ mice (Prusiner et al. 1993). However, *Prnp*$^{0/0}$ mice are unsuitable for testing vaccination regimens since they do not support prion pathogenesis (Büeler et al. 1993).

It was therefore asked whether genes encoding high-affinity anti-PrP antibodies (originally generated in *Prnp*$^{0/0}$ mice) may be utilized to reprogram B-cell responses of prion-susceptible mice that express PrP^{C}. Indeed, the introduction of the epitope-interacting region of heavy chain of 6H4, a high-affinity anti-PrP monoclonal antibody (Korth et al. 1997), into the germline of mice sufficed to produce high-titer anti-PrP^{C} immunity. The 6H4μ heavy chain transgene induced similar anti-PrP^{C} titers in *Prnp*$^{0/0}$, *Prnp*$^{0/+}$ and *Prnp*$^{+/+}$ mice, indicating that deletion of autoreactive B cells does not prevent anti-PrP immunity. The buildup of anti-PrP^{C} titers, however, was more sluggish in the presence of endogenous PrP^{C}, suggesting that some clonal deletion is actually occurring.

How can these observations be interpreted? The total anti-PrP^{C} titer results from pairing of one transgenic μ heavy chain with a large repertoire of endogenous κ and λ chains: some pairings may lead to reactive moieties, while others may be anergic (Figure 19a). Maybe the B-cell clones with the highest affinity to PrP^{C} are being eliminated by the immune tolerization machinery, and only clones with medium affinity are retained (Figure 19a). This would explain the delay in titer buildup in the presence of PrP^{C}, and would be in agreement with our affinity measurements – indicating that the total molar avidity of 6H4μ serum is approximately 100-fold lower that that of the original 6H4 antibody from which the transgene was derived (Figure 19b). But most intriguingly, expression of the 6H4μ heavy chain sufficed to block peripheral prion pathogenesis upon intraperitoneal inoculation of the prion agent (Heppner et al. 2001a).

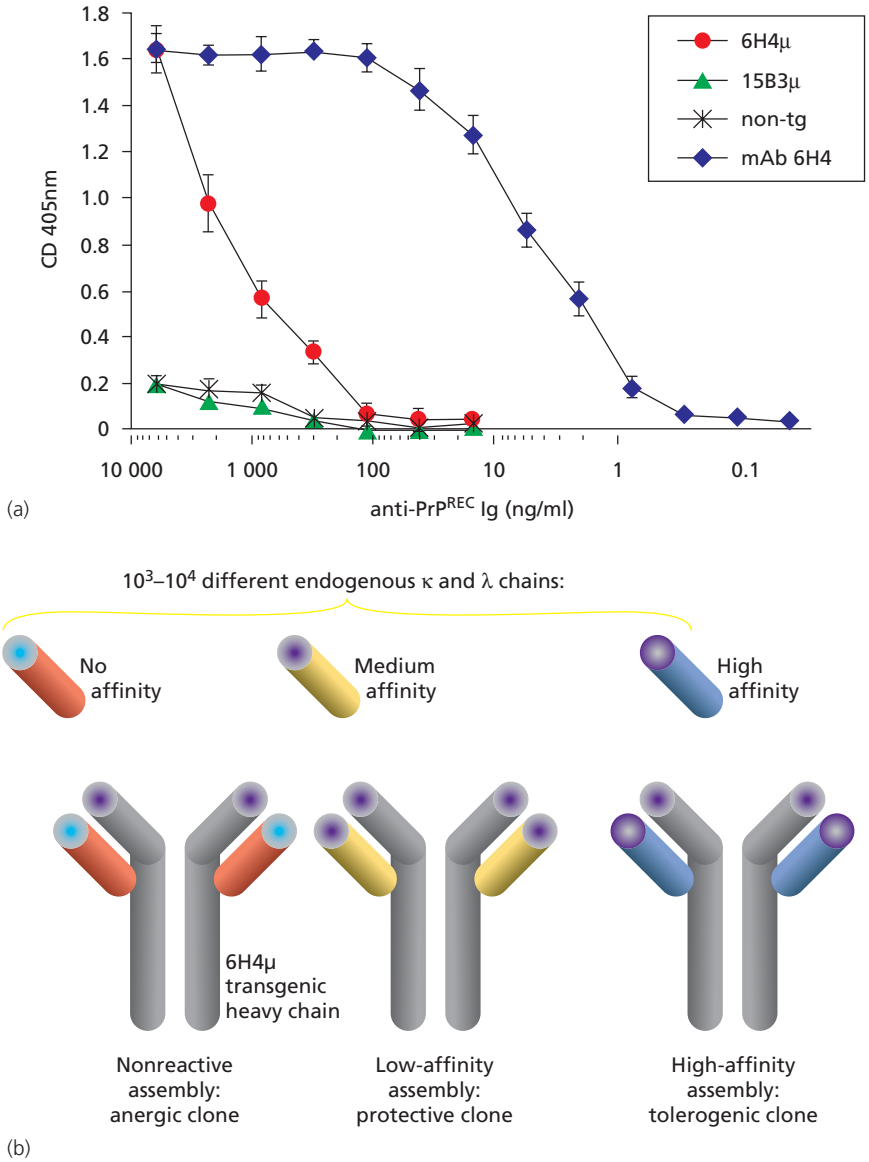

Figure 19 *Affinity and avidity of antibodies against the prion protein.* **(a)** *In order to gain some indication on the relative avidity of the immune response against PrP^C in 6H4 transgenic mice, we compared the binding of serum from transgenic mice to a dilution series of the 6H4 original monoclonal antibody. When normalized against the immunoglobulin concentration, taking into account that the anti-PrP^C antibodies 6H4 transgenic mice are pentameric, we found that the total avidity of the transgenic serum is approximately 2 log units lower than that of the monoclonal antibody from which the transgene was derived. A possible explanation for this phenomenon is depicted in* **(b)**. *While the heavy chain is kept constant in the transgene, it may pair with a large repertoire of endogenous light chains. Some of the pairs will yield very high affinity antibodies, others will have low affinity, but the majority may have no affinity at all for the prion protein. It is possible that some degree of clonal deletion occurs, and that combinations with the highest affinity are eliminated.*

PrP^C is a normal protein expressed by most tissues of the body. Therefore an anti-PrP immune response may conceivably induce an autoimmune disease, and defeat any realistic prospect for prion vaccination. We did not observe any blatant autoimmune disease as a consequence of anti-prion immunization – unless PrP^C was artificially transgenically expressed at nonphysiological, extremely high levels.

The strategy outlined above delivers proof-of-principle that a protective humoral response against prions can be mounted by the mammalian immune system, and suggests that B cells are not intrinsically tolerant to PrP^C. If the latter is generally true, lack of immunity to prions may be due to T-helper tolerance. The latter problem is not trivial, but may perhaps be overcome by presenting PrP^C to the immune system along with highly active adjuvants. These findings, therefore, encourage a reassessment of the possible value of active and passive immunization (Westaway and Carlson 2002), and perhaps of reprogramming B-cell repertoires

by μ-chain transfer, in prophylaxis or in therapy of prion diseases.

Prion immunization and its reduction to practice

As described above, monoclonal antibodies and F(ab) fragments recognizing PrP were shown to prevent de novo scrapie infection, and to abolish PrP^{Sc} as well as prion infectivity in chronically scrapie-infected neuroblastoma cells (Enari et al. 2001). Furthermore, transgenic expression of anti-PrP antibodies in mice arrested peripheral scrapie pathogenesis (Heppner et al. 2001b). In line with these results, White and colleagues confirmed the efficiency of anti-PrP antibodies in preventing prion disease by injecting such antibodies into wild-type mice upon peripheral prion challenge (White et al. 2003).

The prionostatic efficacy of anti-PrP antibodies is highest in extraneural compartments: transgenic 6H4μ mice expressing anti-PrP-specific IgM molecules were not protected when prions were administered intracerebrally (Aguzzi and Heppner, unpublished observations), and passive transfer of PrP-specific IgG immunoglobulins (White et al. 2003) was inefficient when started after the onset of clinical signs. This may be due to the limited influx of immunoglobulins into the central nervous system (CNS) and to the high prion load of clinically symptomatic animals.

By providing stable, sustained titers, active immunization may obviate to some of the problems listed above. However, host tolerance to endogenous PrP^{C} remains a major obstacle to devising active immunization regimens. Nevertheless, several recent studies suggest that the induction of anti-PrP antibodies in wild-type mice is, in principle, feasible (Souan et al. 2001; Koller et al. 2002; Sigurdsson et al. 2002; Arbel et al. 2003; Schwarz et al. 2003; Rossett et al. 2004). While anti-PrP immunoglobulin titers could be measured in most of these studies, the titers were rather low. Accordingly, the biological efficacy of these immunization series, if evaluated at all, was limited.

A systematic exploration of the efficacy of active immunization strategies against PrP (Heikenwälder et al. 2004) found that it was exceedingly difficult to elicit antibody titers to native cell-bound PrP^{C} as displayed on the cell surface of PrP^{C}-overexpressing splenocytes (Raeber et al. 1999b). This suggests that host tolerance to endogenous PrP^{C} is non-permissive to generating high-affinity anti-PrP B-cell clones, or leads to deletion or anergy of the cognate T-cell clones. Expression of PrP^{C} within the thymus did not prevent humoral immune responses to recombinant bacterially expressed PrP completely. However, extrathymic and extraneural PrP^{C} – even if expressed in very small amounts – blocked all immune responses to both PrP^{C} and bacterially expressed PrP. One must conclude, therefore, that while antibodies recognizing cell-surface PrP^{C} interfere with prion pathogenesis in two independent paradigms, humoral immune responses may not be of much value if their affinity does not extend to bona fide eukaryotic PrP^{C} as displayed on cell surfaces.

PROGRESS IN THE DIAGNOSIS OF PRION DISEASES

As with any other disease, early diagnosis would significantly advance the chances of success of any possible intervention approaches. Unfortunately, the situation in prion diagnosis continues to be rather primitive. Presymptomatic diagnosis is virtually impossible, and the earliest possible diagnosis is based on clinical signs and symptoms. Hence, prion infection is typically diagnosed after the disease has considerably progressed.

A significant advance in prion diagnostics was accomplished in 1997 by the discovery that protease-resistant PrP^{Sc} can be detected in tonsillar tissue of vCJD patients (Hill et al. 1997b). It was hence proposed that tonsil biopsy may be the method of choice for diagnosis of vCJD (Hill et al. 1999). Furthermore, there have been reports of individual cases showing detection of PrP^{Sc} at preclinical stages of the disease in tonsil (Schreuder et al. 1996) as well as in the appendix (Hilton et al. 1998), indicating that lymphoid tissue biopsy may represent a potential test for asymptomatic individuals. These observations triggered large screenings of human populations for subclinical vCJD prevelance, using appendectomy and tonsillectomy speciments (Glatzel et al. 2003b). PrP^{Sc}-positive lymphoid tissue were long considered to be a vCJD-specific feature which would not apply to any other forms of human prion diseases (Hill et al. 1999). However, a recent survey of peripheral tissues of patients with sCJD has identified PrP^{Sc} in as many as one-third of skeletal muscle and spleen samples (Glatzel et al. 2003a). In addition, PrP^{Sc} was found in the olfactory epithelium of patients suffering from sCJD (Zanusso et al. 2003). These unexpected findings raise the hope that minimally invasive diagnostic procedures may take the place of brain biopsy in intravital CJD diagnostics.

The sensitivity of PrP^{Sc} detection was significantly improved by the sodium phosphotungstic (NaPTA) precipitation method (Safar et al. 1998). By concentrating PrP^{Sc} prior to western blot analysis, this procedure improves the sensitivity of diagnostic assays by as much as four orders of magnitude (Wadsworth et al. 2001). An interesting development was brought about by the conformation-dependent immunoassay (CDI), in which conformational differences of PrP isoforms are mapped by quantitating the relative binding of antibodies to denatured and native protein (Safar et al. 1998). Rather than relying on protease resistance, the CDI measures a variety of misfolded PrP isoforms,

which may increase its sensitivity (Safar et al. 2002; Bellon et al. 2003).

Be that as it may, all techniques described above suffer from the fact that PrP^{Sc} continues to represent a surrogate marker for prion infectivity – since:

- PrP^{Sc} has not been incontrovertibly shown to be congruent with the prion
- several manipulations in vitro and in vivo can render PrP^{C} protease-resistant without bestowing infectivity on it.

Therefore, determination of prion infectivity by bioassay remains the golden standard: as in Pasteur's age, the concentration of the infectious agent is determined by inoculating serial dilutions of the test material into experimental animals, and the dilution at which 50 percent of the animals contract the disease (termed ID_{50}) is determined. Naturally, this system is riddled with inconveniences: scores of animals need to be sacrificed, and the incubation times are lengthy (transgenetic overexpression of PrP^{C} can help, but only to some extent). Also the method tends to be breathtakingly inaccurate: the inoculation schemes used in most studies typically suffer from standard errors of ± 1 order of magnitude!

A radical improvement of this situation is likely to be brought about by the use of prion-susceptible cell lines (Bosque and Prusiner 2000). The determination of prion infectivity endpoints combines the sensitivity and intrinsic biological validity of the bioassay (i.e. direct measurement of the infectivity) with the speed and convenience of an in vitro methodology amenable to medium-throughput automation (Klohn et al. 2003).

PERSPECTIVES IN PRION IMMUNOLOGY

Until approximately 10 years ago, it was thought that prion diseases are completely independent of the immune system. The lack of overt inflammation in spongiform lesions lent support to this viewpoint. It is fascinating to note that this view has been turned completely upside down, and it is now obvious that the relationships between the infectious agent and various components of the immune system are intimate, complex, and multifaceted. While several crucial questions are still open, notably regarding the true portal of entry of BSE prions into the human body, and the mechanism by which they cause vCJD, a fascinating multitude of unexpected findings has been reported, some of them in extraordinary detail.

In the long run, one would hope that this accrued knowledge will be put into useful practice. To that effect, it is encouraging to note that a sizable number of the steps in prion transport which have been discussed above appears to be rate-limiting. Because of that, these steps lend themselves as a target for interventions, which may be therapeutic or prophylactic (Aguzzi et al. 2001b).

A number of substances appear capable of influencing the outcome of a contact of mammalian organisms with prions: a non-exhaustive list includes compounds as diverse as Congo red (Caughey and Race 1992), amphotericin B (Pocchiari et al. 1987), anthracyclin derivatives (Tagliavini et al. 1997), sulfated polyanions (Caughey and Raymond 1993), pentosan polysulfate (Farquhar et al. 1999), soluble lymphotoxin-β receptors (Montrasio et al. 2000), porphyrins (Priola et al. 2000), branched polyamines (Supattapone et al. 2001), and β-sheet breaker peptides (Soto et al. 2000). However, it is sobering that none of the substances have yet made it to any validated clinical use: quinacrine appears to represent the most recent unfulfilled promise (Collins et al. 2002). On the other hand, the tremendous interest in this field has attracted researchers from various neighboring disciplines, including immunology, genetics, and pharmacology, and therefore it is to be hoped that rational and efficient methods for managing prion infections will be developed in the future.

CONCLUDING REMARKS

Do prions exist in lower organisms?

In *Saccharomyces cerevisiae*, *ure2* and [*URE3*] mutants were described that can grow on ureidosuccinate under conditions of nitrogen repression such as glutamic acid and ammonia (Lacroute 1971). Mutants of *URE2* exhibit mendelian inheritance, whereas [*URE3*] is cytoplasmically inherited (Wickner 1994). The [*URE3*] phenotype can be induced by UV irradiation and by overexpression of ure2p, the gene product of ure2; deletion of ure2 abolishes [*URE3*]. The function of ure2p is unknown but it has substantial homology with glutathione-*S*-transferase; attempts to demonstrate this enzymic activity with purified ure2p have been unsuccessful (Coschigano and Magasanik 1991). Whether the [*URE3*] protein is a post-translationally modified form of ure2p which acts upon unmodified ure2p to produce more of itself remains to be established.

Another yeast prion is the [*PSI*] phenotype (Wickner 1994). [*PSI*] is a non-mendelian inherited trait that can be induced by overexpression of *Sup35* (Cox et al. 1988; Chernoff et al. 1993). The production of [*PSI*] has recently been shown to require the molecular chaperone Hsp104, suggesting that this protein functions in producing an altered form of *Sup35* (Chernoff et al. 1995). Both [*PSI*] and [*URE3*] can be cured by exposure of the yeast to 3 mm GdnHCl. The mechanism responsible for abolishing [*PSI*] and [*URE3*] with a low concentration of GdnHCl is unknown. In the filamentous fungus *Podospora anserina*, the *het-s* locus controls the vegetative incompatibility; conversion from the S^{s} to the s state

seems to be a post-translational, autocatalytic process (Deleu et al. 1993). If any of the examples above cited can be shown to function in a manner similar to prions in animals, many new, more rapid and economical approaches to prion diseases should be forthcoming.

Unresolved problems in prion science

The study of prions has taken several unexpected directions over the past few years. The discovery that prion diseases in humans are uniquely both genetic and infectious has greatly strengthened and extended the prion concept. However, the areas that are still obscure do not relate only to the details: some of these concern the core of the prion concept (Chesebro 1998). In my opinion, there are five large groups of questions regarding the basic science of prion replication and of development of TSE diseases that deserve to be addressed with a vigorous research effort:

- Which are the molecular mechanisms of prion replication? How does the disease-associated prion protein, PrP^{Sc}, achieve the conversion of its cellular sibling, PrP^{C}, into a likeness of itself? Which other proteins assist this process? Can we inhibit this process? If so, how?
- What is the essence of prion strains, which are operationally defined as variants of the infectious agent capable of retaining stable phenotypic traits upon serial passage in syngeneic hosts? The existence of strains is very well known in virology, but it was not predicted to exist in the case of an agent that propagates epigenetically.
- How do prions reach the brain after having entered the body? Which molecules and which cell types are involved in this process of neuroinvasion? Which inhibitory strategies are likely to succeed?
- The mechanisms of neurodegeneration in spongiform encephalopathies are not understood. Which are the pathogenetic cascades that are activated upon accumulation of disease-associated prion protein, and ultimately lead to brain damage?
- What is the physiological function of the highly conserved, normal prion protein, PrP^{C}? The *Prnp* gene encoding PrP^{C} was indentified in 1985 (Oesch et al 1985; Basler et al. 1986), *Prnp* knock-out mice were described in 1992 (Büeler et al., 1992), and some PrP^{C}-interacting proteins have been identified (Oesch et al. 1990; Rieger et al. 1997; Yehiely et al. 1997; Zanata et al. 2002). Yet the function of PrP^{C} remains unknown.

GLOSSARY OF PRION TERMINOLOGY

Prion Agent of transmissible spongiform encephalopathy (TSE), with unconventional properties. The term does not have structural implications other than that a protein is an essential component.

'Protein-only' hypothesis Maintains that the prion is devoid of informational nucleic acid, and that the essential pathogenic component is protein (or glycoprotein). Genetic evidence indicates that the protein is an abnormal form of PrP (perhaps identical with PrP^{Sc}). The association with other 'non-informational' molecules (such as lipids, glycosaminoglycans, or perhaps even short nucleic acids) is not excluded.

PrP^{C} The naturally occurring form of the mature *Prnp* gene product. Its presence in a given cell type is necessary, but not sufficient, for replication of the prion.

PrP^{Sc} An 'abnormal' form of the mature *Prnp* gene product found in tissue of TSE sufferers, defined as being partly resistant to digestion by proteinase K under standardized conditions. It is believed to differ from PrP^{C} only (or mainly) conformationally, and is often considered to be the transmissible agent or prion.

These definitions (Aguzzi and Weissmann 1997) describe our terminology which is, however, not agreed on by convention and is not necessarily used by others.

ACKNOWLEDGMENTS

I am indebted to Stanley B. Prusiner for allowing me to use an earlier version of this chapter as the basis for the first half of the present manuscript. This article is dedicated to the present and past members of my laboratory, whose enthusiastic commitment led to the work described here. Special thanks to Petra Schwarz for maintaining our prion-infected mouse colony in an impeccable shape, and to Susanne Tiefenthaler and Jacqueline Wiedler for excellent assistance. Christina Sigurdson provided crucial help with the chapter on CWD. The work of my laboratory is supported by the Canton of Zurich, the Faculty of Medicine at the University of Zurich, the Swiss Federal Offices of Education and Science, of Health, and of Animal Health, the Swiss National Foundation, the National Center for Competence in Research on neural plasticity and repair, the Migros foundation, the Coop Foundation, the U.K. Department for Environment, Food, & Rural Affairs, the US Department of Defense (National Prion Research Program), and the Stammbach Foundation. Individual members of the Aguzzi lab have been directly supported by the EMBO Fellowship Programme (Isabelle Arrighi), HFSP and Bonizzi-Theler Foundation (Frank Heppner, Mark Zabel), DFG (Michael Klein, Marco Prinz, Kirsten Mertz, Frank Baumann), the Koetser Foundation (Nicolas Genoud), the FAN Society for the Support of Young Academic Scientists (Mathias Heikenwälder, Christoph Huber), the SBF Foundation (Christoph Huber), the Catello family (Mathias Heikenwälder), the Federal Office of Health (Manuela

Maissen), the Center of Neuroscience Zurich and the UBS Bank (Magdalini Polymenidou), the Roche Foundation (Mark Zabel), the UK Biotechnology and Biological Sciences Research Council (Gino Miele), and the Career Development Awards of the University of Zurich (Markus Glatzel, Erich Brunner).

INTRODUCTION

Viral infections of the central nervous system (CNS) represent clinically important, often life-threatening complications of systemic viral infections. Except for rabies, they do not result per se from a pathogen-specific tropism for neural tissue, as most viruses associated with CNS disorders frequently infect humans without involving this organ. Some of these viruses cause clinically significant diseases only when invasion of the CNS takes place, for example certain entero- or arthropod-borne viruses. Other agents, such as herpes simplex or mumps viruses, usually induce a mild illness, which may follow a more severe course when the CNS is infected. The establishment of a CNS viral infection depends not only on the biological properties of the invading agent but also on the breakdown of the host defense mechanisms that normally protect CNS cells from infection. Moreover, the degree of damage to CNS tissues is influenced by several special features that set the CNS apart from other tissues. Brain cells are not unusual in their fine structure, but they are unique in the high degree of cell differentiation and the interaction between cell types, as revealed by the synapses between neurons and the relationship between myelin sheath and axons. These peculiarities, together with the existence of a blood–brain barrier (BBB) in the absence of lymphatic tissue in the CNS, play a major role in the development of neurological disease.

Virological, immunological, and molecular biological studies have provided important information on the etiology and pathogenesis of many acute and chronic disorders of the CNS associated with viral infections of animals and humans. In addition, information obtained from in vitro studies of infected neural cells in culture has helped our understanding of the processes involved in a wide range of virus-induced neurological diseases. Although many unresolved problems still remain, great progress has been made in molecular virology and neuroimmunology. Many sensitive techniques have been developed that allow a better characterization of the virus–cell and virus–host interactions occurring in CNS infections.

Rather than give a complete account of all virus infections of the CNS, this chapter is intended to give an overview of the most common human viral CNS disorders and to promote insights that may emerge by comparing this aspect of human diseases. The single viral agents and their corresponding (peripheral) diseases are dealt with separately in specific chapters.

INTERACTIONS OF VIRUSES WITH THE HUMAN CNS

Pathways of virus spread to the nervous system

Successful infection of the CNS by virus depends on a number of factors, and it is the direct interplay between the host's immune system in controlling or attenuating

infection on the one hand, and the neurotropism and neurovirulence of the infecting virus on the other, that has profound consequences for the host. Virus invasion of the CNS can be established via any of the commonly recognized routes for infection: vector-borne, fecal–oral, direct contact and aerosol.

VECTOR-BORNE

The most common route of infection associated with severe disorders of the CNS is via the bite of an infected arthropod vector which delivers virus inoculum through the dead keratinized layer of the skin into the dermis or bloodstream. Viruses belonging to the families *Alphaviridae*, *Bunyaviridae*, and *Flaviviridae* are usually transmitted to humans through the bite of an infected mosquito or tick, after the virus has replicated to high titers in the salivary glands of the insect. A number of the arthropod-borne viruses (arboviruses) are highly pathogenic and the CNS is often involved. Of the viruses commonly associated with CNS disease, Japanese encephalitis virus, a Flavivirus, is the most important, with thousands of reported infections each year and an associated case fatality rate of about 10 percent (see section on Japanese encephalitis). Infection with arboviruses is limited geographically and seasonally to conditions that support the virus vector.

FECAL–ORAL

The fecal–oral route has long been established as an important mode of transmission of numerous enteroviruses, and classically with epidemics of poliomyelitis. Enteric viruses, which replicate primarily in the alimentary tract, are shed in fecal matter, which in turn may contaminate food and water supplies, particularly in areas of poor sanitation. These viruses are able to resist and survive gastric acidity. Enteric viruses are responsible for large epidemics of disease which, unlike the arboviruses mentioned above, are not restricted geographically. In Europe enteroviruses are the leading cause of CNS disturbances, although 90 percent of these infections are clinically inapparent. Of the remainder, symptoms may range from paralytic poliomyelitis to nonparalytic meningitis, as well as the more rare encephalitides.

DIRECT CONTACT

Direct contact (sexual, prenatal, or by mechanical means, e.g. by needle, bite), as a mode of transmission for a number of viruses that cause CNS disease, is by nature a particularly emotive subject. Infection by direct contact involves the transfer of virus-infected cells or body fluids. These viruses include human immunodeficiency virus (HIV), herpes simplex virus (HSV), rabies virus, and *Cytomegalovirus* (CMV). More rarely, infection of the (CNS) with rabies virus or CMV has been reported following corneal tissue grafts. Vertical transfer of virus from mother to fetus, commonly HSV, CMV, rubella, human T-lymphotropic virus type I (HTLV-I) and HIV, may lead to severe CNS disease in newborns. In addition, breastfeeding by infected mothers is associated with HTLV-I, HIV and CMV infections in newborns.

AEROSOL

Establishment of CNS infection via the respiratory tract is not widely recognized as a common event. The exception to this generalization is mumps virus, when, during epidemics of parotitis, about 0.1–10 percent of infected individuals develop quite severe meningitis. Infection of the CNS by rabies virus has been documented following the inhalation of virus-laden aerosols by visitors to bat caves, where the virus is maintained in the bat population, or in laboratory workers exposed to high concentrations of virus. Aerosols may also be associated with the transmission of other potentially neurotropic pathogens, such as measles virus and varicella-zoster virus.

Regardless of the site of entry, for successful infection of the host by a virus a period of replication at this initial site is required, and the virus must also evade the local immune response. The possible exception to the above concerns arthropod-borne viruses, which are often inoculated directly into the bloodstream and initial replication is usually established in lymphatic tissue. Replication of virus at the site of entry or in lymphatic tissue increases the viral load and allows the establishment of viremia. Once in the bloodstream, virus is able to disseminate throughout the host and infection of susceptible secondary organs and tissues can take place. The ability of the immune system to terminate virus infection rapidly before significant viremia levels are reached largely dictates the outcome of a number of potential viral diseases of the CNS. Two main routes for the invasion of the CNS by virus are recognized: hematogenous and neural.

Entry into the CNS

THE HEMATOGENOUS ROUTE

The bloodstream, with its extensive network of vessels serving every part of the body, forms the perfect dissemination vehicle for invading viruses. The extent to which tissues and organs become exposed to virus depends on the length of time that a high viral load is maintained in the bloodstream and the efficiency with which the immune system can clear virus. Whether infection will be established by the virus depends on a number of factors, including the presence of specific cellular receptors for that virus. Before virus can enter the CNS, the so-called blood–brain barrier must be

circumvented (Zhang 1999). The BBB comprises endothelial cells of the cerebral microvasculature, pericytes, astrocyte foot processes, and the basal lamina, which together are a formidable barrier (Pardridge 1999; Miller 1999). However, the CNS is accessible to activated lymphocytes and macrophages which, if infected with virus, afford access to this normally protected environment (Persidsky 1999). Circumvention of the BBB by the transport of virus within infected cells is thought to be highly significant for CNS infection with mumps and measles viruses (Wolinsky et al. 1976; Fournier et al. 1985) and HIV (Haase 1986). Direct measles virus infection of the endothelial cells of the BBB is commonly found in patients suffering from subacute sclerosing panencephalitis (SSPE) (Allen et al. 1996). The choroid plexus is widely believed to be an important portal of entry for bloodborne virus to the CNS. This is based largely on the fine structure analysis of the choroid plexus itself, in which fenestrated endothelium and a sparse basement membrane combine to form a more permeable region. The choroid plexus is a major target of replication or transport of mumps and arboviruses, which subsequently infect ependymal cells lining the ventricles and finally the underlying brain tissue.

THE NEURAL ROUTE

A number of viruses establish CNS infection by directly infecting nerves of the CNS. Viruses such as HSV, poliovirus, and rabies (Sabin 1956; Martin and Dolvio 1983; Iwasaki et al. 1985) infect peripheral nerve endings and, by retrograde axonal transport, spread through the CNS. Entry into neurons is believed to occur via receptor-mediated endocytosis, after which virus is transported in vesicles. The exact mechanism of transport of virus within nerves remains to be established, although movement is known to occur via fast axonal transport (Kristensson 1982), which involves the passage of viral material in vesicles along microtubules. Viral replication occurs once virus particles reach the neuronal cell body and newly synthesized virion components accumulate at postsynaptic sites. The site of inoculation can influence the ultimate distribution of lesions in the CNS, especially for viruses that spread along neural routes. For example, HSV infection of the genitourinary tract establishes latency of virus in the sacral ganglia, whereas infection with HSV orally establishes latency in the trigeminal ganglia. At the time of primary infection, HSV is transported from the mucous membrane by retrograde axonal transport, whereas during periods of reactivation virus is transported to the periphery by anterograde flow. Once the CNS has been invaded, advancement of infection by many neurotropic viruses occurs through cell-to-cell spread (trans-synaptic transport).

The factors influencing the release of virus from presynaptic nerve terminals and the uptake of progeny at postsynaptic terminals are unknown. It is important to note that direct infection of peripheral nerve endings by virus may also take place during the viremic phase of an infection. For example, during the high-titer viremia found in clinically apparent infections of humans with the *Flavivirus* Japanese encephalitis virus (JEV), the possibility that neurons of the olfactory bulb will be infected is enhanced. Retrograde transport of virus within specialized neurons is then possible. The olfactory mucosa itself offers a unique pathway for the spread of viruses into the CNS, where the apical processes of receptor cells penetrate beyond the surface of the epithelium as olfactory rods. However, olfactory uptake and spread is not a common route of virus infection of the CNS (Johnston 1994). Once in the CNS, the cellular tropism and neurovirulence of virus and its ability to avoid the immune response will largely determine the outcome of disease.

Tropism and neurovirulence

CELLULAR RECEPTORS AND HOST FACTORS

The ability of a virus to infect specific cell populations of the CNS defines its neurotropism, which is influenced either by host cell expression of receptors or by genes important for viral replication. In general, the distribution of specific cellular receptors for viruses within a host governs the susceptibility of tissue(s) or organs to virus infection. In recent years, many cell surface proteins have been identified as viral receptors that normally serve various physiological functions (Schneider-Schaulies 2000; Schweighardt and Atwood 2001) (Table 1).

Besides the viral receptor the virus attachment protein itself plays a central role in the initial interaction of the virus with its target cell. Numerous virus–cell attachment proteins have been identified by analysis of genetic recombinants, genetic reassortants, and mutant viruses (Kennedy 1990). This approach has been used, for example, to define the neurotropism of serotype 3 reovirus, which has been mapped to the *S1* gene that encodes the σ1 protein (Tyler 1991). Similarly, neutralization escape mutants of rabies virus, with a single amino acid substitution in the envelope glycoprotein G that serves in viral cell attachment, revealed a lower virulence than the parent virus (Tyler 1990). A more detailed molecular view of a ligand in virus receptor–molecular interactions was obtained with the X-ray crystallographic analysis of the poliovirus virion. The analysis revealed that a series of peaks in the VP1 capsid proteins surrounded by a broad valley composed of VP1 and VP3 forms the receptor-binding pocket (Almond 1991). It is thought that other picornaviruses may have cell attachment proteins of similar topology. An exception to this is foot-and-mouth disease virus (FMDV), an aphthovirus, for which the virus attachment protein

Rabies virus	Acetylcholine receptor (α-$_1$) Neural cell adhesion molecule (NCAM) Nerve growth factor receptor (NGFR)	Lentz 1990; Thoulouze et al. 1998; Tuffereau et al. 1998

(VAP) is exposed on VP1 (Mason et al. 1994). Mutations occurring in the VAP may be responsible for altered tropism of the virus, or even defective virus that is no longer able to bind to its receptor. This may be manifested by attenuation of virus infectivity, and is thought to be important in relation to the immunogenicity of vaccines.

In further attempts to unravel which factors govern the neurovirulence of poliovirus, a combination of nucleotide sequencing and gene cloning identified the genetic differences between wildtype and live attenuated vaccine strains (Almond 1991). Of the changes detected, the most significant were localized in the 5′ nontranslated region (NTR) at positions 480, 481, and 472 of poliovirus serotypes 1, 2, and 3, respectively. These mutations were associated with the ability of the virus to replicate in the brains of mice or neuroblastoma cells in culture (La Monica et al. 1987). A more detailed investigation of both the structure and the related function of mutated 5′ NTR regions of poliovirus revealed that attenuating mutations in vaccine strains act through the disruption of a stem–loop structure in the region of nucleotide positions 470–540. Computer-generated analysis has hinted that the greater the disruption of the system structure, the greater the temperature sensitivity and the degree of attenuation. Further analysis of the intracellular protein interactions associated with this poliovirus stem–loop structure may provide an explanation of why motor neurons are the specific targets of these viruses.

In addition to viral factors, host factors also influence viral tropism and virulence and modulate the viral pathogenesis of CNS infections. In this context, a lack of enzymatic activity required for maturational cleavage of viral proteins, or completion of the virus replicating cycles, will lead to incomplete infection of target cells, thereby limiting tropism and spread of the virus. On the other hand, this may facilitate the establishment of a persistent infection, as has been demonstrated in the case of SSPE (Billeter et al. 1994). Moreover, it has been observed that many neurotropic viruses more readily invade the CNS of the young, owing to an immature immune response, reduced capacity to produce interferon, and dependence of the susceptibility of viral infection on the stage of cell differentiation, as well as the age-specific nature and distribution of receptor proteins (Coyle 1991). Bias of infection for a particular gender has also been noted. The CNS disorder tropical spastic paraparesis/HTLV-I associated myelopathy (TSP/HAM), for which HTLV-I is the proposed

etiological agent, has a prevalence in females, with a female:male ratio of 1.6:1.

Neurovirulence and viral gene expression

Neurovirulence is the capacity of a virus to multiply and to extend infection after it has invaded the nervous system. This property, together with the effectiveness of the host immune response, determines the degree of tissue damage. Point mutations in envelope proteins of several viruses have been shown to influence neurovirulence in animal models. Some examples are Sindbis virus (Lee et al. 2002), murine coronavirus (Philips et al. 2002), measles virus (Moeller et al. 2001), and yellow fever virus/Japanese encephalitis virus chimera (Arroyo et al. 2001).

Many viruses contain nontranscribed genetic elements, referred to as promoters or enhancers, that regulate the transcription of specific genes. It is interesting that virus enhancers may exhibit cell or tissue specificity, and possibly species specificity, thus promoting or limiting virus infection. Important roles for viral enhancer elements in determining cell type-specific gene expression have also been described for picornaviruses. In the poliovirus-induced pathogenesis the internal ribosomal entry site (IRES) plays an important role for neurovirulence (Ohka and Nomoto 2001).

The available data suggest that, in general, the outer capsid or envelope glycoproteins of neurotropic viruses are probably important determinants of virulence. This assumption is based, for instance, on the observation that amino acid sequence changes – of proteins, or genetic reassortments between virulent and avirulent strains of a given neurotropic virus – can lead to an attenuated infection. On the other hand, not all changes in viral genes result in attenuation, as mutations causing reversions to neurovirulence have been seen in poliovirus isolates from vaccine recipients (Almond 1987). Moreover, when one region of a viral protein is linked to neurotropism and neurovirulence, changes in that protein could have dramatic effects on the resulting infections, as documented in studies of Theiler's murine encephalomyelitis virus infections (Nash 1991). Usually not only one gene contributes to the neurovirulence of a virus, as found for example for Theiler's virus, in which mutations of the envelope proteins, as well as the polymerase, influence the outcome of the disease (Reddi and Lipton, 2002; van Eyll and Michiels 2000). Taken together, the interplay of host and viral factors determines the tropism and virulence of viruses that infect the CNS.

Virus–cell interactions in the CNS

The interaction of infectious viruses with susceptible cells leads in general to cell destruction, and is largely determined by the genetic constitution of the host cell and by the type of viral agent. This destruction can occur following cytolysis, persistent or even latent infection, cell transformation, or be caused by infection-independent mechanisms. After infectious virus has reached the CNS, disease develops only if viral spread is accomplished and sufficient numbers of susceptible cells are infected, resulting in brain dysfunction. In this respect, a number of unique features of the CNS are noteworthy. First, the CNS contains a highly differentiated cell population, with complex functionally integrated cell-to-cell connections and highly specialized cytoplasmic membranes. This probably results in the great variability in virus receptor sites and their density on cells. Second, CNS tissue is unique in its high metabolic rate and a low regenerative capacity. Although persistent infection by a noncytopathogenic virus in cells of tissue with a low energy requirement and a high rate of regeneration may be tolerated, in CNS tissue such infections may interfere with normal cell functions, especially when neurons are affected. Third, the brain's relative isolation from the immune system is another feature that plays an important role in the establishment and pathogenesis of CNS infections.

ACUTE INFECTIONS

Acute infections lead to cell death and the release of progeny virus. Cell destruction is induced by the products of the viral genome or their effect on the regulatory mechanism of the cell. For some viruses, such as herpes and polio viruses, the molecular events during a lytic infection have been well described for tissue culture systems, and it may be inferred that similar processes occur during CNS infections. One of the most severe acute viral infections of the CNS is caused by herpes simplex virus (HSV), which results mainly from the primary infection. Productive replication in brain tissue leads to cell destruction, which in its extent and pathology depends on the neuroinvasiveness and neurovirulence of the virus and on the effectiveness of the host defense mechanisms. Extensive molecular biological studies have defined several regions on the viral genome as specific contributors to these processes (Stevens 1993). Among the HSV genes, 37 seem not to be necessary for HSV replication in tissue culture, and are referred to as 'supplemental essential genes.' They may be linked to the properties of neuroinvasiveness and neurovirulence by allowing the virus to invade the CNS, to replicate in a variety of different brain cells, and to spread efficiently from cell to cell. Another destructive disease of nervous tissue occurs after poliovirus infection (Melnick 1990). Following primary replication of poliovirus in the tonsils, the lymph nodes of the neck, and Peyer's patches in the small intestine, the virus spreads along the axons of peripheral nerves, and may invade the spinal cord and brain. Here, neuronal tissue can be damaged or

completely destroyed as a consequence of intracellular replication. The anterior and, in severe cases, the posterior horn cells of the spinal cord are most prominently involved, resulting in a flaccid paralysis (see Picornaviruses).

PERSISTENT INFECTIONS

Within the group of viruses that can establish persistent infections, a variety of virus–cell and virus–host interactions exist that lead to a number of different disease processes:

- Latent viral infections are characterized by long periods of pretended viral absence followed by intermittent episodes of viral replication and the formation of infectious virus (recurrence). This may either remain clinically silent or result in clinical disease (recrudescence). During latency, the virus remains within the host in a quiescent form.
- In chronic viral infections virus can be reproducibly and continuously recovered from the host, with or without the development of clinical disease. Disease may be caused by the replication of virus or by immunopathological mechanisms.
- In slow virus infections, a long incubation period of months to years is followed by a slow, progressive disease course that is usually fatal. The concentration of virus in the CNS increases until disease becomes clinically apparent.

The establishment and maintenance of persistent infections in the CNS may be governed by viral factors or host cell factors, or both, depending on the individual virus–host-cell relationships. As a general mechanism, virus-induced apoptosis may be an important pathogenic mechanism of CNS damage. On the other hand, virus-mediated inhibition of the apoptotic pathway has been linked to the establishment of persistent infections in brain cells (Levine et al. 1991). In the human nervous system, only the latent and the slow virus type of infection are found. The classic latent infection is caused by HSV types 1 and 2. HSV is transmitted from human to human by skin or mucous membrane contact, and is able to remain latent in the nervous system for the lifetime of the host. Its occurrence is not restricted to sensory neurons, and it has also been detected in neurons of peripheral nerve ganglia, the adrenal medulla, the retina and the CNS (Stevens 1993). The establishment of the latent phase is controlled and executed by the neuron rather than by the virus itself, and HSV gene expression is almost completely abolished except for the expression of a set of so-called latency-associated transcripts (LAT)(Taylor et al. 2002). No infectious virus can be isolated during latency. Although the underlying molecular events that trigger viral reactivation are still unknown, clinical observations indicate that recurrence is associated with physical or emotional stress, immune suppression, UV light, or nerve damage. HSV in latently infected neurons is refractive to the immune system and cannot be cleared from those cells. The role of the immune system in controlling HSV infection is not entirely clear, because recurrences can be observed even in the presence of an apparently normal cell-mediated and humoral immune response. Although there seems to be no impact on nerve function during silent periods of latency, reactivation of HSV leads to the destruction of infected neurons.

The best-studied slow virus disease of humans associated with a conventional virus is subacute sclerosing panencephalitis SSPE (ter Meulen et al. 1983). The disease develops after the establishment of a persistent measles virus infection in brain cells months to years after acute measles. How and when the virus reaches the CNS, and the mechanisms that trigger the disease, remain unknown. In brain material obtained post mortem, the accumulation of viral nucleocapsids in virtually any CNS cell population, together with a general failure to reisolate infectious virus, points to the presence of a defective viral replication cycle (see below). In general, gene functions required for intracellular amplification of the viral genome are functionally maintained, whereas those associated with viral maturation and budding are highly restricted. This allows the virus to survive and replicate intracellularly while evading immune surveillance. In fact, an exceedingly high humoral immune response against measles virus proteins, except for the matrix (M) protein, in both serum and CSF of patients with SSPE is pathognomonic.

Infection-independent mechanisms

Experimental evidence suggests that some viruses may trigger apoptosis in neural cells, thereby leading to rapid destruction of the host cell before the virus is efficiently replicated (Levine et al. 1991). Viral invasion of the CNS may not always lead to infection of susceptible cells, but it may trigger pathological changes in the absence of viral spread. This is particularly important in parainfectious conditions, such as acute measles encephalitis, in which the presence of the infectious agent cannot be unequivocally demonstrated, or HIV, in which the infected CNS cells can support only minimal viral replication. As is apparent from tissue culture studies and animal experiments, HIV gene products such as gp120, tat, and nef, as well as soluble factors and nitric oxide released from virus-infected microglial cells, may contribute to the pathogenesis of HIV brain infections (Patrick et al. 2002). This occurs by the induction of neuronal damage and the functional impairment of both neuronal and macroglial cells that, per se, seem not to be susceptible to viral infection.

Viral impact on specific neural cell functions

The interaction of a virus with the CNS may cause severe dysfunction of the infected cell, even if only restricted areas of the CNS are involved. In rat astrocytoma cells persistently infected with measles virus, a strong reduction in the cAMP response to catecholamines was observed, the density of β-adrenergic receptors was decreased by 50 percent and their G protein coupling was affected (Halbach and Koschel 1979; Koschel and Münzel 1980). The endothelin-1-induced Ca^{2+} signal was absent in the same cells, 95 percent of the binding sites for endothelin-1 being lost (Tas and Koschel 1991).

A further example of the direct disturbance of brain cell functions is infection with rabies virus (RV). This virus causes a nonlytic infection of brain cells that rapidly eads to the death of the infected individual. In contrast to the limited cytopathology, death seems to result from interference of the virus with neuronal cell functions in vital centers of the brain that regulate sleep, body temperature, and respiration (Tsiang 1993). The uptake and release of γ-aminobutyric acid (GABA) was reduced by 45 percent in the cortical neurons of rabies-infected embryonic rats (Ladogana et al. 1994), and binding of 5-hydroxytryptamine to serotonin receptor subtypes was reduced by 50 percent in infected rat brains (Ceccaldi et al. 1993). It is conceivable that disturbances of specialized receptor sytems for neurotransmitter and neurohormone turnover, as well as for the generation of chemical signals and electrical potentials, might be the main cause of death in this viral infection, rather than cytopathic effects or immunopathogenesis.

Induction of cytokine and chemokine expression in the brain

Cytokines are produced in response to viral infection in the CNS and are secreted either from infected brain cells or from mononuclear cell infiltrates. Virus-induced cytokine patterns in CSF and in brain tissue of both humans and experimentally infected animals have been intensively studied. Although individual variations may be observed between different virus infections, there seems to be a common set of cytokines induced in the CNS, as in the periphery. These include type I (IFN-α/β) and type II (IFN-γ) interferons, the proinflammatory cytokines interleukin (IL)-1 and tumor necrosis factor (TNF)-α, IL-6, and, generally in lower amounts, IL-2 (Maudsley et al. 1989; Plata-Salaman 1991). For example, in the CSF of SSPE patients elevated levels of IFN-α/β are observed, and brain cells staining for IFN-γ and TNF-α have been detected in autopsy material (Neumann 2001; Joncas et al. 1976; Cosby et al. 1989; Hofman et al. 1991). In the brains of HIV-1 infected patients, where CD4+ microglial cells are the major cell population supporting viral replication, these cells are the source of intrathecal synthesis of IL-1, IL-6, granulocyte–macrophage colony-stimulating factor (GM-CSF), and TNF-α (Merrill and Chen 1991). In addition to the cytokines, a set of infection-induced chemokines attracts inflammatory mononuclear cells across the BBB. Besides lymphoid cells and endothelial cells, as neural cells microglia and astrocytes are the main producers of chemokines such as macrophage inflammatory proteins (MIP-1α, 1β, and 2), macrophage chemotactic proteins (MCP-1, -2, -3), interferon-γ-inducible protein (IP-10), IL-8, growth-related oncogene (GRO α and β), and regulated upon activation of normal T cell expressed and secreted (RANTES). Together with cytokines, which induce or enhance the expression of adhesion molecules on endothelial cells of the BBB, these chemokines promote the migration of monocytes, lymphocytes, eosinophils, and basophils across the BBB into the brain (Persidsky 1999). Viral infection of the CNS parenchyma strongly stimulates local chemokine expression. In simian immunodeficiency virus (SIV)-induced neuropathogenesis in primates the chemokines MIP-1α, MIP-1β, RANTES, MCP-3, and IP-10 play a major role in recruting inflammatory cell infiltrates (Sasseville et al. 1996). In tissue culture it has been shown that the HIV transactivator tat stimulates the expression of MCP-1 by astroctyes. In addition, this chemokine was detected in the brains and CSF of patients with HIV-associated dementia (Conant et al. 1998).

The multiple effects of cytokines in the CNS may be beneficial in stimulating immunological surveillance and intracellular viral resistance (mainly type I and II IFNs and TNF-α) (Schijns et al. 1991; Shankar et al. 1992). This occurs by recruitment and activation of cells of the immune system as well as by induction of MHC molecules (Campbell 1991; Neumann 2001; Plata-Salaman 1991) or antiviral proteins such as MxA, RNA-dependent protein kinase R (PKR), or 2′,5′-A synthetase in brain cells that directly interfere with intracellular viral replication (Staeheli 1990). Triggering of immune responses and inflammatory reactions by proinflammatory cytokines such as IL-1 and TNF-α, together with the induction of neurotoxins (Giulian et al. 1990) and reactive oxygen intermediates (Nathan 1992), may, however, also contribute directly to the immunopathology observed in most viral CNS conditions. Proinflammatory cytokines such as IL-1 or TNF-α produced by immune cells or by CNS cells in response to infection may be essential to the process of neuronal destruction (Quagliarello et al. 1991; Selmaj 1992), as indicated by the meningitis and BBB damage that followed injection of these cytokines into rat brains. Moreover, it has been shown for experimental allergic encephalitis that neurospecific T cells recruit activated inflammatory cells through the action of TNF-α and IFN-γ (Ruddle et al. 1990). In addition, these cytokines can prime macrophages for the production of inducible

reactive oxygen and nitrogen intermediates (Ding et al. 1988), which are thought to play an important role in cytotoxicity (Nathan 1992).

Direct analysis of cytokine expression in human CNS diseases is often difficult to perform, because the production of cytokines may be localized, the levels may be very low, and cytokines normally are rather unstable once secreted. Moreover, the role of cytokines in the development of viral CNS infection and in viral neuropathogenesis cannot be studied in humans for obvious reasons, and so suitable animal models must be used. For example, experimentally induced CNS infections with borna disease virus (BDV) in rats represent a recent example of an animal model to study the role of cytokines in neurological disorders (Bode 1995; Rott and Becht 1995; Stitz et al. 1995; Briese et al. 1999). Induction of IL-1α, IL-2, IL-6, TNF-α, and IFN-γ mRNA synthesis has been found in rat brains 2 weeks after intranasal infection, and IL-2 as well as IFN-γmRNA expression correlated well with the appearance of $CD4^+$ and $CD8^+$ lymphocytes during the early stages of BDV infection (Shankar et al. 1992). Moreover, mRNA levels for inducible nitric oxide synthetase (iNOS) were upregulated (Koprowski et al. 1993). It is interesting that the levels of iNOS mRNA correlated not only with the degree of neurological involvement and CNS inflammation but also with the levels of TNF-α, IL-1, and IL-6 mRNA (Selmaj 1992), potential mediators of iNOS expression (Nathan 1992). In the chronic phase of BDV infection of the CNS, levels of IL-1, IL-6, and TNF-α decreased dramatically, whereas mRNA levels for IFN-γ were greatly elevated, probably indicating that IFN-γ may act to reduce inflammation and to improve neurological signs during the transition phase from acute to chronic disease. In fact, IFN-γ has a pronounced synergistic effect in the TNF- and IL-1-mediated induction of manganese superoxide dismutase, which has been linked to the protection of uninfected cells from reactive oxygen toxicity during immune responses (Harris et al. 1991). To date, BDV has not been identified as a clear etiological agent of any known human disease (Carbone 2001).

MHC expression in the brain and its relation to viral infection

An effective immunological response to viral infections of the CNS is undoubtedly hampered by the relative lack of MHC and costimulatory molecule expression in this tissue. MHC class I expression is believed to be virtually absent from the surface of neurons, whereas MHC class II expression is confined to microglia and pericytes at the BBB (Pardridge 1999). Not only is MHC class I 'passively' absent, but surface contact with neurons also suppresses its expression on the surface of microglial cells (Hoek et al. 2000). In tissue culture, astrocytes and endothelial cells have also been found to express MHC class II after induction. Much attention has been focused on the ability of certain cytokines, such as IFN-γ and TNF-α, to induce or upregulate MHC class I and II, and adhesion molecules such as ICAM-1 on glial cells (Frohman et al. 1989). However, the presence of these factors in the CNS indicates that an inflammatory process had already been initiated, which is not likely to occur soon after a virus has entered the CNS. In support of this notion, infection-dependent upregulation of MHC class I expression on a variety of cell types (reviewed in Maudsley et al. 1989), and also MHC class II induction on otherwise negative cells (including astrocytes), has been described (Massa et al. 1986, 1987). Interestingly, infected neurons can be an intrathecal source of IFN-γ and express MHC class I after inhibition of their electrical activity, either experimentally or after infection (Neumann et al. 1997).

Although it is certain that induction or augmentation of immunoregulatory surface molecules on the surface of brain cells is a prerequisite for an efficient immune response, their role in neuropathogenesis is unclear. For instance, MHC class II expression was readily inducible in the SJL and CBA mouse strains, which are susceptible to experimentally induced CNS infections with Theiler's virus, but not in the resistant BALB/c mice (Nash et al. 1985). In contrast, BN rats, which live well with experimental *Coronavirus* JHM or MV infections, showed a constitutive high MHC class II expression in the brain, whereas in Lewis rats, in which MHC class II expression occurs as a consequence of the viral infection, immunopathological (autoimmune) processes are observed in a significant proportion of animals. This illustrates that the early presence of immunoregulatory molecules in the brain may provide protection, whereas the same process could lead to pathology and disease when MHC molecules are expressed several days or weeks later (Sedgwick and Dörries 1991). Induction of MHC molecules on neural cells is, however, not sufficient to result in elimination of virus, as illustrated by observations in brain tissue from patients with progressive multifocal leukoencephalopathy (PML), a slow papovavirus infection predominantly involving oligodendrocytes. Here, both MHC class I and II are expressed in the lesions, yet viral clearance does not occur, probably because no reactive T cells are generated by the immunosuppressed patient. This may allow the establishment of persistence and ultimately chronic viral infection with progressive disease (Achim and Wiley 1992).

The immune response to viral infections in the CNS

PASSAGE OF EFFECTOR LYMPHOCYTES INTO THE CNS

The BBB is the sentinel in the development of an inflammatory response in the CNS. Adhesion of lympho-

cytes and their subsequent migration through the capillary endothelium is essential for the development of an inflammatory reaction. Adhesion molecules expressed on the brain capillary endothelium act as important ligands to receptors on the surface of lymphocytes, and mediate both adhesion and subsequent migration (Cross 1992) (Figure 1). Two families of molecules on the endothelium are well known in the initiation of adhesion. The initial binding seems to be mediated by those belonging to the selectin (CD62) family (E-selectin, L-selectin, and P-selectin). The second family comprises the Ig superfamily of adhesion molecules such as ICAM-1 (CD54) and VCAM-1 (CD106), which bind to integrin molecules on lymphocytes (Springer 1994; Risau et al. 1998; Pardridge 1999).

Migration is mediated by the secretion of chemoattractant molecules released by the endothelium, as well as by astrocytes and microglial cells (Ransohoff et al. 1993; Persidsky 1999; Zhang 1999). Because adhesion to the capillary endothelium is an important step before cell migration, it follows that factors influencing the expression of the receptor molecules on the capillary endothelium or on the lymphocyte surface are likely to influence the extent and severity of the inflammatory response. Proinflammatory cytokines such as IL-1, TNF-α, and IFN-γ increase the expression of the Ig superfamily of adhesion receptors. In fact, ICAM-1 and -2 and VCAM-1 are expressed on CNS microvessels in experimental allergic encephalomyelitis (EAE), and its expression coincides with inflammatory cell infiltration (Engelhardt 1998; Cannella et al. 1991). Furthermore, in the human brain, ICAM-1 is expressed on vessels in viral encephalitic lesions (Sobel et al. 1990). Studies in vitro have shown that antibodies to proinflammatory cytokines, or cytokines that have an antagonistic effect, such as transforming growth factor-β_2 (TGF-β_2), alter the adhesion of lymphocytes to the capillary endothelium (Fabry et al. 1995). The anti-inflammatory properties of TGF-β have been exploited in the amelioration of two distinct T cell-mediated EAEs (Racke et al. 1991, 1993), and it can interfere with the adhesion of lymphocytes to endothelial cells, possibly inhibiting the entry of effector cells into the CNS (Cai et al. 1991; Gamble and Vadas 1991). In support of this suggestion, TGF-β treatment in EAE does not influence the appearance of sensitized cells in peripheral blood and lymph nodes, but does prevent the accumulation of T cells in the brain and spinal cord. This suggests that the protective effect of TGF-β is exerted at the level of the target organ, the CNS, its vascular endothelium, or both (Santambrogio et al. 1993). It has been shown that T cells require prior activation to cross the BBB (Hickey et al. 1991). However, once the BBB was breached, no activation-dependent differences in the homing pattern of T lymphocytes were observed (Trotter and Steinman 1985).

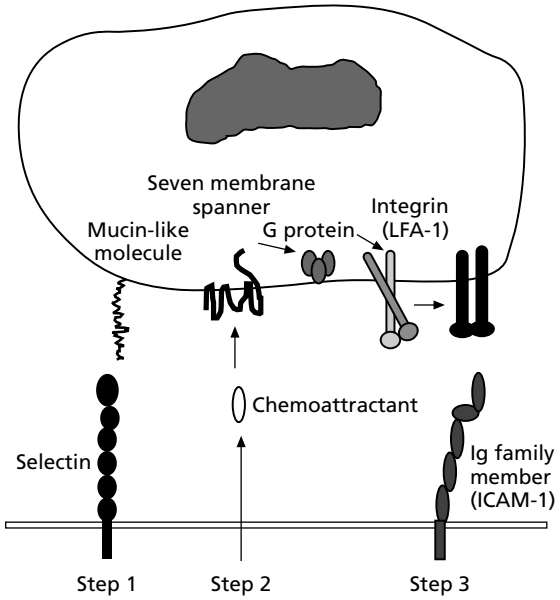

Figure 1 *Sequential steps in the traffic of leukocyte adhesion to the vascular endothelium. Selectins (CD62) on the surface of vascular endothelial cells initially interact with carbohydrate residues, often displayed on mucin-like molecules on flowing leukocytes to mediate a labile adhesion (Step 1). This interaction brings leukocytes into close proximity with chemoattractants (released from the endothelial cells lining the vessel wall) which bind to receptors that span the membrane seven times on the surface of leukocytes. Binding of chemoattractants to their receptors subsequently triggers the activation of G proteins, which then transduce signals to activate integrin adhesiveness (e.g. by activating leukocyte function antigen 1, LFA-1) (Step 2). The interaction of the latter with surface proteins of the Ig superfamily (expressed on the endothelial cells, such as intercellular adhesion molecule 1, ICAM-1) mediates strong adhesion, leading to an arrest of the rolling leukocyte (Step 3). Following directional cues from chemoattractants, and using integrins for traction, leukocytes then cross the endothelial lining of the blood–brain barrier and enter the CNS.*

THE HUMORAL IMMUNE RESPONSE IN THE CNS

The control of virus infection depends on the efficient generation of both humoral and cell-mediated immune responses. Antibodies, which attack predominantly extracellular virus particles released from infected cells, are required to limit the spread of some viruses in the host. For example, it seems that the humoral immune reaction is essential in controlling poliovirus infections. For infections with other viruses, such as varicella-zoster, *Cytomegalovirus*, or measles virus, T-cell responses may be more important than antibody. In this context it is important to remember that the immune response to viral infections of the CNS is initiated in peripheral lymphoid tissue, with subsequent entry of activated (end-differentiated) T cells into the meninges, brain parenchyma, and cerebrospinal fluid (Sedgwick et al. 1991a, 1991b).

Inhibition of virus entry into the brain and blockade of intracerebral viral spread

Specific antibodies are the main tool of the infected host in preventing extracellular viral spread from primary

sites of infection to other organs during viremia (Sissons and Oldstone 1985). Virtually all viral CNS infections are preceded by primary peripheral infection, and so it is obvious that virus neutralization and opsonization during viremia comprise one of the most efficient defense reactions preventing viral entry into the CNS. Agammaglobulinemic patients suffer more frequently from persistent CNS infections than do fully immunocompetent hosts (Smith et al. 1992), and peripheral virus-specific antibodies usually prevent neuroinvasion in perinatal viral hosts that do not display full immune competence. For example, lethal encephalomyelitis experimentally induced by the murine *Coronavirus* JHM (JHMV) in newborn or suckling rats is prevented by nursing the babies from JHMV-immunized mothers (Wege et al. 1983), and teratogenic effects induced by lymphocytic choriomeningitis virus (LCMV) in neonates are not observed when they are nursed by immunized mothers or injected with LCMV-specific neutralizing monoclonal antibodies (Baldridge and Buchmeier 1992; Baldridge et al. 1993). Moreover, experimental virus infections of the CNS in immunocompetent hosts usually remain subclinical, provided high titers of virus-neutralizing antibodies are mounted (Jubelt et al. 1991; Rima et al. 1991).

Nevertheless, in some instances viruses escape extracerebral neutralization and invade the CNS. If retrograde transport occurs along the axons of peripheral nerves, the virus is inaccessible for an immune system. Neither virus-specific antibodies nor cytotoxic T lymphocytes (CTL) can prevent the axonal transport of the virus to the CNS, particularly because nerve cells are thought to be unable to upregulate MHC class I molecules (Momburg et al. 1986). Using leukocytes as 'Trojan horses' is another way to escape neutralization by antibodies, although this hypothesis has so far not been supported by direct experimental evidence. Viral infection of peripheral recirculating monocytes may enhance invasion of the perivascular space in the CNS, because, in contrast to ramified microglia, the perivascular type of this cell is frequently exchanged by peripheral monocytes (Sedgwick et al. 1991a, 1991b, 1993).

Once in its target cell, the virus continues replicating and spreading in the CNS until immune effector cells are recruited into the brain parenchyma. Plasma cells of the B-lymphocyte lineage home to virus-infected sites in the tissue (Dörries et al. 1991), where they secrete virus-specific antibodies (Schwender et al. 1991), and cytotoxic T lymphocytes provide an early virus-specific defense mechanism in the brain parenchyma. Although the latter may efficiently lyse virus-infected cells, the formation of secondary virus-infected foci in the tissue by extracellular spread of the virus is prevented only when virus-specific antibodies are secreted intracerebrally in close proximity to infected sites. This has been confirmed in several animal models of virus-induced encephalitis. In addition to extracellular spread, virus-specific antibodies may inhibit dissemination from cell to cell, for example by interfering with cell fusion (Dietzschold et al. 1992). Moreover, antiviral antibodies may be directly involved in attenuating intracellular viral replication in vivo and in vitro. This concept, known as antibody-induced antigenic modulation (Fujinami and Oldstone 1980), has been established for MV infections in brain cells and mice with severe combined immunodeficiency (SCID) infected with Sindbis virus (Levine et al. 1991).

Although it is generally assumed that the protective effect of a virus-neutralizing antibody in the CNS is mainly due to binding of its Fab part to viral epitopes necessary for infection of the target cell, the Fc part of the antibody molecule may also contribute. A monoclonal antibody specific for the yellow fever virus (YFV) nonstructural protein NS1 protects mice from encephalitis only when given as an intact molecule, but not as a F(ab)2 fragment, which normally neutralizes YFV efficiently in vitro. Moreover, only monoclonal antibodies of the IgG_{2a} subclass efficiently prevented acute encephalitis in this virus system, indicating that only binding of a distinct IgG subclass to NS1 allows recognition by FcR expressing cells. Similar observations have been made for Semliki Forest virus (SFV) infection of mice, in which IgG_{2a} is the dominant subclass in the CSF, as well as for LCMV-induced encephalitis, which can be prevented with an IgG_{2a} monoclonal antibody (Baldridge and Buchmeier 1992). In rabies virus-infected mice, however, protection from lethal disease is achieved by both IgG_1 and IgG_{2a} subclasses (Dietzschold et al. 1992).

Successful action of the humoral immune response requires very rapid migration of virus-specific plasma cells into the brain parenchyma. This is usually achieved if viral CNS infection occurs concomitantly with the acute peripheral infection and pre-existing plasma cells can immediately enter the brain tissue. When viral CNS infection occurs late after primary infection, the immune response has to be initiated in local secondary lymphatics, such as the cervical lymph nodes. The period until humoral effector systems reach the brain parenchyma may be determined by the genetic background of the host, as documented for *Coronavirus* JHM-induced encephalomyelitis in two genetically different rat strains (Schwender et al. 1991).

The effect of a late or a rather unspecific recruitment of humoral immunity to the CNS facilitates viral spread within the CNS. Consequently, large infected areas will result in a vigorous infiltration of virus-specific T cells, leading to enhancement of neurological disease. This intimate relation between virus-specific humoral response and T cell-mediated immunopathology was shown in acute LCMV-induced encephalitis of mice. In this model, mice injected with neutralizing antibodies before and shortly after viral infection were protected from lethal encephalitis, and CTL responses were diminished compared with unprotected mice (Wright and Buchmeier 1991).

Enhancement of viral pathogenesis by humoral effector systems

Humoral immunity is not generally thought to contribute to the pathology of viral CNS infection. Nevertheless, there are theoretical considerations and experimental data obtained in vitro that do not strictly rule out disease-enhancing properties of humoral immune responses. As in the periphery, intrathecal antibody synthesis could help to augment viral pathogenesis by antibody-dependent enhancement (ADE): i.e. antibody-complexed viral particles can be taken up by cells either by binding to Fc receptors (FcR) or, in the case of activation of the complement cascade, by attachment via the C3 receptor. In both cases, cells of the monocyte/macrophage lineage, such as microglial cells, are prime targets for ADE in the CNS (Aloisi 2001; Homsy et al. 1989) In addition, the engagement of FcR triggers activation of macrophages or microglia, which may lead to unspecific tissue destruction. Binding of immune complexes to the FcR can stimulate the release of toxic substances, causing the destruction of healthy cells surrounding the infected areas. This assumption is supported by the observation in vitro of macrophage-dependent oligodendroglia cell degeneration in mixed glial cell cultures when they are treated with immune complexes formed by canine distemper virus (CDV) and CDV-specific antibodies (Botteron et al. 1992).

The presence of virus-specific antibodies in the CNS opens one pathway allowing a complement-dependent immunological effector mechanism to operate: the antibody-activated cytolytic action of complement (Speth et al. 2001). Activation of the complement cascade in the CSF has been demonstrated in patients suffering from HIV-1 infection (Reboul et al. 1989). Opsonized virions will bind to cellular complement receptors, an interaction which can amplify the infection of cells with HIV-1 rather than induce lysis of the virus (Stoiber et al. 2001). There is, however, no evidence for antibody-mediated tissue destruction in the CNS of AIDS patients (Lenhardt and Wiley 1989). Although not proven, there is some reason to suggest that complement-mediated lysis could contribute to the pathogenesis of SSPE, caused by a persistent measles virus infection of the human CNS. One of the cellular receptors for measles virus, CD46, was found to be absent in CNS lesions of SSPE patients, whereas it is present on a fraction of cells in uninfected regions of the brain (McQuaid and Cosby 2001; Ogata et al. 1997). Because the normal function of CD46 is to protect cells from autologous lysis by activated complement (Liszweski et al. 1991), the sera and CSF of SSPE patients reveal high complement activity (Oldstone et al. 1975), and CD46 down-regulation enhances the complement-mediated lysis of cells in tissue culture (Schnorr et al. 1995), it is tempting to speculate that this mechanism may contribute to the pathology of SSPE.

Viral persistence and virus-specific antibodies

Incomplete elimination of virus from the CNS may result in persistent infection that is usually accompanied by a long-lasting intrathecal antibody synthesis with specificity for viral proteins (Rammohan et al. 1983; Tyor et al. 1992). Over time there is selection of high-avidity antiviral antibodies, and the respective clones are preferentially recruited to the CNS. In this case, isoelectric focusing of CSF specimens will show a restricted 'oligoclonal pattern' of antibody clones, compared to the polyclonal distribution detectable in paired serum specimens. The presence of these oligoclonal bands can therefore be used as a diagnostic marker in viral infections of the CNS (Felgenhauer and Reiber 1992).

In addition to intrathecal virus-specific antibody synthesis being a reliable indicator of viral infection of the CNS, the long-lasting presence of antiviral antibodies at high titers may contribute to the selection of virus variants. In fact, changes in neural cell tropism have been shown for neurotropic JHMV grown in the presence of virus-neutralizing monoclonal antibodies (Buchmeier et al. 1984).

THE CELL-MEDIATED IMMUNE RESPONSE

T cell-mediated immune protection is usually mediated by cell destruction. Because a timely T-cell immune response encounters a small number of infected cells, the disease should be limited in most acute viral encephalitides, and the benefits will outweigh the harmful effects of the cell-mediated immune response. Paradoxically, the host's immune response to viral infection, which is usually protective outside the CNS, can be destructive when operating within this isolated compartment with such a low regenerative capacity. Cell lysis and toxic cytokines may themselves cause pathological changes while helping to clear virus, particularly during a long-lasting persistent infection.

The role of $CD4^+$ and $CD8^+$ T cells

Although both $CD4^+$ and $CD8^+$ T cells can be relatively easily isolated and grown in culture from the CSF of patients with viral encephalitis and meningoencephalitis, their relative contributions to antiviral defense are uncertain. As is apparent in some animal models, the presence and function of $CD4^+$ cells are more important than $CD8^+$ T cells in viral CNS infections. This is in contrast to the situation in peripheral tissues in which, for example, during acute and chronic viral hepatitis cytotoxic MHC class I-restricted $CD8^+$ T cells attack virus-infected hepatocytes and thus mediate protection as well as cell destruction (Almond et al. 1991).

Although there is still some controversy, results obtained in the Theiler's virus model in mice indicate that the ability to generate $CD8^+$ T cells is not essential for viral clearance. In both C57BL/10 mice, which develop an acute encephalitis followed by subsequent clearance of

virus from the CNS, and SJL mice, which experience a persistent viral infection with demyelination lesions, there are $CD8^+$ CTLs in the CNS (Lindsley et al. 1991). Furthermore, β_2-microglobulin-deficient transgenic mice that lack MHC class I and, therefore, functional $CD8^+$ cells, develop persistent encephalitis with extensive demyelination. However, neither antibody titers nor viral persistence was significantly affected (Pullen et al. 1993).

Consistent with these findings, $CD4^+$ cells proved indispensable in achieving viral clearance from the CNS of rats after transfer into animals experimentally infected with MV, whereas $CD8^+$ cells were not vital for recovery from the acute infection. It must be remembered, however, that in different species different virus-specific immune effector cells are generated in the control of viral infections in the periphery; even within a single species there is no unique T-cell subset used for antiviral defense. In many murine virus infections, including HSV, influenza A virus, LCMV, and mouse poxvirus, $CD8^+$ CTLs are important in combating infection (Moskophidis et al. 1987; Nash et al. 1987; Ahmed et al. 1988; Askonas et al. 1988). However, the clearance of murine hepatitis virus from the brain by $CD8^+$ T cells depends on $CD4^+$ help (Williamson and Stohlman 1990), and in the protective immunity to retroviruses both $CD8^+$ and $CD4^+$ T cells were only partially effective, whereas the combination of both led to full protection (Hom et al. 1991). In contrast, recovery from acute murine CMV infection can proceed in the absence of the $CD8^+$ subset, and it is mediated by $CD4^+$ T cells that develop a compensatory protective activity absent from normal mice (Jonjic et al. 1990). $CD4^+$ T cells seem to be required for the maintenance of spontaneous recovery from friend murine leukemia virus-induced leukemia (Robertson et al. 1992). These examples illustrate that there is no general assignment of a determinative role in vivo to either T-lymphocyte subset in the recovery from viral infections. It seems, however, that in the CNS antiviral cell-mediated activity is largely dependent on $CD4^+$ T cells.

Mechanisms of T cell-mediated antiviral activity in the brain

The mechanism of the antiviral activity of $CD4^+$ T cells in vivo has not been completely elucidated. A detailed characterization in vitro revealed that all protective T-cell lines produce large amounts of IL-2, IFN-γ, and TNF-α, but not IL-4 or IL-6, defining them as Th1 cells (Liebert and Finke 1995). If cytokines secreted by Th1 cells are important, two requirements should be met: virus-primed T cells have to invade the CNS and home in on sites of infection; and blocking cytokine function should abolish protection. Adoptive transfer experiments in MV-infected rats as well as in mice, using a genetic marker, revealed that MV-specific $CD4^+$ T cells from a donor animal enter the brain of the host. These cells accumulated in infected areas, where they represented $\leqslant$5 percent of all infiltrating T cells in immunocompetent animals. Furthermore, the neutralization of IFN-γ by the administration of antibodies rendered all mice susceptible to MV-induced acute encephalitis, suggesting that cytokines may indeed play an important role in the immune surveillance of the CNS. The mechanism of cytokine activity may be to assist in recruiting effector cells into the CNS (see also under Virus cell interaction in the CNS). The main source of IFN-γ and TNF-α in MV infection of the murine CNS seems to be $CD4^+$ T cells.

In the Theiler's murine encephalomyelitis virus (TMEV) encephalitis model in mice, susceptibility to infection is associated with MHC and maps to the class I locus H-2D, which is highly upregulated in the CNS, in contrast to the H-2K locus (Nash et al. 1987). In susceptible strains $CD8^+$ T cells apparently fail to recognize viral antigens in the context of MHC class I, so the virus persists and eventually causes disease. After depletion of $CD8^+$ T cells in vivo, virus clearance is delayed and demyelinating disease develops, indicating that $CD8^+$ T cells are not involved in demyelination and are not vital for recovery from acute infection. In contrast, depletion of $CD8^+$ cells after the acute phase does reduce disease. Observations made in β_2-microglobulin-deficient transgenic mice, however, suggest that $CD8^+$ T cells may play a role in clearing viral persistence from glial cells (Pullen et al. 1993). Depletion studies of $CD4^+$ cells in the TMEV model suggest that the major role of $CD4^+$ T cells in picornavirus infections is probably to control the early stages of infection by providing B-cell help and thus enable the production of neutralizing antibody (Virelizier 1989). TMEV-specific proliferation of $CD4^+$ MHC class II-restricted T cells was found in both resistant and susceptible strains (Clatch et al. 1987).

There is a strong correlation in a number of susceptible strains between demyelination and a $CD4^+$ T cell-mediated DTH response, and one DTH T-cell epitope in susceptible mice has been mapped to the VP2 protein (Geretry et al. 1994). The incidence of demyelinating disease was reduced following suppression of MHC II restricted $CD4^+$ T-cell function after viremia. After TMEV infection and initial T-cell infiltration into the CNS, MHC class II induction on astrocytes is a key step in allowing local antigen presentation and amplification of immunopathological responses within the CNS, and hence the development of demyelinating disease (Borrow and Nash 1992). A bystander effect caused by the induction of mononuclear cell infiltration, and activation of macrophages, which in turn can lead to damage on myelin sheaths, is probably responsible for the observed immunopathology.

Virus-induced cell-mediated autoimmune reactions against brain antigens

Another possibility involves T cells reactive against brain cell antigens, which could be induced during the

course of infection and may exacerbate current pathology or initiate new lesions. There are several possibilities of how a virus could induce strong cell-mediated immunity (CMI) responses to brain antigen:

- When enveloped viruses multiply in living cells, they may incorporate host antigens into their envelope. In this context these antigens might then be recognized by the host and thus elicit an immune reaction.
- Viruses with a tropism for lymphocytes and macrophages might be involved in the destruction of lymphocyte subpopulations or the generation/expansion of autoreactive lymphocyte clones.
- Immune responses raised against certain viral antigens may cross-react with normal host cell antigens and lead to autoimmunity by molecular mimicry (Oldstone 1989; Fujinami and Oldstone 1985). Synthetic peptides derived from common viruses (based on motifs required for MHC class II binding and T-cell receptor recognition) can activate human T-cell lines specific for MBP (Wucherpfennig and Strominger 1995).

The frequency of induction of T cells reactive against brain antigens, and their role in the pathology of human viral CNS infections, are unclear. One study suggests that a significant proliferative response of isolated peripheral lymphocytes occurs against myelin basic protein (MBP) in patients with acute measles encephalomyelitis (Johnston et al. 1984). Moreover, MBP was detected in the CSF of such patients as a consequence of myelin breakdown. MBP-specific lymphoproliferative responses have also been seen after postinfectious encephalomyelitis following rubella virus, varicella-zoster virus, and respiratory infection, and in patients with postexposure rabies immunization (Johnston and Griffin 1986). The latter disorder is probably the human equivalent of EAE, because these patients received rabies vaccine prepared in brain tissue. Continuing the analogy to EAE, it is not surprising that an MBP-specific lymphoproliferative response in these virus infections is considered to be of pathogenic importance. In experimental CNS infections autoimmune T cells do not seem to be involved in the induction of demyelination in Theiler's virus in mice, as tolerance induced to myelin antigens blocked the induction of EAE but did not affect the development of demyelinating disease (Kennedy et al. 1990). However, in rats infected with JHMV or MV, MBP-reactive $CD4^+$ T cells were detected that could transfer EAE to naive uninfected animals (Watanabe et al. 1983; Liebert et al. 1988). These observations support the hypothesis that viruses could be involved in the initiation of autoimmune processes.

Consequences of antiviral mechanisms in the CNS

In summary, immune responses generated in the periphery encounter great difficulties when combating CNS virus infections. If neurons are infected, elimination of the cells may not be of any advantage to the host as the immune response, although beneficial in the periphery, would inflict enormous damage when attacking cells that lack the capacity to regenerate. Hence, rapid elimination of infected cells is necessary to prevent virus amplification. In contrast, the development of a delayed immune response may allow the virus to spread in the CNS and, even if ultimately effective against the virus, may be destructive to the host. Thus, precautions are built into the system to prevent potentially damaging and disease-inducing immune responses during persistent infections in which the virus, at least temporarily, does not destroy its host cell.

The fine regulation of intracerebral immune surveillance has yet to be elucidated. However, it is clear that a delicate balance is normally maintained between the morphological and functional integrity of the CNS and the ability of the immune system to combat virus and eliminate infected cells. At present the evidence indicates that:

- The immune response to viral infections of the CNS is initiated in peripheral lymphoid tissues, followed by entry of activated end-differentiated T and B cells into the CSF, meninges, and brain parenchyma.
- During viral infections different sets of cytokines and chemokines are induced.
- Together with interferon-induced proteins, these factors contribute to the establishment of persistent infections, which may depend on downregulation of replication of certain viruses by lack of certain factors, or the restriction of viral gene expression, or both.
- During viral infections, MHC class I or II antigens are expressed extensively on microglial cells which present viral antigen produced by infected cells, and also on astrocytes oligodendrocytes, and damaged neurons.
- Full development of the inflammatory response requires virus-specific T cells; natural killer (NK) cells, γ/δ T cells, mononuclear phagocytes, B cells, and plasma cells participate in a bystander response.
- In many viral systems T cells are required for viral elimination, but clearance of virus may also depend on the timely presence of virus-specific antibodies.
- Immunopathology and autoimmunity may result from inopportune or inefficient T-cell responses generated after the viral agent has succeeded in establishing a persistent infection in brain cells as a result of immune-mediated damage during attempted viral clearance.

VIRUSES AND ASSOCIATED CNS DISORDERS IN HUMANS

As mentioned previously, except for rabies virus, human pathogenic viruses do not per se reveal a tropism for the

CNS, but rather cause CNS diseases in the course of an infection in the periphery. A summary of the relative frequencies of the ability of human pathogenic viruses to cause CNS diseases is given in Table 2. For example, CNS involvement is quite frequent with mumps virus infections, whereas the proportion of patients with measles developing CNS complications is generally small. The same applies to EBV infections, which are ubiquitous and normally clinically inapparent, CNS complications being observed only rarely. The following sections thus focus on viral infections of the CNS that are of major clinical interest and which have been investigated in more detail.

Polyomaviruses

Progressive multifocal leukoencephalopathy (PML) is a demyelinating disease of the CNS resulting from infection of oligodendrocytes with JC virus (JCV), a *Polyomavirus* (Richards 1988, Dörries 2000) (see Polyomaviruses). Until the AIDS epidemic, experience with this disease was limited. Once regarded by most neurologists as a clinical curiosity, PML has now been recognized as an AIDS-associated disorder and the HIV-encoded transactivator Tat has been found to be an activator of the JCL promoter (Remenick et al. 1991). Current estimates suggest that 1–4 percent of all HIV-infected people will develop PML (Berger et al. 1987; Berger and Major 1999). In AIDS patients, as in those with other underlying diseases, PML usually progresses inexorably to death within a mean of 4 months. More than 80 percent succumb within 1 year of diagnosis. However, on rare occasions individuals with PML experience both clinical and radiographic recovery, including full neurological recovery, in the absence of specific therapeutic intervention.

The spread of JCV is thought to occur via the respiratory route (Shah 1990). To date, no disease has been convincingly associated with the acute infection. Usually, asymptomatic persistent infections with JCV (and the closely related BK virus) are established; consequently, 80–90 percent of the healthy adult population have IgG antibodies against JCV (Padgett and Walker 1983). Kidney, CNS, and in some cases peripheral blood mononuclear cells, have been identified as sites of persistent infection (Houff et al. 1988; Arthur et al. 1989; Elsner and Dörries 1992; Dörries et al. 1994). It is not yet entirely clear how these persistent infections are established and maintained. Although heterogeneity within the JCV control regions in brain isolates could be defined, these changes could be linked neither to the persistent phenotype of the infection nor to the efficiency and frequency of reactivation (Elsner and Dörries 1992). On the other hand, it has been suggested that the cell type specificity of JCV in vitro and in vivo is controlled by host and viral transcription factors that actively regulate JCV gene expression by interacting with the viral control region (Feigenbaum et al. 1987; Chowdhury et al. 1990; Lynch and Frisque 1991; Ranganathan and Khalili 1993). Reactivation of viral replication leading to PML is almost exclusively confined to immunosuppressed individuals (Walker and Frisque 1986), strongly suggesting that the host's immune system plays a major role in controlling viral replication in persistence. However, there is no evidence as to how the immune response controls virus persistence and prevents reactivation. Because only a minority of patients with underlying cellular immunodeficiency ultimately develop PML, it is possible that the presence of JCV and immunosuppression alone is not sufficient for its development.

The AIDS epidemic has dramatically altered the epidemiology of PML (Holman et al. 1991). Instead of affecting chiefly elderly people, PML has become a disease of the young and middle-aged affected with AIDS. It is interesting that this disease rarely occurs in immunosuppressed children with HIV infection (Berger et al. 1992), perhaps as a result of the smaller percentage of children infected with JCV. The high prevalence of antibodies in the adult population and the rarity of PML in children supports the contention that PML results from reactivation of JCV in individuals who have become immunosuppressed. Until the early 1980s (before the AIDS epidemic), the vast majority of patients with PML had lymphoproliferative disorders leading to immunosuppression, such as Hodgkin's disease, chronic lymphocytic leukemia and lymphosarcoma, tuberculosis, lupus erythematosus, or sarcoidosis (Brooks and Walker 1984). In contrast, AIDS has been estimated to be the underlying disease behind PML in 55–85 percent of all current cases in which PML was reported within 1 year

Table 2 *Viruses causing acute meningoencephalitis and acute encephalitis in humans*

Frequent	Infrequent	Rare
Herpes simplex virus 1 and 2	Varicella-zoster virus	Adenovirus
Mumps	Measles	Epstein–Barr virus
Enteroviruses	Rubella	Reovirus
Arboviruses	Influenza virus A and B	Parainfluenza virus 1–3
Rabies	Cytomegalovirus	Respiratory syncytial virus
		Human parvovirus
		Lymphocytic choriomeningitis virus

after the initial diagnosis of AIDS (Gullota et al. 1992; Kaye et al. 1992; Major et al. 1992).

The clinical hallmark of PML is the presence of focal neurological changes associated with radiographic evidence of white matter lesions, depending on the location of the CNS infection. Cardinal features of PML, apparent on clinical examination, include an insidiously progressive psychomotor slowing, impaired memory, and apathy. The most common presentations include weakness, visual deficits, and cognitive abnormalities, which occur in approximately one-third of patients (Brooks and Walker 1984). Weakness is typically a hemiparesis, but monoparesis, hemiplegia, and quadriparesis may be observed as the disease progresses. Other motor disturbances include limb and trunk ataxia, resulting most often from cerebellar involvement. Nearly one-third of patients have cerebellar signs at the time of diagnosis (von Einsiedel et al. 1993). Extrapyramidal disease is rare at onset, but bradykinesia and rigidity may be detected in a substantial minority of patients with advanced disease. Dystonia and severe dysarthria have also been observed as a consequence of lesions in the basal ganglia. Neuro-ophthalmic symptoms occur in 50 percent of patients and are the presenting manifestation in 30–45 percent. The most common visual deficits are homonymous hemianopia or quadrantanopia due to lesions of the optic tracts. The spectrum of cognitive changes observed is quite broad. Unlike the slowly evolving global dementia of the HIV-associated dementia complex, the mental impairments of PML often advance more rapidly and typically occur in conjunction with focal neurological deficits.

Neuropathologically, the cardinal feature of PML is demyelination, i.e. the loss of oligodendroglial cells and myelin sheaths (Figure 2). Demyelination is typically multifocal, but on rare occasions may also be unifocal. Although these lesions may develop in any location in the white matter, they have a predilection for the parieto-occipital regions. Not infrequently, lesions involve the cerebellum, brainstem and, less commonly, the spinal cord (Bauer et al. 1969; Kuchelmeister et al. 1993; von Einsiedel et al. 1993).

Other histopathological hallmarks of PML include hyperchromatic, enlarged oligodendroglial nuclei, and enlarged bizarre astrocytes with lobulated hyperchromatic nuclei (Figure 2). The abnormal astrocytes may undergo mitosis and have quite a malignant appearance. In situ hybridization for JCV DNA allows the detection of virions in the nuclei of infected oligodendroglial cells. Virions are detected less frequently in reactive astrocytes, and only rarely in macrophages engaged in removing the affected oligodendrocytes (Mazlo and

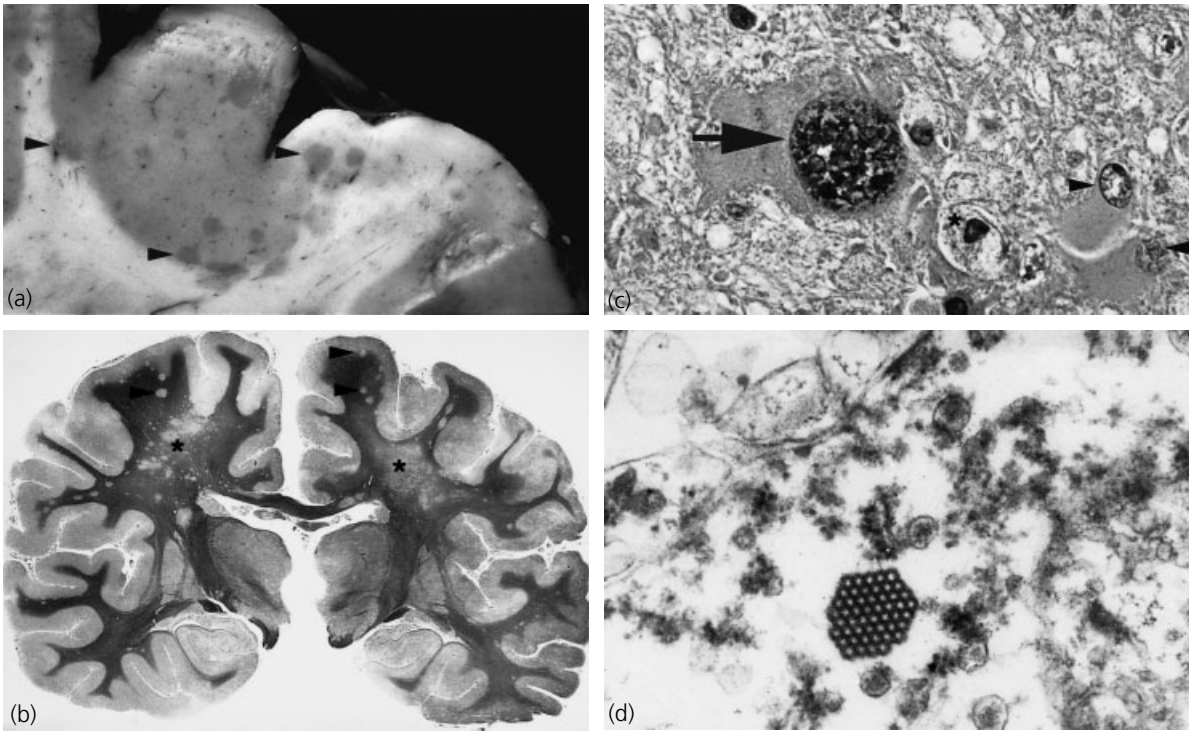

Figure 2 (a) *Close-up of the cortex of a patient who died from PML. Several small foci of demyelination are situated mainly at the border between the gray and the white matter.* **(b)** *Whole mount of the cerebrum of the same patient, stained with a myelinotropic dye. Again, there are several round areas of demyelination, as well as larger polycyclical (several circular confluent) regions of confluent foci in the central white matter.* **(c)** *Swollen, grotesquely deformed oligodendrocyte with a very large nucleus (×400). For comparison, see the two reactive astrocytes at the right of the picture (arrowed).* **(d)** *Electron micrograph showing papovaviruses within the affected oligodendrocytes. Tariska 1992). The subcellular distribution of virions, particularly in cells usually not involved in papovavirus infection (the nucleus and cytoplasm of neurons), has been reported in two cases (Boldorini et al. 1993). Although neuropathological findings do not reveal fundamental differences between cases of AIDS and non-AIDS PML, the former more frequently present with extensive lesions of a particularly destructive, necrotizing character.

The application of quantitative PCR to CSF samples enables premortem diagnosis with less invasive procedures than brain biopsy (Dörries 2000). Confirmation of PML requires the demonstration of typical histopathological changes and the detection of JCV in brain samples obtained from biopsies or at autopsy using conventional techniques, including electron microscopy, virus isolation, immunocytochemistry, and in situ hybridization. Recently, it was found that the newly approved cidofovir diphosphate, a structural analog of deoxycytidine trisphosphate, is not only a potent inhibitor of human herpes and papillomaviruses, but also a selective antipolyomavirus agent.

Alphaherpesviruses

Of the numerous herpesviruses so far characterized, eight have been isolated from humans. Among these, three members of the subfamily *Alphaherpesvirinae*, herpes simplex virus-1 and -2, and varicella-zoster virus (VZV), have been identified as etiological agents in the pathogenesis of human disease processes in both the peripheral and the central nervous system. HSV is responsible for the viral encephalitis with the highest fatality rate. Alphaherpesviruses have a variable host range and short replication cycles and spread rapidly in infected cell cultures, resulting in complete cell destruction. Paradoxically, they can establish latent, lifelong infections in their natural hosts, including those with natural or vaccine-induced immunity. These latent infections occur primarily, but not exclusively, in neural tissue of sensory and autonomic nerve ganglia and the CNS.

Human herpesviruses -6, -7, and -8 have been isolated from human peripheral blood mononuclear cells (PBMC) in recent years. Their association with human CNS diseases has not yet been fully defined, although a pathogenic role of HHV-6 has been suggested for multiple sclerosis (Challoner et al. 1995; Gutierrez and Vergara 2002).

HERPES SIMPLEX VIRUS

Following infection, HSV-1 and HSV-2 replicate at the mucocutaneous surface before entering nerve axons. Virus then moves centripetally via retrograde fast axonal transport to cell bodies of neurons in sensory and autonomic nerve ganglia, and in some cases to the CNS (Figure 3). Following retrograde transport, the virus replicates in the sensory ganglia that innervate the site of infection. In experimental work in animals there is evidence of lytic virus infection in neurons and accessory cells, and virus can be recovered from ganglionic homogenates. Once replication in the sensory ganglia is complete, antiviral drugs cannot eliminate the virus if it enters its latent state. In acutely infected ganglia two types of virus–neuron interaction can occur, resulting in either lytic or latent infection. Cellular factors involved in repressing immediate early gene expression may be paramount in this. After acute ganglionic infection subsides, virus persists in neurons, probably for the lifetime of the host. Infectious virus cannot be recovered from ganglionic homogenates during the latent phase of infection, but can be isolated from ganglionic explant cultures. Periodically, latent virus is reactivated either spontaneously or by a variety of stimuli. During this reactivation process, virus (or perhaps subviral particles) is transported centrifugally via the nerve cell axon to the original peripheral infection site, where replication can then recur.

The exact role of the cell in establishing latent HSV-1 infections is still unclear, because of the small number of latently infected cells present in vivo as well as the difficulty of establishing authentic in vitro latency systems. The dependence of latency on the presence of nerve growth factor (NGF) in primary cultures of sympathetic and sensory neurons has been described (Wilcox and Johnson 1988; Wilcox et al. 1990). Moreover, neurons in culture express factors that inhibit the expression of HSV-1 immediate–early genes (Ash 1986; Kemp et al. 1990; Wheatley et al. 1991; Lillycrop et al. 1993) and therefore arrest HSV-1 replication at an early stage, before irreversible cell damage.

Some molecular aspects of HSV latency and reactivation have been described (for review see Millhouse and Wigdahl 2000). The genome persists as a circularized or a linear concatenated structure that is not integrated into the cellular DNA in human and mouse tissue. The viral DNA is not extensively methylated, and estimates suggest that 20–30 copies of the viral genome may be present in individual cells. A set of RNAs, predominantly stable introns of 1.5 and 2 kb length, is produced in latently infected neurons, where they are the only viral transcripts detectable (latency-associated transcripts (LAT)) (Figure 4). They extend from a region in IR_L (large internal repeat region) without an assigned coding role into an oppositely orientated coding region. Mutations in the region encoding LATs have been reported as affecting entry into or reactivation from the latent state. It seems that LAT elements have been conserved in evolution, thus strongly suggesting that there are important functions that may include the silencing of genes such as *ICP0*, an activator of the viral replication, or the expression of proteins contributing to reactivation. Recently, an anti-apoptotic function of the

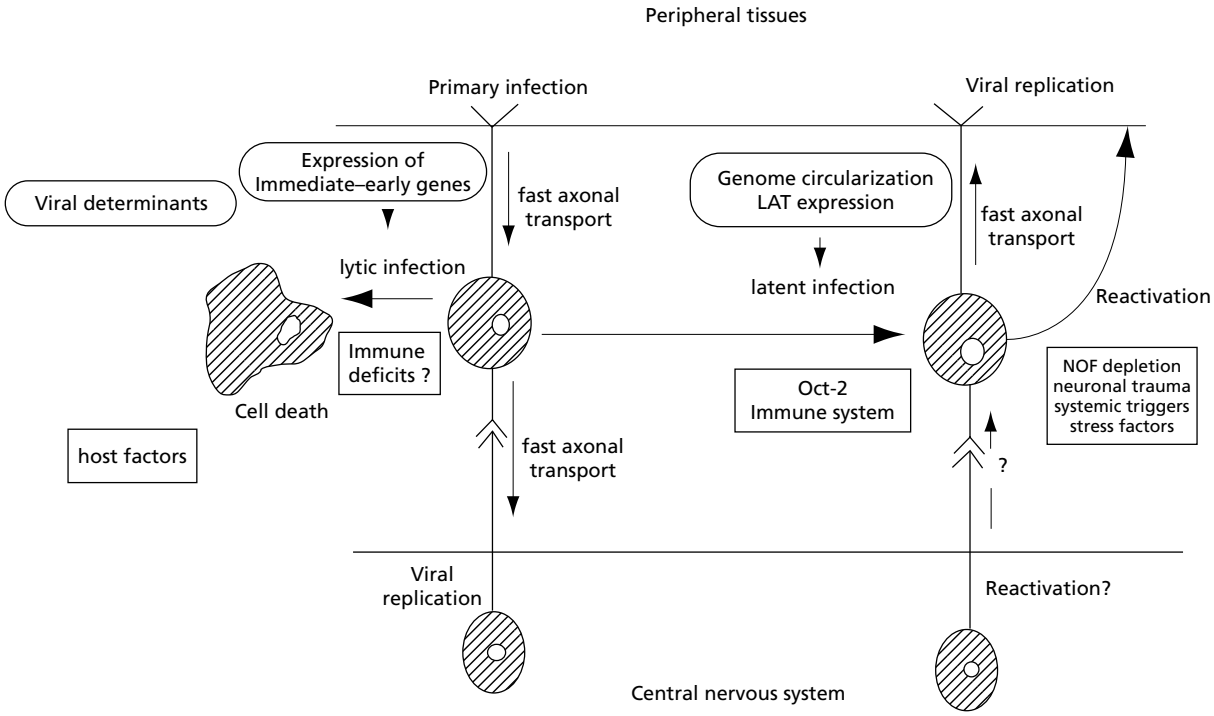

Figure 3 *Schematic representation of mechanisms of HSV-1 replication in the nervous system. After primary infection at peripheral tissues, the virion travels via fast axonal transport to peripheral sensory ganglia (PSG). Under conditions favoring viral replication (e.g. immune disruption), expression of HSV-1 immediate–early genes, followed by a complete viral replication cycle, will ensue, leading to neuronal cell death. Again by fast axonal transport, the virus may seed the CNS, causing an acute lytic infection (primary HSV-1 encephalitis). By contrast, in the presence of an effective immune system, viral replication will be prevented in PSG and probably CNS neurons (due at least in part to host cell factors such as neuronal-specific Oct-2 transcription factor). This may lead to either an abortive (not reactivatable) or a latent infection that is characterized by the circularization of the viral genomic DNA and a marked restriction of viral gene expression where no immediate–early genes, but only latency-associated transcripts (LATs), are expressed. Under specific systemic (e.g. menstruation) and local triggering conditions, the latent genome can reactivate in PSG, travel to the periphery, and replicate there. The ability of reactivated HSV-1 to invade the CNS is uncertain, as is reactivation from latent infections established in the CNS. NGF, neuronal growth factor.*

LATs has been described which promotes neuronal survival (Perng et al. 2001).

Primary CNS infection with HSV

Infection with HSV-1, generally limited to the oropharynx, can be transmitted by respiratory droplets or through direct contact of a susceptible individual with infected secretions. Thus, initial replication of virus occurs in the oropharyngeal mucosa. The trigeminal ganglia become colonized and harbor latent virus. HSV-2 infection is usually the consequence of transmission via a genital route. In these circumstances, virus replicates in the vaginal tract or on penile skin and eventually seeds the sacral ganglia. After recovery from the primary infection only a small percentage of individuals experience recurrent infections. HSV encephalitis is mainly associated with HSV-1 infection, whereas ascending myelitis or meningitis is linked mainly to HSV-2 (Shyu et al. 1993). Of these clinical entities, encephalitis is the most common and most severe HSV infection of the CNS. The clinical course is variable, depending on the location as well as the acuteness of the infection.

HSV infections of the newborn can be aquired in utero, intrapartum (75–80 percent of all cases), or postnatally. The clinical presentation of infection reflects the site and extent of viral replication. Neonatal HSV infection is almost invariably symptomatic and frequently lethal. Intrauterine infection is apparent at birth and is characterized by severe manifestations, such as microcephaly or hydrocephaly. Intrapartum or postnatally acquired HSV infections may lead to encephalitis or disseminated infection that involves multiple organs, including acute brain infections. In infants with disseminated infections the virus probably seeds the brain by a blood-borne route, resulting in multiple areas of cortical hemorrhagic necrosis. In contrast, infants who present only with encephalitis probably develop brain disease as a consequence of retrograde axonal transmission of virus to the CNS. Clinical manifestations of encephalitis with or without associated disseminated disease include seizures (both focal and generalized), lethargy, irritability, tremors, poor feeding, temperature instability, a

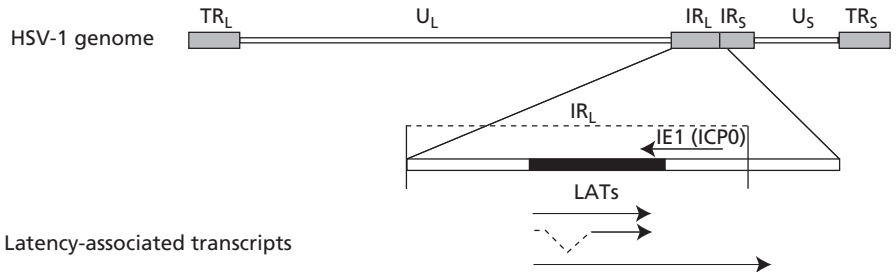

Figure 4 *The HSV-1 genome is a linear DNA molecule containing unique long (U_L) and short (U_S) regions bounded by the terminal and internal repeat regions (TR and IR, respectively). The region encoding the major species of latency-associated transcripts (LATs) that are expressed during viral latency is located within the IR_L region (as indicated by the black bar in the enlarged section). As also indicated, some LATs extend from the LAT locus into the IR_S region. The major LAT species expressed partly overlap with viral genes encoded in the opposite direction on the genome, as exemplified for the immediate–early 1 gene (*IE1 *or* ICP0*). LATs may interfere with the expression of these genes because they are antisense to their mRNAs, leading to the formation of dsRNA molecules.*

bulging fontanelle, and pyramidal tract signs. Cultures of CSF yield virus in 25–40 percent of cases. Likely findings on CSF examination include pleocytosis and proteinosis, which increase with progressive disease. Death occurs in 50 percent of untreated infants with localized CNS disease, and is usually related to brainstem involvement. With rare exceptions, survivors are left with neurological impairment.

Clinical manifestations of HSV encephalitis in older children and adults reflect the areas of pathology in the brain. These include primarily a focal encephalitis associated with fever, altered consciousness, bizarre behavior, disordered mentation, and localized neurological signs. These clinical findings are generally associated with neurodiagnostic evidence of localized temporal lobe disease. Histopathological findings include widespread areas of hemorrhagic necrosis, mirroring the area of infection, with oligodendrocytic involvement, gliosis and, frequently, astrocytosis late in the disease course (Figure 5). Primary HSV-2 infections can, independent of gender, be associated with fever, dysuria, localized inguinal adenopathy, and malaise. The severity of primary infection and its association with complications is statistically higher in women than in men, for unknown reasons. Systemic complaints are common in both sexes, approaching 70 percent of all cases. The most common complications include aseptic meningitis (approximately 20 percent). Following primary genital herpetic infection, sacral radiculomyelitis (which can lead to neuralgias) and meningoencephalitis can also occur. The relationship between HSV infections of the brain and chronic degenerative disease and psychiatric disorders requires further investigation.

Latent infection by HSV

Despite the wide range of anti-HSV immune responses to the initial infection, the nonreplicating latent virus can persist in the ganglia for the lifetime of the patient. Whether latency per se causes any neurological injury is unknown, but it is well recognized that latent HSV is the source of virus responsible for recurrent infections in the peripheral nervous system. It is assumed that latent virus is reactivated to a replication-competent form and transported via sensory nerves to cutaneous or ocular sites, where further replication results in recurrent HSV infections. The pathological changes induced by the replication of HSV are similar in both primary and recurrent infection.

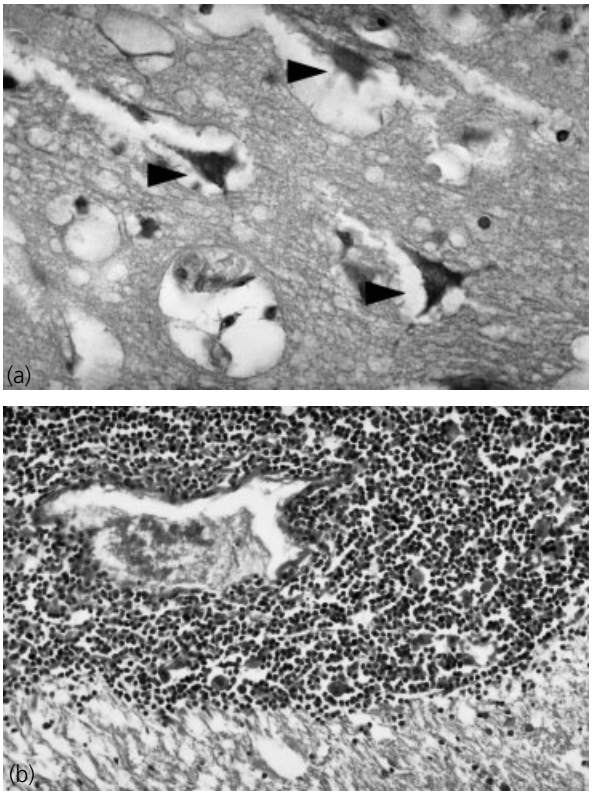

Figure 5 *Herpes simplex type 1 encephalitis.* **(a)** *Strongly positive intraneuronal staining with anti-HSV-1 immunostain (arrowed) (×400).* **(b)** *Massive accumulation of inflammatory cells (predominantly lymphocytes) in the neighborhood of small vessels ('cuffing') (×50). (Courtesy of Dr Adriano Aguzzi.)*

HSV encephalitis in immunocompetent individuals is about 1 million times less frequent than the peripheral disease. The source of virus behind HSV-1 encephalitis in immunocompetent individuals is unclear, as the ability of HSV-1 to reactivate in the CNS seems to be extremely limited. Despite the presence of HSV-1 nucleic acid in the human brain (Fraser et al. 1981; Steiner and Kennedy 1995), there is no convincing evidence of recurrent encephalitis induced by HSV-1, and attempts to reactivate it from explanted CNS tissue have generally failed. On rare occasions reactivated virus may be transported from the trigeminal ganglia to the cerebral cortex, resulting in HSV encephalitis. However, not all cases of HSV encephalitis are caused by the strain responsible for cold sores in an individual. Therefore, it is assumed that, in about half of patients, HSV encephalitis occurs as a primary infection (Whitley 1990). Moreover, even with a history of a prior HSV-1 infection, a second primary infection with another HSV-1 strain may be responsible for the encephalitis.

Diagnosis and treatment of HSV encephalitis

The severity of HSV-associated CNS complications warrants the application of rapid and specific diagnostic approaches in order to achieve effective treatment. Seroconversion or an increase in serum antibody titer are not diagnostic of CNS infection. Serological diagnosis requires proof of intrathecal synthesis of virus-specific antibodies, which is evident only when the quantity of specific antibodies in the CNS cannot be explained by transport of antibodies from the periphery across the BBB into the CNS. Classically, CNS HSV IgG antibody is distinguished from peripheral blood-derived HSV antibody appearing in the CSF by the calculation of an antibody index (CSF HSV IgG:serum HSV IgG/CSF albumin:serum albumin); HSV antibody index values >1.5 are considered indicative of intrathecal Ig synthesis. Several approaches are available to determine intrathecal antibody synthesis, including techniques such as enzyme linked immunosorbent assay (ELISA), isoelectric focusing (IEF) or Western blotting using protein antigens (virus purified, or expressed as recombinant proteins) (Klapper and Cleator 1992). For the detection of viral antigens or nucleic acids, brain biopsies stained with virus-specific antibodies or hybridized with virus-specific probes have been used successfully (with a sensitivity of 80–85 percent and a specificity of 100 percent). More recently, PCR-based analysis of CSF samples has been widely used as a less invasive, highly sensitive method more appropriate for clinical application for the diagnosis of HSV encephalitis, particularly in the acute phase of disease in the absence of virus-specific antibodies and in suspicious relapses (Calvario et al. 2002).

The currently accepted antiviral treatment is acyclovir, and new therapeutic drugs, i.e. penciclovir and oral prodrugs, valacyclovir, and Famciclovir (Naesens and De Clercq 2001), potent therapeutic antiviral drugs that specifically interfere with HSV polymerase function and are highly effective in reducing both mortality and morbidity. In fact, the early and systemic application of aciclovir has reduced the mortality of HSV encephalitis from 70 to 20 percent of affected patients.

The use of steroid treatment in HSV encephalitis is a matter of controversy. As brain edema is believed to represent the major cause of mortality associated with herpes encephalitis, reduction of intracranial pressure is another important consideration in the overall treatment.

VARICELLA-ZOSTER CNS COMPLICATIONS

As the name implies, varicella-zoster virus (VZV) causes two distinct clinical symptoms: chickenpox and shingles (for review see Wood 2000). Chickenpox (varicella) is a ubiquitous, highly contagious disease that spreads rapidly in a susceptible population, and is seen predominantly in childhood as the manifestation of primary infection with this virus. In contrast, shingles (herpes zoster) is the manifestation of a recurrent VZV infection. It usually occurs in the elderly or in immunocompromised individuals, and is characterized by a painful vesicular eruption, generally limited to a single dermatome. A live attenuated vaccine against VZV infection is available (Takahashi et al. 1974; Black et al. 1999).

As with HSV, a primary infection with VZV is thought to pass centripetally from skin and mucosal lesions to the corresponding sensory ganglia via contiguous sensory nerve endings and sensory nerve fibers. At the same time, some seeding of ganglia might also occur through direct spread of the virus owing to a varicella-associated viremia. Once in the ganglion, the virus sets up a latent infection in the neuronal cells without replicating or damaging them.

Immune responses to VZV may play a role in maintaining the latent state, and certainly seem to be responsible for preventing clinically apparent reactivation. Reactivation of VZV occurs only rarely, usually once in an individual's lifetime. The main factors that trigger reactivation include generalized immunosuppression, such as HIV infection, or certain cancers (e.g. Hodgkin's disease), suggesting that alteration in the host immunity to VZV may allow the development of zoster. Accumulating evidence points to CMI as the principal factor in the appearance of zoster. Zoster is seen most frequently in cases where CMI is lost (e.g. in bone marrow transplantation), and is accompanied by acute inflammation of the corresponding sensory nerve and ganglion. Acute lymphocytic inflammation, focal hemorrhage and neuronal destruction have also been described. In addition, the sensory nerve shows degeneration and demyelination, both peripherally and centrally, and the presence of viral antigen in neuronal and satellite cells and within the corresponding sensory nerves has been described.

VZV latency and reactivation are quite different from HSV latency and reactivation (reviewed by Hay and Ruyechan 1994). In contrast to HSV, VZV seems able to establish ganglionic latency in nonneural cells (satellite cells that surround the neurons) and to express several lytic cycle viral genes while latent; these genes probably represent very early events in viral multiplication. LAT-like molecules have not been described in these infections, and VZV has no genomic region directly corresponding to LAT. The proposed block at the molecular level, however, may be quite weak, allowing small amounts of virus to be produced on a regular basis.

CNS involvement in varicella is seen in about one case per 1 000. It occurs most often in children aged 5–14 years. The pathogenesis of the neurological complications of varicella is not well understood. Direct invasion of the CNS is seen in some cases, particularly with disseminated visceral infection, whereas other CNS manifestations seem to be immune mediated in origin. Involvement of the ganglia and nerves precedes the development of cutaneous lesions. Similar changes are often observed in adjacent ganglia. The inflammatory and degenerative changes can be traced peripherally to the cutaneous lesions and centrally into the adjacent segments of the spinal cord or brainstem. The myelitis is generally unilateral and predominantly involves the posterior horns. Degeneration with neuronal necrosis and neuronophagia may also involve the posterior columns and the gray matter. A mild lymphocytic meningitis is frequently present and is most intense in the involved area. Anterior nerve root degeneration can be associated with a motor neuron radiculitis. VZV can be isolated from CSF and nerve tissue, which suggests that these changes represent direct viral invasion. CNS involvement is responsible for 20 percent of admissions to hospital. The most common presentation is acute cerebellitis, which appears towards the end of the first or the beginning of the second week after the onset of the rash and is usually transient. A more serious form of encephalitis occurring earlier during the course of varicella is a progressive encephalopathy with loss of conciousness and convulsions. If the brain swelling cannot be reduced the patient may assume a decorticate position. Less common neurological presentations seen in varicella include meningoencephalitis, transverse myelitis, peripheral neuritis, and Reye's syndrome.

In contrast to neuralgia, the most common and important clinical manifestation of herpes zoster encephalitis is a rare complication. Typically, the rash involves the cranial or upper cervical nerves, and little is known about its pathogenesis. Lesions of disseminated herpes zoster are identical to those of fatal varicella. In zoster meningoencephalitis there are lesions ranging from mononuclear infiltration of the meninges to necrotizing encephalitis with axonal degeneration, macrophage infiltration, and characteristic intranuclear inclusions and viral particles in the glial cells.

Enteroviruses

The genus *Enterovirus* belongs to the family *Picornaviridae* (see Picornaviruses). It contains a number of viruses that give rise to infections of the CNS, notably polioviruses, enteroviruses, coxsackie, and echoviruses. Epidemics of poliovirus, for instance, were once a worldwide scourge, but with widespread vaccination and the eradication program since 1988 the number of annual cases could be reduced from approximately 350 000 to 497 in 2001, mostly in Africa and Asia. Of the 853 confirmed polio cases in 2002, 651 occured in India. Aseptic meningitis due to other enteroviruses is now the most frequent neurological infection of viral origin. It may occur sporadically or in epidemic form, with significant morbidity and, depending on specific host factors, mortality. Enteroviruses multiply in the lymphoid tissue of the alimentary tract and cause a wide range of syndromes. The extent to which enteroviruses are responsible for CNS disease is very difficult to gauge because of both underreporting and the subclinical nature of infection in approximately 90 percent of cases. Children are the main targets of enterovirus infection, and also serve as a mode for virus dissemination. In general, gender does not seem to predispose to a certain type of disease, although cases of childhood paralytic poliomyelitis are twice as common in males as in females.

POLIOMYELITIS

Natural infection with poliovirus occurs via the oral route, whereupon virus replicates in the tonsils, the lymphatic tissue which drains the neck, Peyer's patches, and the small intestine. Whether infection of lymphoid tissue such as the tonsils is achieved after initial replication of virus in the gut and subsequent viremia, or during the initial infection following ingestion, is a topic of debate. It is generally held that, for successful invasion of the CNS by poliovirus, a viremic phase is required, although some evidence suggests that direct infection of the CNS can take place via nerve endings in the gut.

Once poliovirus has gained access to the CNS the outcome of disease can be devastating, and is based largely on the highly cytopathic nature of poliovirus replication. The majority of infections (90–95 percent) are, however, silent, although virus may be recovered in the stools or from throat swabs of infected persons. Abortive infections (4–8 percent) include self-limiting forms of poliovirus infection and may present as an upper respiratory tract infection, gastroenteritis, or an influenza-like illness. Nonparalytic poliomyelitis (1–2 percent) presents initially as an abortive infection that is followed by invasion of the CNS by virus. Accompanying the assault on the CNS by virus are symptoms of aseptic meningitis with back pain and muscle spasms.

Paralytic poliomyelitis/polio encephalitis (0.1–2 percent), such as nonparalytic poliomyelitis, will generally present as an abortive infection during the prodromal stages, although there is often no evidence of an early phase of infection. The illness may be biphasic (often seen in children), with meningeal irritation and, finally, the onset of asymmetric flaccid paralysis (when whole muscle groups are involved) or paresis (when muscle group involvement is somewhat limited). Poliomyelitis can be divided into three basic types (spinal, bulbar, and bulbospinal), depending on the site of nerve cell involvement. Bulbar paralysis is more common in children and generally does not involve the limbs, whereas adults presenting with bulbar poliomyelitis typically have limb paralysis.

The gross pathology of poliovirus infection has been widely studied (Bodian and Horstmann 1965). Classically, there is extensive damage to the large anterior horn cells of the spinal cord. When paralysis is associated with poliomyelitis the cervical and lumbar areas (which serve limbs) are particularly affected. In fatal cases of poliomyelitis there may also be involvement of the brainstem motor nuclei, as seen in bulbar poliomyelitis, or of nerve cells of the motor cortex or thalamus and hypothalamus. After infection of cells of the CNS by poliovirus, the earliest histological change is vascular engorgement, rapidly followed by perivascular infiltration. The infiltrate comprises mainly lymphocytes and, to some degree, polymorphonuclear neutrophils, plasma cells and microglia. Cell damage is largely due to cytolytic replication of poliovirus within cells. Infected nerves swell and undergo satellitosis before being phagocytosed by mononuclear cells. Viral destruction of cells results in degeneration of axons and axon sheaths, followed by atrophy of the affected area and astrocytic scarring. Flaccid paralysis accompanies these changes, followed by a widespread atrophy of muscle no longer innervated by affected nerves. Death is often due to respiratory failure as a result of respiratory paralysis or secondary complications (e.g. bacterial pneumonia). People affected by paralytic poliomyelitis may develop new muscle weakness and prominent midday fatigue 25–30 years later as part of the postpolio syndrome (PPS) (Munsat 1991; Stone 1994; Dalakas 2002). The basis for the muscle weakness is an ongoing motor neuron deterioration related to the extensive motor unit remodeling during recovery from poliomyelitis, leading to post-poliomyelitis progressive muscular atrophy, whereas the basis for midday fatigue may be related to the abnormal presence of cytokines, possibly owing to persistence of poliovirus in the CNS.

ENTEROVIRUS

Of the numerous serotypes of enteroviruses that are recognized, two deserve special recognition with respect to disease involvement of the CNS: enterovirus serotypes 70 and 71 (for review, see Yin-Murphy 1994). Both are transmitted by the fecal–oral route, although ocular infections with enterovirus 70 may be mediated by facecloths and bath towels, etc. Although enterovirus 70 has a marked predilection for epithelial cells of the conjunctiva, the fact that patients may exhibit signs of CNS involvement suggests neurotropism. However, enterovirus 70 has yet to be isolated from the CSF or CNS of infected patients.

The three forms of CNS disease caused by enterovirus 70 are the spinal form, the cranial form, and a combination of the two. The spinal form is by far the most commonly encountered and is characterized by an asymmetrical flaccid paralysis or paresis, with one or more limbs involved. Paralysis is the manifestation of infection of the anterior horn cells of the spinal cord by enterovirus 70. Atrophy of the affected muscle groups resembles poliomyelitis. In the cranial form, acute motor cranial nerve palsy is seen which may involve single nerves or groups of nerves. In the spinal cord there is marked degeneration of anterior horn cells and neuroglial cell proliferation. Immunofluorescence staining for enterovirus 70 antigen reveals the presence of virus in the microglial or neuronal cells, or both.

Although expression of clinical disease of the CNS by enterovirus 70 is somewhat rare, enterovirus 71 has caused epidemics of aseptic meningitis and encephalitis (Minn 2002). Originally described in California, the virus has been associated with neurological disease on a worldwide scale. The major clinical manifestation is that of aseptic meningitis, which may often be concomitant with encephalitis, bulbospinal disturbances, and polyneuritis. Children under 5 years of age are particularly susceptible to the most severe forms of enterovirus 71-associated neurological disease, including aseptic meningitis, brainstem and/or cerebellar encephalitis, and acute flaccid paralysis. Because the majority of patients are hospitalized for possible bacterial infection, a rapid test such as RT-PCR for the diagnosis of enteroviral meningitis may reduce hospitalizations and unnecessary treatments (Stellrecht et al. 2002). Studies in primates with strains of virus isolated from patients with CNS disease show degeneration and necrosis of the neurons and neuronophagia by polymorphonuclear and mononuclear cells. Analysis of the CNS reveals predominantly perivascular cuffing in the lumbar and cervical cord, with minor involvement of specific areas of the brain (including the medulla oblongata and midbrain).

COXSACKIE VIRUSES

Coxsackie viruses A and B also enter the host primarily via the oral route and follow essentially the same path as poliovirus, with replication in the Peyer's patches of the alimentary tract. Most infections are clinically silent, although some individuals exhibit greater susceptibility than others (a male:female infection ratio of 1.5:2.0 is observed for clinical disease). The reasons for this

discrepancy remain elusive. Nervous system involvement has been documented for coxsackie viruses A7 and A9, and for B1–B6, which induce an aseptic meningitis and poliovirus-like paralysis. coxsackie virus B may also cause chronic meningitis and/or encephalitis in immunocompromised persons. Encephalitis, ataxia, and paralysis of the cranial nerves are rare. Both coxsackie viruses A and B are responsible for aseptic meningitis, although echoviruses (see below) are more frequently involved. Pathological changes with encephalitic and poliomyelitis cases in laboratory animals include brown fat necrosis and myocarditis, which is widespread in animals infected with coxsackie B virus (for review see Whitton 2002).

ECHOVIRUSES

Echoviruses have been associated with a number of syndromes, including aseptic meningitis, encephalitis, paralysis, ataxia, and Guillain–Barré syndrome, to list those affecting the CNS. Humans are the only recognized host for echoviruses, and several epidemics of disease have been attributed to them. Assigning a particular serotype to a specific syndrome has not been possible, although Guillain–Barré syndrome has been linked to infection with echovirus 9. In addition, echovirus 4 has been isolated from patients with bilateral limb paralysis. Similar syndromes have been noted for adults and children infected with echovirus serotypes 6, 9, 14, 17, 19, and 30. Primary infection results in replication of virus in the alimentary tract, after which other organs are seeded following an initial viremia. The nature of the secondary target is largely random. Occasional peripheral neuropathies have been documented following expression of the virus in the CNS. Initial clinical symptoms of CNS invasion by echoviruses can mimic bulbospinal poliomyelitis, although the major clinical manifestation is that of lymphocytic meningitis. Neonatal infection with echoviruses may lead to encephalitis with white matter sclerosis. In general, infection of newborns and younger children with echovirus is more severe than in older people.

Flaviviruses

There are currently about 70 registered flaviviruses (see Flaviviruses), of which about 50 percent are associated with human disease (Heinz et al. 2000). Of those that cause significant CNS disease, Japanese encephalitis virus (JEV), which causes epidemics over much of Asia, carries the highest mortality rate of any flavivirus. In epidemics, mortality rates range from 10 to 20 percent in most outbreaks to >30 percent (Umenai et al. 1985; Bu' Lock 1986). tick-borne encephalitis virus (TBEV) has long been recognized as a public health problem in eastern Europe. In Russia, the virus caused high mortality in the 1930s, prompting a great effort to isolate the causative agent and to produce a vaccine (Silber and Soloviev 1946). A number of subtypes of TBE have been defined in different geographical locations, including eastern subtypes such as Sofyn, the agent of Russian spring–summer encephalitis (RSSE) (Silber and Soloviev 1946), and western subtypes, such as Hypr (Blaskovic et al. 1967) and Neudörfl (Ackerman et al. 1986). Mosquito-borne JEV continues to threaten large populations, even though massive vaccination campaigns have been undertaken. Vaccination may, however, be undermined to a large degree by the high antigenic variation in different subtypes of JEV. Other mosquito-borne flaviviruses that tend to involve the CNS include St. Louis encephalitis (SLEV) and Murray Valley encephalitis (MVEV). SLE became a serious public health problem in the USA in the 1960s and continues to cause concern during sporadic outbreaks (Kokernot et al. 1969). MVE causes epidemics in Australia, disease occurring intermittently in areas that have experienced periods of high rainfall. Epidemics in the southern hemisphere are usually recorded from January to March and coincide with high population levels of the mosquito vector. Recently, the emergence of JEV and West Nile virus (WNV) in new geographic areas several thousand kilometres from their known habitats has caused considerable concern. JEV appeared in the Australian zoogeographic region in 1995 about 3 000 km from its nearest known focus in Bali, and WNV jumped from the Middle East to the United States in 1999 (Mackenzie et al. 2002b; Roehrig et al. 2002). The JEV group of the genus *Flavivirus* comprises several viruses, including *Japanese encephalitis*, *West Nile*, *St. Louis encephalitis*, and *Murray Valley viruses*.

JAPANESE ENCEPHALITIS VIRUS

Japanese encephalitis (JE) occurs in epidemic form in temperate areas of Asia, the northern parts of tropical southeast Asia, and northern parts of Australia. With respect to number of cases (30 000–50 000 annually) and associated morbidity and mortality, JE is the most important of the arbovirus encephalitides, which is transmitted to humans via the bite of an infected mosquito (*Culex* spp.) and the case fatality rate of which is up to 35 percent (Solomon and Vaughn 2002). JEV has a major mammalian amplifying host in the pig, and indeed most epidemic activity is driven by mosquito–pig transmission cycles.

After humans become infected, virus is thought to replicate in the skin and is transported to local lymph nodes, probably in migrating dendritic cells.

How JEV invades the CNS is unknown. After a variable incubation period of 6–16 days the disease may be asymptomatic or fulminant in course. Death may be rapid, occurring 10 days after onset in some cases. For patients who develop encephalitis, the disease pattern begins with headache, cough, coryza, nausea, vomiting, and gastroenteritis, proceeding to the onset of high fever

and alterations in sensory perception (including confusion or delirium, which may result in coma). Other patients present with aseptic meningitis and have no encephalitic features. Seizures are uncommon in adults, but are often (20 percent or more) seen in children. Facial motor weakness is often observed and upper motor neuron paralysis and paresis are common. Neurological sequelae are common (up to 70 percent) in survivors of symptomatic JEV infection, and are particularly severe in children. Such sequelae include convulsive disorders, motor abnormalities, impaired intellect, and emotional disturbances.

The areas of the brain infected by JEV include the cerebral cortex, the cerebellum, and the spinal cord. The highest concentration of infected neurons is in the thalamus and brainstem. Once in the CNS JEV virus replicates very efficiently in neurons, and it is the destruction of these cells by virus that is directly related to the manifestation of encephalitis. The brain and meninges of JE patients show edema, congestion, and focal hemorrhages. Microscopically, there is degeneration and necrosis of neurons, with accompanying neuronophagia in the cerebral cortex, cerebellum, and spinal cord. There is marked destruction of Purkinje cells in the cerebellum, as well as perivascular cuffing and inflammatory infiltrates in surrounding neural tissue. JE antigen is usually not detected in glial cells.

Vaccination against JEV ideally should be routinely practiced in all areas where the virus causes human disease (Monath 2002). For a laboratory confirmation of JE, rapid diagnostic kits based on ELISA techniques are available. There is currently no specific antiviral treatment.

WEST NILE VIRUS

Although mosquitos are the vector for WNV, birds are instrumental in its spread, acting both as a viral reservoir and in geographical spread. Geographically, WNV infections have been described in Egypt (1951–1975), Israel (1951–1980), France, Spain, Africa, India, Pakistan, since 1996 in Romania, and since 1999 in the eastern states of the USA (Murgue et al. 2002; Roehrig et al., 2002).

After an incubation period of 2–6 days patients develop a sudden onset of high fever with chills, malaise, headache, backache, arthralgia, myalgia, and retro-orbital pain, which is made worse by eye movement (Solomon and Vaughn 2002). Other nonspecific features are common. A rash appears from the second to the fifth day of illness in about 50 percent of patients, and is more common in young children. Neurological manifestations of WNV infection are similar to those of JEV infection, including aseptic meningitis, encephalitis, myelitis, or combinations of the three. After 1–7 days of a febrile prodrome, with headache, weakness, and gastrointestinal symptoms, patients become drowsy, confused, and disorientated. Although in most cases the prodrome is nonspecific, up to 16 percent of patients may have features suggestive of WN fever, including eye pain, facial congestion, pharyngeal or conjunctival hyperemia, lymphadenopathy, arthralgia, or cutaneous eruptions. In some patients the illness is biphasic, with two fever peaks. Focal neurological signs include upper motor neuron weakness, lower cranial nerve palsies, tremor, and ataxia. WNV infection may also cause a flaccid paralysis of the limbs and respiratory muscles, which may require ventilation. Urinary incontinence or retention may also occur. The case fatality rate for patients with symptoms of the CNS due to WNV infection is 5–10 percent. Whereas younger patients are more likely to present with WN fever or aseptic meningitis, older patients are more likely to develop encephalitis and to die.

WNV infections are most frequently diagnosed by assessment of the antibody response in an IgM antibody capture ELISA. There is currently no specific antiviral treatment.

ST. LOUIS ENCEPHALITIS VIRUS

St. Louis encephalitis virus is a mosquito-borne *Flavivirus* that occurs in both endemic and epidemic forms in the USA and represents the most important arbovirus disease of North America. The virus is transmitted by *Culex* spp.

Clinically, infection with SLEV can range from inapparent infections to fulminant encephalitis and death. Patients usually present with or progress rapidly to one of three established syndromes: febrile headache, aseptic meningitis, or encephalitis. The febrile headache is often accompanied by vomiting and nausea. Analysis of the CSF may reveal pleocytosis. There are no apparent signs of meningeal involvement or neurological abnormalities. Aseptic meningitis presents as an acute febrile illness with signs of meningeal irritation and pleocytosis in the CSF. Encephalitis attributed to SLEV infection also includes meningoencephalitis and encephalomyelitis. Alterations in the state of consciousness or localized neurological abnormalities, or both, may be seen. Brinker and co-workers (Brinker et al. 1979) analyzed data from 18 reports of patients with SLE. It is estimated that 70–80 percent of patients suffer from headache, nuchal rigidity, and an altered level of consciousness. Almost 50 percent display tremors, pathological reflexes, and confusion. Some 20–30 percent of patients exhibit multiple cranial nerve abnormalities, hypoactive deep tendon reflexes, positive Babinski signs, or myalgia. More significantly, 11–20 percent of those infected have VIIth cranial nerve lesions, lower motor neuron lesions, hyperactive deep tendon reflexes, or myoclonus, and progress to coma. Up to 10 percent exhibit convulsions, paresis, photophobia, nystagmus, or ataxia. There is a striking increase in case fatality rates for SLEV infection, depending on age. A fatality rate of approximately 2 percent is observed for young adults, rising to 22 percent for the elderly. Of those infected

with SLEV, approximately 50 percent with fatal disease die within 1 week after the onset of symptoms.

MURRAY VALLEY ENCEPHALITIS

Murray Valley encephalitis virus is the major *Flavivirus* in Australia and Papua New Guinea (Mackenzie et al. 2002a).

Antigenically, it is closely related to both JE and SLE viruses. In a number of respects the clinical presentation of patients suffering from MVE is similar to that of JE infection. Clinically, the disease begins with a prodrome of fever, headache, photophobia, myalgia, nausea, and vomiting. There are often early signs of CNS involvement that include drowsiness, speech difficulties, disorientation, and ataxia. Patients who do not progress to coma generally have a favorable prognosis, but may display sequelae including tremors, incontinence, stiffened limbs and neck, and speech impediments. Patients who enter coma often develop respiratory paralysis, necessitating mechanical aid for breathing. Fatalities are usually the result of secondary infection or extensive brain destruction, accompanied by decerebrate rigidity.

TICK-BORNE ENCEPHALITIS

The tick-borne encephalitis (TBE) complex of the family *Flaviviridae* comprises 14 antigenically related viruses, eight of which are significant human pathogens (Heinz et al. 2000). The two most important are Russian spring–summer encephalitis (RSSE) and Central European encephalitis (CEE). These differ in pathogenicity, the former being associated with much higher rates of morbidity and mortality.

RSSE is characterized by a gradual onset following 10–14 days' incubation after the transmission of virus from the bite of an infected tick. The patient suffers a prodromal phase of severe headache, nausea, photophobia, weakness, fever, and chills. The body temperature may rise as high as 41°C and the fever lasts 5–7 days. These symptoms are followed by neck stiffness, sensory changes, visual disturbances, and variable neurological dysfunction, including paresis, paralysis, sensory loss, and convulsions (Silber and Soloviev 1946). The more severe cases can develop central paralysis or involve the brainstem or spinal cord, which may lead to bulbospinal or spinal paralysis. In fatal cases death occurs within the first week after onset, with case fatality rates of approximately 30 percent (Gresikova and Beran 1981). Disease is more severe in children than in adults. Recovery from infection is protracted, with neurological sequelae in 30–69 percent of survivors, manifested by residual flaccid paralysis of the shoulders and arms. These sequelae probably reflect permanent damage to neurons.

In comparison to RSSE, infection with CEE subtypes of virus is much milder, with a number of abortive infections. Classically, CEE is a biphasic illness with a prodromal period resembling influenza that either resolves completely or is followed by the sudden onset of encephalitis. Onset of illness is often rapid, with fever, severe headache, photophobia, nuchal rigidity, nausea, and vomiting. Patients who present with brainstem involvement or have ascending paralysis generally have a poor prognosis. Although case fatality rates range between 1 and 5 percent, 20 percent of survivors suffer minor neuropsychiatric sequelae (Radsel-Medvescek et al. 1980). It is interesting that a small percentage of patients who recover from CEE have a progressive chronic encephalitis with remissions and relapses (Silber and Soloviev 1946).

Clinical signs are swelling, congestion, and petechial hemorrhages in the brain, similar to other flavivirus encephalitides. There is also meningeal and perivascular inflammation, with neuronal degeneration and necrosis, neuronophagia, and glial nodule formation in the cerebellar cortex, brainstem, basal ganglia, and spinal cord. Far Eastern subtypes have a tropism for neurons of the gray matter of the medulla oblongata and upper cervical cord. The predominance of lower motor neuron paralysis of the upper extremities, observed in many cases of encephalitis, may be explained by the vulnerability of the anterior horn cells of the cervical cord to virus infection.

Retroviruses

In this section, two neurotropic human pathogenic retroviruses, HIV and human T-lymphotropic virus (also known as human T-cell leukemia virus-1 (HTLV-1)), that cause distinct syndromes affecting the CNS are considered (see also Retroviruses and associated diseases in humans and Human immunodeficiency virus), Both viruses have a prolonged incubation period (average of 8–10 years for HIV, and up to 40 years for HTLV-I-associated myelopathy). Some similarities exist between modes of transmission via the transfer of body fluids containing free virus or, more often, infected cells. HIV and HTLV-I both have a primary tropism for lymphocytes.

HIV-ASSOCIATED DEMENTIA

Exactly how HIV gains access to the CNS is unknown. In early acute infections HIV can be detected as free virus in the CSF of patients with no apparent neurological disturbances. Crossing of the BBB is believed to occur through passage of the virus in infected peripheral blood macrophages or activated T cells (Gartner 2000; Patrick et al. 2002). In the brain, HIV infects mainly microglial cells. Additional evidence points to possible infection of brain capillary endothelial cells, which are CD4-negative, but chemokine receptor and SIGNR-positive (Mukhtar et al. 2002; Soilleux et al. 2002). Furthermore, galactosylceramide (GalC) has been proposed to fulfill a receptor function in brain-derived

cells (Harouse et al. 1991). Differences in tropism between strains of HIV could be demonstrated. In general, macrophage-tropic strains replicate more efficiently in cells of neural origin than strains of a T-cell tropic nature.

AIDS itself is often characterized by a high prevalence of marked and extensive neurological disturbances. In numerical terms, it is suggested that as many as 80 percent of AIDS patients will have neuropathological abnormalities at postmortem, and that as many as half of these will have suffered neurological disturbances prior to death. Transient neurological disturbances can also be detected at the time of seroconversion, and may include aseptic meningitis (characterized by headache, fever, and cellular pleocytosis of the CSF), acute encephalopathy, and myelopathy. All these disturbances are usually self-limiting during early infection. As HIV infection progresses to AIDS a new spectrum of neurological complications may emerge, which are globally described as the AIDS dementia complex or HIV-associated dementia (HAD) (Cortegis 1994). The primary stages of HAD show mild impairment of memory, as well as loss of concentration and the ability to process information. Symptoms may then progress to severe cognitive dysfunction and possibly paralysis. Morphologically, features associated with HAD include either a diffuse leukoencephalopathy with severe reduction in myelin, or areas of discrete demyelination and multinucleated giant cells (Figure 6). Clinically, HAD is suspected in AIDS patients presenting with memory loss, disturbances in concentration, depression, and motor complaints. Specific afflictions associated with HAD include peripheral neuropathy, cerebral tumors, and vascular lesions. Peripheral neuropathies are often observed in severely immunosuppressed patients who present with painful paraesthesiae. These are due to axonal degeneration of small myelinated and unmyelinated fibers as a result of exposure to toxic factors (see below). It is interesting to note that the inflammatory neuropathies, including demyelinating polyneuropathy, are identical in clinical course to Guillain–Barré syndrome or chronic inflammatory demyelinating polyneuropathy (Cornblath et al. 1987; Tyor et al. 1995). In the latter condition the nerves show perivascular lymphocytic and monocytic infiltrates, believed to be mediated by T cells and macrophages. Cerebrovascular

The hallmark of HIV leukoencephalopathy is diffuse reduction of myelin stain in the central white matter.* **(b)** *Whole mount of the cerebellum of the same patient. Leukoencephalopathy is evident in the deep cerebellar white matter.* **(c)** *High-power micrograph of HIV leukoencephalopathy, showing loss of myelin and typical multinucleated giant cells (arrows) (×200).* **(d)** *Immunostaining of a multinucleated giant cell for the HIV protein p24, showing granular immunoreactivity (arrows) (×400). (Courtesy of Dr Adriano Aguzzi.)*

complications such as vasculitis and hemorrhages are often found in areas of cerebral tumor or demyelination. Hemorrhages may occur as a result of alterations in coagulation (Snider et al. 1983).

Mechanism of CNS disturbances in neuro-AIDS

Despite the observation that HAD is associated with HIV infection of microglia/macrophages, the number of HIV-infected cells and the amount of viral antigen in the CNS do not correlate well with measures of cognitive decline (Glass et al. 1995). Direct viral infection of susceptible cells of the CNS may induce syncytia formation, producing multinucleated giant cells. Multinucleated giant cells are usually formed by macrophages or microglial cells and are considered a hallmark of subacute encephalitis in HIV-infected brains and spinal cord, but not in peripheral nerves (Cornblath et al. 1987) (Figure 6). As only a restricted number of cells of the CNS are susceptible to infection by HIV, secondary mechanisms of cellular injury are paramount in producing neurological disturbances in AIDS patients.

The release of neurotoxic soluble factors by cells in response to viral assault or to binding of virus proteins is an important facet of the disease process of HIV.

Infection of monocytes or macrophages by HIV is known to stimulate the synthesis and release of a number of cytokines, including chemokines, IL-1β, TNF-α, interferons, and nitric oxide (NO) (Garden 2002; Ryan et al. 2002; Wang et al. 2002). Possibly the most notable change associated with HIV dementia with AIDS is the upregulation of TNF-α. TNF-α levels were higher in patients with advanced dementia and those with multinucleated giant cells or diffuse myelin pallor (Wilt et al. 1995). The release of cytokines makes the BBB more permeable to inflammatory cells, which may then infiltrate the CNS to establish additional neurological sequelae. Although significant levels of quinolinic acid have been reported in the CNS of HIV-1 seropositive patients, whether there is a direct causal relationship with the observed neurological findings remains questionable. Induction of TGF-β by macrophages and astrocytes has also been linked to CNS disorders (Wahl et al. 1991). Studies examining levels of specific chemokines in patients with HAD have shown that β-chemokines (RANTES and MIP-1α) are elevated in the CSF of patients, but higher levels were associated with the preservation of cognitive function (Letendre et al. 1999). Microglia also release excitatory amino acids and related substances that most likely contribute to the neuronal disfunction in HAD, including glutamate, quinolinate, L-cysteine, and the amine Ntox (Garden 2002). These substances can induce N-methyl-D-aspartate (NMDA) receptor-mediated neuronal apoptosis.

Autoimmunity is also thought to be important in the process of HIV-induced neurological disease, and may be based on the partial identity between viral antigens and antigenic determinants on cells (i.e. molecular mimicry). An autoimmune process was proposed following the observation that small demyelinated regions of the brain seem similar to those in post-infectious encephalomyelitis or experimental allergic encephalitis (Kumar et al. 1989). AIDS patients with peripheral neuropathy have autoantibodies to an unidentified protein on the surface of neurons. In addition, fluorescence studies have shown antibody attached to the perineurium in tissues from AIDS patients. AIDS patients suffering from peripheral neuropathy who undergo subsequent plasmapheresis obtain relief of symptoms similar to that observed in the autoimmune conditions of Guillain–Barré syndrome and thrombocytopenic purpura. Autoantibodies to peripheral nerves are associated with peripheral neuropathy. A likely target in the nervous system is the myelin sheath of nerves. Antibody levels to myelin basic protein have been described in CSF of AIDS patients that correlate directly with the severity of dementia (Liuzzi et al. 1994). Cross-reactivity of anti-gp41 antibodies with certain proteins of astrocytes could compromise the function of these cells. Moreover, cross-reaction of anti-V3 antibody with human brain proteins may also be an important part of the pathogenic process. Further brain-reactive proteins in the sera of infected patients may lead to immune complex disease.

A number of HIV products (e.g. gp120) are toxic to cultured human brain cells in vitro. NMDA antagonists have been shown to reduce toxic effects attributed to gp120 interaction (Lipton et al. 1991). The same viral protein can also affect the permeability of the cell membrane, leading to ion influx/efflux and loss of electrical potential. Inhibitors of the p38 MAP kinase have been shown to abrogate neuronal apoptosis due to HIV gp120 exposure or α-chemokine (SDF-1) toxicity (Kaul and Lipton 1999). The HIV proteins gp41 and Tat have been shown to be toxic for cultured cells: Tat exhibits some homology with a neurotoxin and induces cellular aggregation and fascicle formation in primary rat cortical brain cells (Garry and Koch 1992). In addition, Tat may induce differentiation of these cells (Kolson et al. 1993). The clinical relevance of these findings, however, remains unclear. When discussing HIV infection, it is also important to consider that neurotropic effects may reflect infection with an additional agent. A number of studies have shown the presence of viruses such as *Cytomegalovirus* (Figure 7), or polyomaviruses in the CNS of AIDS patients, and have led to the suggestion that secondary infections are the primary cause of neurological disturbances.

HTLV-I ASSOCIATED MYELOPATHY/TROPICAL SPASTIC PARAPARESIS

Human T-lymphotropic virus type I infects 10–20 million people worldwide, and is endemic in southern Japan, the

Caribbean, Central and South America, the Middle East, Melanesia, and equatorial regions of Africa.

HTLV-I was established as an etiologic agent of acute T-cell leukemia (ATL). A correlation between tumor cells and a monoclonal or oligoclonal pattern of viral genome integration, infection of lymphocytes in vitro resulting in immortalized T cells, and the establishment of HTLV-I oncogenic animal model systems has been reported (Cann and Chen 1990). In 1985 it was discovered that a number of HTLV-I-seropositive patients in the Caribbean and Japan were suffering from a chronic myelopathy. Since then, increasing evidence has accumulated linking HTLV-I infection with what is now termed HTLV-I-associated myelopathy (HAM) or tropical spastic paraparesis (TSP), collectively known as HAM/TSP, which is developed by 0.25–3 percent of virus carriers (Jacobson 2002).

HAM/TSP presents as a clinical disease very distinct from ATL. The disorder is characterized by weakness and spasticity of the extremities, hyperreflexia, peripheral sensory loss, and chronic inflammation. The development of HAM/TSP correlates with the presence of lesions in the white matter of the spinal cord, including demyelination and axonal changes. In the subacute disease there is progressive paralysis of the lower extremities and associated impotence, incontinence, and sensory symptoms, paradoxically often with minimal sensory findings on examination. Lesions are localized primarily in the thoracic spinal cord, with little, if any, cerebral involvement. In cases of late disease, hyalinization of vessels with necrosis and demyelination of the spinal cord, particularly in the throracic region, is observed. Because many patients are infected through breastfeeding from infected mothers or via sexual transmission, the virus is thought to be transmitted by infected lymphocytes. The incubation period is particularly long, with onset often in the fourth or fifth decade of life.

Gross examination of the brain reveals no apparent abnormalities, although the majority of cases exhibit severe loss of myelin and atrophy of the spinal cord, and some thickening of the meninges. These clinical findings are associated with HAM/TSP patients with a long history of illness, whereas in cases with a clinical history of 1 year or less the spinal cord often seems normal (Fukura et al. 1989). The major finding in HAM/TSP cases is a chronic inflammatory process, with perivascular infiltrates involving the gray and, more often, the white matter of the spinal cord. Numerous inflammatory cells, including $CD4^+$ and $CD8^+$ T cells, B cells, and foamy macrophages, are present in damaged areas of the spinal cord parenchyma (Wu et al. 1993). Later in the disease, immunohistochemical analysis of the affected lesions shows the predominance of $CD8^+$ T cells (Umehara et al. 1993). HTLV-I sequence analysis of PBMCs of HAM/TSP patients demonstrates a pattern of polyclonal integration, in contrast to an oligoclonal or monoclonal pattern associated with ATL patients. Most HAM/TSP patients have higher titers of anti-HTLV-I antibodies than do asymptomatic HTLV-I patients. The amount of proviral DNA in HAM/TSP patients correlates with the number of CTL. HTLV-I-specific sequences have been localized to astrocytes in affected areas of the CNS (Lehky et al. 1995). An autoimmune basis for HAM/TSP has been proposed after the isolation of circulating MHC class I-restricted CTLs from HAM/TSP patients. The CTLs show specific activity against a nine amino acid peptide of the HTLV-I tax protein, and are restricted to the HLA-A201 haplotype (Elovaara et al. 1993; Koenig et al. 1993). The presence of HTLV-I-specific CTL correlates with the production of several cytokines and chemokines, such as IFN-γ, TNF-α, IL-2, MIP-1α/β, and matrix metalloproteinases (Biddison et al. 1997; Kubota et al. 1998; Giraudon et al. 2000). In HLA-A201 patients the increased HTLV-I proviral DNA loads in CSF in comparison to PBMC were propotional to the frequency of tax-specific $CD8^+$ T cells. This observation supports the hypothesis that the HTLV-I proviral load may drive the increased virus-specific immune responses that have been suggested to be immunopathogenic in HAM/TSP (Soldan 2001). The

data led to the following immunopathogenesis model of HAM/TSP: processing and presentation of HTLV-I-specific peptides in association with high proviral loads and viral protein expression in $CD4^+$ and $CD8^+$ T cells may lead to the activation and expansion of antigen-specific T-cell responses in the CNS. Numbers of inflammatory $CD8^+$ T cells in the spinal cord lesions of HAM/TSP patients tend to increase with disease progression, and together with inflammatory cytokines and chemokines, immunopathogenesis may be enhanced.

To help in understanding the disease process involved in HAM/TSP, an animal model using Wistar–King–Aptekman (WKA) rats has been developed in which the characteristics and distribution of lesions in the rat CNS are similar to those observed in human cases (Ishiguro et al. 1992; Kasai et al. 1999). After an icubation period of approximately 15 months the rats develop a chronic progressive myelopathy with paraparesis of the hind limbs. HTLV-I proviral DNA was localized in some microglia/macrophages in spinal cord lesions. In addition, provirus was evident not only in ED-1-negative lymphoid cells, but also in ED-1-positive macrophages from lymph nodes. These infected microglia/macrophages may relate to cause the myeloneuropathy through neurotoxic cytokine synthesis. The expression of the antiapoptotic gene *bcl-2* was strongly downregulated in oligodendrocytes of infected rats. This may increase the susceptibility to TNF-α-induced apoptosis of oligodendrocytes and result in the development of the characteristic disease (Jiang et al. 2000).

Paramyxoviruses

The two paramyxoviruses frequently liable to cause CNS diseases are mumps and measles viruses, both members of the subfamily *Paramyxovirinae*.

MUMPS VIRUS INFECTIONS OF THE CNS

Mumps is a highly communicable and generally self-limited infection caused by mumps virus (MuV). It occurs in epidemics among susceptible school-aged children and is characterized clinically by nonsuppurative salivary gland enlargement. Although parotitis is the most obvious manifestation, mumps is clearly a systemic infection that can involve virtually all organs, including the CNS. Indeed, CNS involvement during acute mumps infection occurs with such high frequency that it should be considered a primary manifestation, rather than a complication. The spectrum of CNS infections caused by mumps virus ranges from aseptic meningitis, which is very common but usually mild, to fulminant encephalitis, which is very rare but potentially fatal. The term 'mumps meningoencephalitis' is often used to designate overlap syndromes that have features of both these typical forms. Mumps vaccine has successfully been used by many countries, and high coverage has shown a rapid decline in mumps morbidity (Galazka et al. 1999).

Mumps is a highly contagious infection that is transmitted from human to human (the only known natural host) by droplets. Infected individuals may transmit the virus for about 10–16 days. During the incubation period (which averages 18 days), primary viral replication takes place in epithelial cells of the upper respiratory tract, followed by spread of the virus to regional lymph nodes and subsequent viremia, with systemic dissemination.

Symptomatic CNS involvement occurs in 10–20 percent of cases (Russell and Donald 1958; Galazka et al. 1999). The vast majority of cases of CNS MuV infections are uncomplicated aseptic meningitis, whereas symptomatic encephalitis occurs in >0.1 percent of cases (Klemola et al. 1965; Levitt et al. 1970). The incidence of CNS inflammation as evidenced by pleocytosis in the CSF (observed in only 60 percent of cases) is actually much higher than the incidence of clinical meningoencephalitis (Bang and Bang 1943).

Although differences in neurotropism among MuV isolates have been demonstrated in animal models, there is no direct evidence that cases of human mumps encephalitis are caused by virus strains with enhanced neurotropism or virulence.

Patients with symptomatic mumps CNS infection most often present with fever, vomiting, and headache. Other frequent findings include nuchal rigidity, lethargy, and abdominal pain (possibly from pancreatitis). Defervescence is usually the first sign of clinical recovery, which is normally complete within 7–10 days. Patients with simple mumps aseptic meningitis have signs of meningeal irritation, however, with normal cortical function. Cases of mumps encephalitis present with seizures, markedly depressed levels of consciousness, and focal neurological signs. Typical findings also include psychiatric disturbances, lethargy, and stupor. CNS symptoms appear about 5 days after the onset of parotitis, although they may accompany or even precede the development of salivary gland enlargement. No association between the parotitis and the frequency or severity of CNS manifestations has been established. Other neurological manifestations of mumps include myelitis and polyneuropathy.

Confirmation of CNS involvement in patients with mumps is based on examination of the CSF. CSF findings do not differ significantly between mumps patients with meningitis and those with encephalitis. MuV can be isolated from CSF in 30–50 percent of patients with CSF pleocytosis (Björvatn and Wolontis 1971; Wolontis and Björvatn 1973). The spinal fluid opening pressure is normal. Infiltrating cells are predominantly lymphocytes, but significant amounts of polymorphonuclear leukocytes may be seen in the early stages of infection. CSF pleocytosis resolves slowly, and complete normalization of the spinal fluid may require several weeks (Azimi et al. 1975). No correlation has been established

between the magnitude of the CSF pleocytosis and the severity of clinical illness.

MuV spreads readily to the CNS, either as free plasma virus or within infected mononuclear cells (Fleischer and Kreth 1982). Initially, viral replication occurs in choroidal epithelial cells, with shedding of progeny virus into the CSF (Herndon et al. 1974). The development of mumps encephalitis probably results from a direct extension of the virus from ependymal cells into neurons within the brain parenchyma, as has been demonstrated in experimentally induced mumps encephalitis in hamsters (Wolinsky et al. 1974). Because of the low case:fatality ratio, autopsy reports describing the pathological findings in mumps meningoencephalitis are rare and variable (reviewed in Gnann 1991). Histological changes are seen in the white matter of the cerebral hemispheres and cerebellum, and in the white and gray matter of the brainstem and spinal cord. The most commonly recorded features are diffuse edema of the brain, limited mononuclear cell infiltration of the meninges, perivascular infiltration with mononuclear cells, glial cell proliferation, focal areas of neuronal cell destruction, and localized demyelination. A few cases of purported chronic mumps encephalitis have been described, but available data are insufficient to support a role for mumps virus in chronic CNS infection (Ito et al. 1991).

MEASLES VIRUS INFECTIONS OF THE CNS

Measles virus (MV) is a highly contagious agent that leads to a well-defined acute disease in unvaccinated individuals, followed by seroconversion and a lifelong immunity against reinfection. As hallmarks of acute measles, a transient, marked lymphopenia and immunosuppression are observed which favor the establishment and fatal outcome of opportunistic infections, and are the main reasons for the annual death toll of approximately 1 million children worldwide, particularly in developing countries (Clements and Cutts 1995; Schneider-Schaulies and ter Meulen 2002). Before the advent of vaccination, approximately 8 million deaths were due to measles annually. Vaccination protects not only from complications such as otitis media, pneumonia, and diarrhea, but also from acute and subacute encephalitis (Duclos and Ward 1998). Patients with a history of acute measles develop a lifelong immunity.

MV infections have also been linked etiologically to the establishment of CNS disease processes that include an early acute measles encephalitis and two late complications: subacute sclerosing panencephalitis and measles inclusion body encephalitis (MIBE). Moreover, some studies have suggested a pathogenic role of MV for other disease processes, including multiple sclerosis (ter Meulen and Katz 1997), chronic liver disease (Robertson et al. 1987; Andjaparidze et al. 1989), Paget's disease (Basle et al. 1986), otosclerosis (McKenna and Mills 1989) and, more recently, Crohn's disease (Wakefield et al. 1993). However, none of these diseases has been linked unequivocally to measles virus.

Acute measles encephalitis

CNS involvement in the course of measles is fairly common, as EEG and CSF changes are found in half of all patients with acute measles (Gibbs et al. 1959; Reinicke et al. 1974). Acute encephalitis is observed in 0.5–1 per 1 000 cases (Katz 1995). In general, about 15 percent of cases are fatal, and 20–40 percent of those who recover are left with lasting neurological sequelae. Encephalitis usually develops within about 8 days after the onset of measles. Occasionally, it may also occur during the prodromal stage. Measles encephalitis is characterized by a resurgence of fever, headache, seizures, cerebellar ataxia, and coma. As is commonly seen in postinfectious encephalitis induced by other viruses, demyelination, perivascular cuffing, gliosis, and the appearance of fat-laden macrophages near the blood vessel walls are detectable histopathologically. Petechial hemorrhages may be present, and in some cases inclusion bodies have been observed in brain cells. CSF findings in measles encephalitis usually consist of mild pleocytosis and the absence of MV-specific antibodies. Long-term sequelae include selective brain damage, with retardation, recurrent convulsive seizures, hemiplegia, and paraplegia. It is not entirely clear what pathogenic role MV plays in the development of acute measles encephalitis. MV has been occasionally recovered from CSF samples (McLean et al. 1966) and brain tissue of patients (ter Meulen et al. 1972; Ogura et al. 1997), including the detection of MV-specific nucleic acids by PCR techniques (Nakayama et al. 1995). Because there is no evidence that MV is regularly present in the nervous system, and because there is an aberrant immune reaction to brain antigens, acute measles encephalitis is considered an autoimmune disease (Griffin 1995).

Measles inclusion body encephalitis

MIBE has been recognized only recently and is confined to immunosuppressed children with, for example, leukemia undergoing axial irradiation therapy. The incubation period ranges from weeks to several months. The condition commences with convulsions, myoclonic jerks as seen in SSPE. The seizures are often focal and localized to one site; other findings include hemiplegia, coma, or stupor. However, the disease course is more rapid than that of SSPE, and proceeds to death within weeks or a few months. Characteristically, no or only low titers of MV-specific antibodies are mounted in the serum and CSF of patients.

Subacute sclerosing panencephalitis

SSPE is a rare, fatal, slowly progressive degenerative disease of the CNS. It is generally seen in children and young adults aged 5–15 years after acute measles, with an incidence of approximately 1 in 100 000 cases – after infection with wildtype virus, and not after vaccination (Duclos and Ward 1998). Boys are more likely than girls to develop SSPE, and half the patients have contracted measles before the age of 2 years. No unusual features of acute measles have ever been demonstrated. The course of SSPE is variable and usually starts with a generalized intellectual deterioration, which may last for weeks or months, until definite neurological signs or motor dysfunctions such as dyspraxia, generalized convulsions, aphasia, visual disturbances, and mild repetitive simultaneous myoclonic jerks appear. Viral invasion of the retina leads, in 75 percent of cases, to a chorioretinitis, often affecting the macular area, followed by blindness. Finally, the disease proceeds to progressive cerebral degeneration, leading to coma and inevitable death. The illness generally lasts for 1–3 years, but more rapid forms have been described. Neuropathological findings include a diffuse encephalitis affecting both the gray and the white matter, characterized by perivascular cuffing and diffuse lymphocytic infiltrations. Gliosis is usually observed. Neurons, oligodendroglial cells, fibrous astrocytes, and endothelial cells contain large aggregates of intranuclear inclusion bodies that contain MV nucleocapsid structures, visible on immunohistological examination (Allen et al. 1996). Giant cell formation or membrane changes consistent with virus maturation have not been detected.

Characteristic EEG changes are usually the first diagnostic hint and are regarded as characteristic and even pathognomonic for SSPE. They consist of periodic high-amplitude slow-wave complexes that are synchronous with myoclonic jerks recurring at 3.5–20-second intervals. These periodic complexes (Radermecker) are remarkably stereotypical in an individual patient, in that their form remains identical in any given lead. They are bilateral, usually synchronous, and symmetrical. Moreover, they usually consist of two or more δ waves and are biphasic, triphasic, or polyphasic in appearance. This EEG pattern, however, is variable within the course of the disease and from one patient to another, and may disappear as the disease progresses. Other important pathognomonic findings are the very high titers of measles antibodies in serum – except those against the M protein – and a pronounced increase in the γ-globulin in the CSF. In the CSF, the humoral immune response is oligoclonally restricted, as revealed by isoelectric focusing (Dörries and ter Meulen 1984). This indicates that antibodies are synthesized intrathecally by a restricted number of plasma cells that have invaded the CNS.

VIRUS–HOST INTERACTIONS

Acute MV infections are characterized by the marked tropism of the virus for PBMCs, including lymphocytes, monocytes/macrophages, and dendritic cells (Borrow and Oldstone 1995; Ohgimoto et al. 2001). The virus is present in a highly cell-associated form and is efficiently spread via infected PBMCs, in which both viral nucleic acid and proteins can easily be detected and from which infectious virus can be recovered. Subsequently, endothelial cells and underlying tissue in various organs are infected. Infected PBMCs have been proposed as potential carriers, but have not been positively identified. Exactly how and when the virus reaches the brain in SSPE is not known. Some PCR-based studies described MV-specific nucleic acids in autopsy brain material obtained from patients with no history of measles-associated CNS illness (Katayama et al. 1995), suggesting that persistent MV infections of the brain may be more frequent than initially thought and may stay clinically inapparent throughout life. It is also not known which cellular receptors mediate the infection of neural cells, as the known receptors – CD150 for wildtype and vaccine MV (Tatsuo et al. 2000; Erlenhoefer et al. 2001) and CD46 only for vaccine strains (Dörig et al. 1993; Naniche et al. 1993) – owing to their cell type-specific expression, are not sufficient to explain the CNS infection (Ogata et al. 1997; McQuaid and Cosby 2002). Virus spread in the brain occurs directly from cell to cell, most likely involving local microfusion events (summarized in Schneider-Schaulies et al. 2001).

No specific defects of cell-mediated immunity have been detected in SSPE, yet in both CNS diseases, SSPE and MIBE, large amounts of MV nucleocapsid structures are present within infected cells (ter Meulen et al. 1983). However, rescue of infectious virus in tissue culture is rarely possible (Ogura et al. 1997), indicating that the viral replication cycle is defective. As with other persistent infections, MV gene expression is markedly restricted during persistence. Viral envelope proteins are generally expressed at extremely low levels, whereas internal proteins required for intracellular viral reproduction (N, P) can be detected easily. As characterized mainly in autopsy material, this is generally achieved by particular restrictions of the viral envelope-specific mRNAs (M, F, and H), and by mutations within the envelope-specific genes that interfere with a functional expression of the corresponding proteins (reviewed in Billeter et al. 1994) (summarized in Figure 8). It is significant for the pathogenesis that mutations introduced into the envelope gene reading frames are of two types: point mutations, caused by the naturally high infidelity of the viral polymerase during transcription/replication, and clustered hypermutations, ascribed to a cellular unwinding/modifying enzyme complex. Functional alterations or complete abolition of the MV envelope proteins seem to readily explain why the

formation of infectious virus particles, viral budding, and the formation of giant cells are not encountered in persistent MV CNS infections (Cathomen et al. 1998). Moreover, important antigenic structures are mainly lacking on the surface of infected cells, which thus escape detection by the MV-specific humoral immune response.

Although it is not understood what triggers the development of a MV CNS disease, some progress has been made in understanding which factors lead to and maintain the establishment of a persistent MV infection in brain cells. Increasing evidence suggests that MV that infects brain cells is primarily nondefective, and that host factors initially attenuate viral gene expression on both transcriptional and translational levels (reviewed by Schneider-Schaulies et al. 1994). In addition, MV-specific double-stranded RNA intermediates, as formed accidentally during viral transcription and replication, serve as targets for a cellular enzyme (dsRNA adenosine deaminase activity (DRADA)) present in large amounts in brain cells in vitro. This enzyme introduces up to 50 percent of nucleotide transitions within a given double-stranded target RNA, thus profoundly altering the coding sequences (Billeter et al. 1994) (Figure 9, p. 33). There is still, however, some controversy about whether mutations within the viral genome are a prerequisite for the establishment of persistent MV infection in brain cells, whether mutant viruses have a selective advantage in replication and spread in the brain, or if mutations are important for the long-term maintenance of MV persistence. The last possibility is weakened by the high variability of the mutations encountered in individual patients with SSPE and MIBE, and also by the finding that, at least in an animal model, persistent MV CNS infections have been established in the absence of detectable mutations. In summary, the IFN response and its possible lack in neurons, a steep viral expression gradient, the accumulation of point and hypermutations within envelope genes, the antibody-induced antigenic modulation, and the observed cell-to-cell spread of nucleocapsids support the persistent brain infection, with failure of the immune response to eliminate the virus (for review see Schneider-Schaulies et al. 1995).

In newborn rodents the hamster neurotropic strain HNT, or the rat brain-adapted MV strain CAM/RB, spread efficiently, causing an age-dependent lethal acute encephalitis or subacute encephalitis (for review see Liebert and Finke 1995). Resistance and susceptibility to MV-induced encephalitis correlate with the MHC haplotype of the respective inbred strain. In resistent mouse strains depletion of the $CD4^+$ T cell subset by mAb led to a breakdown of resistance, whereas depletion of $CD8^+$ T cells had no effect. A breakdown of resistance is also observed after neutralization of IFN-γ, leading to the generation of a Th2 response. Further investigation of this measles encephalitis model revealed that $CD4^+$ T cells are able to protect either alone (resistant mice), through cooperation with $CD8^+$ T cells (intermediate susceptible), or after immunization as secondary T cells (susceptible mice), and $CD8^+$ T cells are able to protect alone after immunization if they are cytolytic (Weidinger et al. 2000). As found earlier in nontransgenic mice, IFN-γ has also a critical role in the protection of CD46-transgenic mice against MV encephalitis (Patterson et al. 2002). Interestingly, this protection functions in a noncytolytic manner without neuronal loss.

CONCLUSIONS AND OUTLOOK

The observation that viruses can induce slowly progressive neurological diseases with diverse pathologies has led to speculations that other neurological diseases of unknown cause may have a viral etiology, the prime candidate being multiple sclerosis. This potential, together with epidemiological, neuropathological, immunological, and clinical findings, has encouraged extensive virological studies in pursuit of relevant infectious agents. Although several claims have been made for viruses isolated from multiple sclerosis patients, no infectious agent has yet been linked to the disease. Other diseases, such as amyotrophic lateral sclerosis, continuous focal epilepsy, or Alzheimer's disease, also reveal certain features that would be compatible with a viral infection. Recently, borna disease virus, which has been linked to a variety of neurological diseases in several animal hosts, has also been associated with certain psychiatric disorders in humans, such as schizophrenia and manic depression. No direct evidence is yet available to support the possibility that viruses cause these diseases, but their involvement cannot be ruled out.

A better understanding of the pathogenesis of viral CNS infections is a prerequisite to obtaining new and more effective means of prevention. However, each virus has different protection requirements. On the other hand, neurotropic virus infections also offer interesting possibilities for studying the structure and function of the nervous system, as in studies using neurotropic rabies or HSV for tracing neural pathways (Kruypers and Ugolini 1990). Moreover, neurotropic viruses are also used as vehicles to bring foreign genes to the CNS. Gene therapy approaches have been used in animal experiments to reduce tumor growth in brain tissue (Tapscott et al. 1994). It is therefore conceivable that a controlled viral infection of the CNS might be used for the selective expression of, for example, pharmacological agents or neurotransmitters in order to influence functional aspects of the CNS. Thus, studies of viral infections of the CNS offer new perspectives, leading to a better understanding of the pathogenesis of disease.

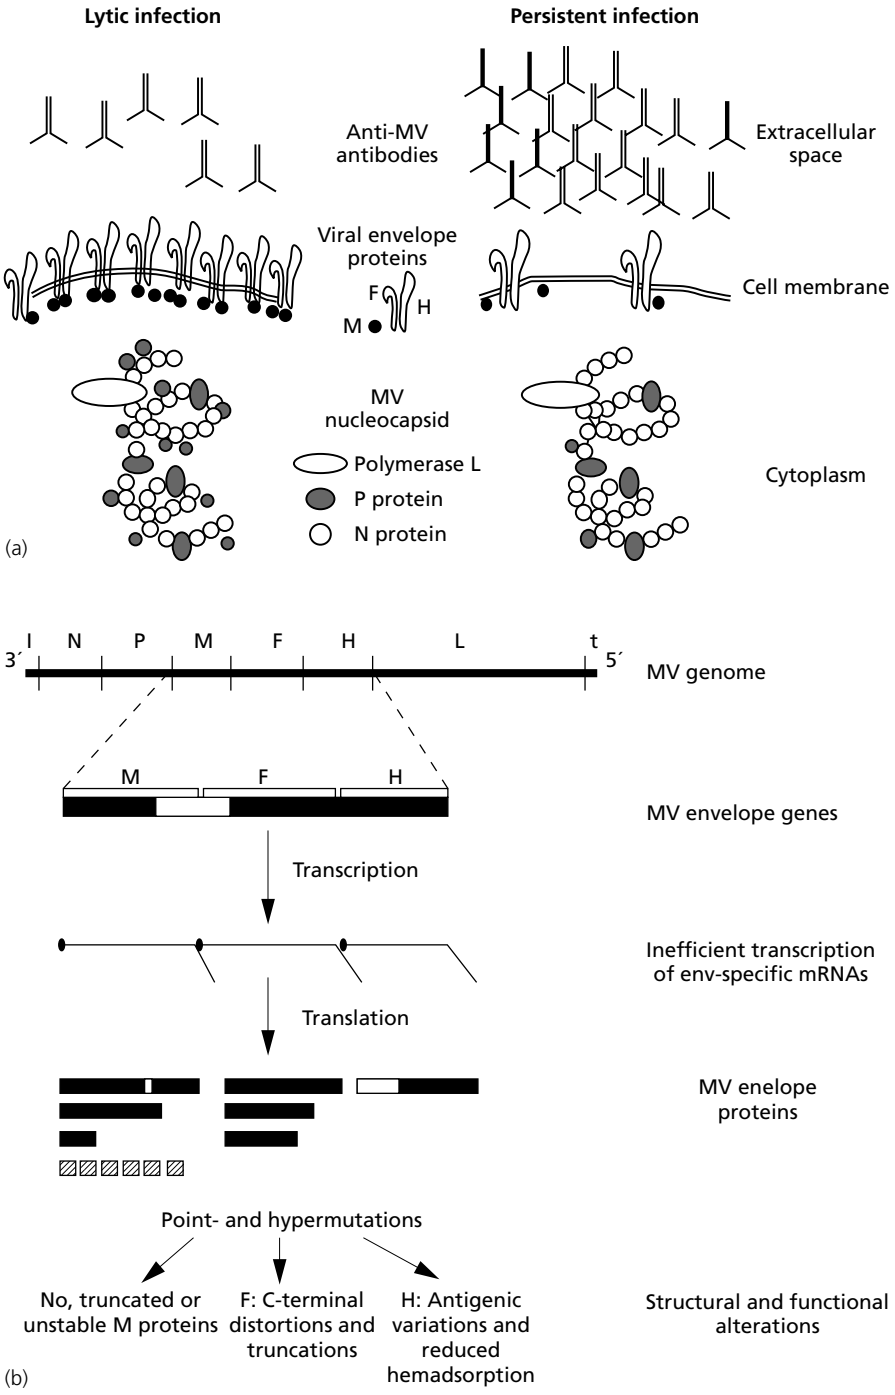

Figure 8 *Mechanisms of Measles virus persistence in the human CNS.* **(a)** *During acute infection the viral ribonucleocapsid particle (RNP) consisting of the genomic RNA encapsidated by the N protein and the transcriptase complex (L and P proteins) is amplified intracellularly. Concomitantly, the viral glycoproteins F and H (expressed as complexes) are expressed at the surface of the infected cell, with the M protein underlying their integration sites. In persistent infections the RNP structures are easily detected in large amounts in the cytoplasm (and the nucleus) of the infected brain cell. The expression of both the glycoproteins and the M protein is generally low or even absent. Pathognomonic for SSPE, a humoral hyperimmune reaction to viral antigens (mainly to N and H protein) is observed both in CSF and in serum.* **(b)** *The structural genes of MV are encoded in a linear arrangement along the MV genome: l represents the leader, t the trailer region that contains the viral promoter sequences and encapsidation sites. In persistent infections, the expression of the MV envelope genes* M, F, *and* H *(shown enlarged, the white region indicates a 1-kb noncoding region separating the* M *and* F *reading frames) is greatly reduced by different mechanisms: (1) the frequency of the corresponding mRNAs is very low, and (2) their reading frames are more or less affected by mutations that lead to complete abolition or truncated or distorted expression of the corresponding gene product. Most mutations have been encountered within the* M *gene, and all F proteins characterized so far have truncated C termini. Both point mutations (introduced by the viral polymerase) and hypermutations (clustered transitions most probably introduced by a cellular enzyme complex; see Figure 9) have been described.*

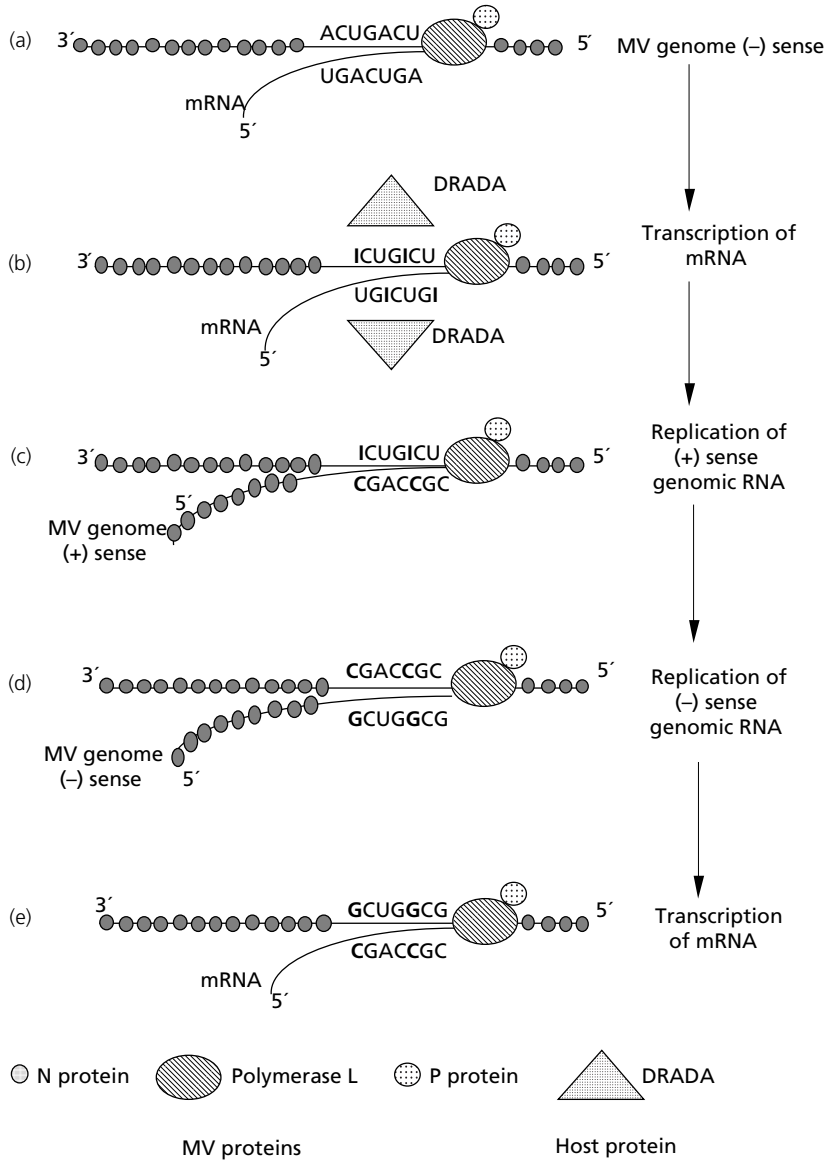

Figure 9 *DRADA (dsRNA adenosine deaminase activity): a cellular enzyme altering viral sequences. DRADA, initially detected and described in vitro in extracts of frog oocytes, is able to introduce clustered transitions into dsRNA structures both in vivo and in vitro. Increasing evidence suggests that unencapsidated viral dsRNAs (step a), accidentally formed during transcription/replication of negative-strand RNA viruses, may serve as targets for this cellular enzyme activity (step b) that deaminates adenosine (A) to inosine (I) residues. During replication of the positive-strand genome a cytidine (C) residue will be introduced instead of the expected uridine (U) into the positive-strand intermediate (step c); upon replication of this altered (+) genome, G will be introduced into the (–) genomic RNA (step d), which will in turn lead to the introduction of C into the mRNA (step e), replacing the initial U (step a). Although DRADA is mainly found in the nucleus, some activity has been consistently detected in the cytoplasm, in particular of neural cells.*

INTRODUCTION

General factors in transmission of infection

The virus infections that may be transmitted from the mother during gestation or perinatally to the fetus or neonate are listed in Table 1. The importance of the various infections depends both on the frequency of maternal infection in the epidemiological situations prevailing in different geographic areas and on the frequency and seriousness of the infections in the embryo, the fetus, and the neonate. In this chapter, the various infections with known consequences for the fetus and infant are discussed more in order of importance than on a taxonomic basis. Details of the viruses themselves are given in their respective chapters in this volume. Virus infections in pregnancy with possible or suspected consequences for the fetus and infant (measles virus, mumps virus, Epstein–Barr virus, influenza a virus, human herpesvirus 6, human herpesvirus 7, and human herpesvirus 8, molluscum contagiosum virus, hantavirus, denguevirus, adenovirus, human respiratory syncytial virus, West Nile virus, TT virus, SEN virus) cannot be discussed on account of shortage of space. Full description of infections in pregnancy is published elsewhere (Enders 2005).

Transmission of a virus to the products of conception may occur within the uterus (congenital or prenatal infection), and during delivery or shortly thereafter (perinatal infection) (Table 2). Some viruses are transmitted only when the mother has an acute primary infection in pregnancy, others from chronically infected mothers. All such infections can be transmitted if maternal primary infection occurs shortly before delivery.

In pregnancy, the immune response is modified by a shift towards a Th2-type profile, which is associated with immunological tolerance (Reinhard et al. 1998). It has been hypothesized that this allows protection of the fetal allograft but may also influence the immune defense against microorganisms (Wegmann et al. 1993). However, data from animals and humans fit the Th1/Th2 concept, but newer results (e.g. the role of NK cells) suggest that the Th1/Th2 paradigm in pregnancy is an oversimplification and the situation is more complex (Chaouat et al. 2004).

In certain viral infections, though with some exceptions, the presence of antibodies in the female before conception protects both her and the fetus against infection and disease. In the presence of certain vaccine-acquired antibodies (e.g. rubella, measles, mumps, varicella) silent reinfection of the mother may occur, but usually without causing infection or disease of the fetus. Antibodies to viruses that establish latent or chronic infection

(e.g. herpesviruses, human immunodeficiency viruses) before conception cannot prevent reactivation or recurrence, with consequent risks of fetal or neonatal infection.

The consequences of maternal infection for the embryo, fetus, or neonate are mainly determined by the gestational age and additional factors, such as the type of virus and its pathogenicity for the developing fetus. In the first few weeks of gestation many organisms may infect the pregnant woman and may lead to death and resorption of the embryo. Therefore the incidence of such infections is not known. The effect of embryonic or fetal infection may be apparent as early as the 6th to 8th week of gestation (WG) (WG 6–8). Infection acquired in utero may result in resorption of the embryo, abortion (until WG 20); intrauterine death (after WG 21); stillbirth (after WG 37); intrauterine growth retardation; prematurity (defined as the birth of a viable infant before the 37th week of gestation); malformation and other systemic abnormalities, and the sequelae of chronic postnatal infection. Signs of disease may be absent at birth, but serious sequelae may become apparent months or years later. Structural defects may occur following early maternal infection at the time of organogenesis (WG 3–8), for example caused by rubella. Maternal infection after WG 9 may lead to systemic abnormalities due to inhibition of organ development. Neonatal disease may also be caused by late intrauterine or perinatal infection.

The total rate of pregnancy loss after implantation due to all causes amounts to 31 percent (Wilcox et al. 1988). In cases with later implantation (>8–10 days after ovulation) the risk of early pregnancy loss markedly increases (Wilcox et al. 1999). Among the factors – mostly of unknown nature – that can affect the outcome of pregnancy, only 5–10 percent are attributable to maternal microbial infections and, of these, approximately 2 percent lead to congenital malformation or systemic abnormalities. These low rates are due to the existence of complex mechanisms of protection. The placenta is a powerful barrier with a wide variety of macrophages and lymphocytes. It allows the transit of maternal IgG, while preventing a large number of infective agents from reaching the embryo or the fetus. Furthermore, cellular immunity develops by the 12th week of gestation when antigen-presenting cells are detectable and the expression of MHC class I and II molecules by a variety of fetal tissues is evident (Lewis and Wilson 2001).

Diagnostic procedures

For the laboratory diagnosis of maternal, intrauterine, and perinatally acquired infections, new techniques for detecting both viruses and their antibodies have become available. The traditional methods for detecting viruses and viral antigens have been replaced or supplemented by detection of specific nucleic acid by various molecular biological techniques, such as the polymerase chain

Table 2 *Transmission of viral infections to embryo, fetus, and neonate*

Transmission	Mode	Time of gestation	Infections
Transovarian	Infected sperm	Early	Seldom: CMV, HIV-1
Intrauterine	Hematogenous transplacental	1st to 39th week	Rubella virus, CMV, parvovirus B19, VZV, coxsackie and echoviruses, HIV-1,[a] HBV,[a] HCV[a]
	Local extension from foci of infection (e.g. ovaries)		
	Ascending from vaginal tract	Late, after rupture of membranes	CMV, HSV, HIV-1
Perinatal	Infected birth canal	Delivery	CMV, HSV, HIV-1, HBV, HCV, HPV
Early postnatal	Breast milk/environment	After birth	CMV, HSV, HBV, HIV-1, HCV?

reaction (PCR). For serology, basic and newly developed supplementary tests are now available. Whether the virological or serological route for diagnosis is pursued depends on the particular agent and on the availability of sensitive and specific assays for detecting it.

Unless stated otherwise, the techniques for diagnosing the various viral infections are the same as those used in nonpregnant people and are described in the relevant chapters in this volume.

Direct tests on the fetus commenced in 1983 (Daffos et al. 1983); the methods include ultrasound screening at low and high levels, detection of fetal infection by identification of the agent in chorionic villi biopsies, amniotic fluid, and fetal blood (Table 3) and by tests for specific IgM/IgA antibodies and cellular immunity in fetal blood. Methods for ensuring the purity of fetal blood samples are essential, and nonspecific biological, biochemical, and immunological factors reflecting fetal functions are also applied (Forestier et al. 1988). The optimal time for chorionic villi sampling (CVS) is at about WG 11, when the risk of spontaneous abortion is lowest. In case of positive results, CVS has the advantage of early decision on further management of the pregnancy, however there is a risk of false-positive results due to contamination with maternal blood still containing the infectious agent. The added risk of fetal complications after amniocentesis is 0.2–1 percent (Hanson et al. 1990; Blackwell et al. 2002; Scott et al. 2002) and the risk linked to fetal blood sampling by experienced teams is 0.5–1 percent in healthy fetuses (Maxwell et al. 1991).

Invasive prenatal diagnosis has been applied to pregnancies complicated by infections with, for example, rubella virus, cytomegalovirus, parvovirus B19, varicella-zoster virus, *Toxoplasma gondii* and *Borrelia burgdorferi* infections (Enders and Jonatha 1987; Daffos et al. 1988; Enders 1994; Hohlfeld et al. 1994; Tercanli et al. 1996; Enders and Miller 2000; Enders et al. 2001, 2004). Prenatal diagnosis has proved helpful in rescuing many unaffected fetuses from being lost by termination of pregnancy.

To interpret the results obtained by tests on the fetus (Table 3), the pathogenicity of the agent for mother and fetus, the time of maternal infection during gestation, and the specificity and sensitivity of the various methods must be considered. The ultrasound findings at high level are of major importance when deciding to continue or terminate a pregnancy. The predictive value of tests on the fetus can be fully estimated only by follow-up investigations: in cases of therapeutic abortion by detection of the virus or other agent in fetal tissue; or, if pregnancy continues, by tests for agents and specific antibodies in the infant.

In pediatric diagnosis, congenital infection can be assumed if either virus or IgM antibodies are detected in samples collected shortly after birth; perinatal or early postnatal infection is diagnosed if tests for virus and IgM antibody were negative soon after birth, but positive in samples obtained 3–4 weeks later (Tables 4 and 5).

It should be remembered that, even though clinically apparent congenital virus infections are infrequent, there are some important ones whose risk can now be reduced by preventive measures (vaccination in childhood and before pregnancy, safe sexual behavior before and during pregnancy, hygienic measures, and for certain infections passive prophylaxis in case of contact or therapy). Great progress has been made in achieving a correct laboratory diagnosis followed by intervention, such as prenatal diagnosis, therapy in utero, e.g. red cell intrauterine transfusion or therapeutic abortion if appropriate. The need and value of the formerly so-called TORCH or STORCH screening (Editorial 1990), now known under the acronym TORCHES-CLAP (*Toxoplasma gondii*, rubella virus, cytomegalovirus,

Herpes simplex virus, enteroviruses, syphilis (*Treponema pallidum*), chickenpox (varicella-zoster virus), Lyme disease (*Borrelia burgdorferi*), acquired immune deficiency syndrome (AIDS) (human immunodeficiency virus), parvovirus B19, not to mention hepatitis B virus, hepatitis C virus, hepatitis D virus, hepatitis G virus, hepatitis E virus, papillomavirus, and lymphocytic choriomeningitis virus) should be re-evaluated from time to time (Sutherland 1993; Klein and Remington 2001). This appears necessary with respect to changing epidemiology due to increasing vaccination and progress in preventing certain infections important for pregnancy. Moreover, globalization provides opportunities for the emergence/re-emergence of infectious diseases. The role of newly recognized viral pathogens in pregnancy, imported or in the respective geographic area, has to be elucidated.

CYTOMEGALOVIRUS

Cytomegalovirus (CMV), a gammaherpesvirus, is the most frequent viral cause of congenital infection in humans, with symptomatic disease at birth, and short- and long-term sequelae. CMV establishes latency and persists so for life, periodically reactivating from this latent state. In immunocompetent persons, including pregnant women, primary CMV infection is usually asymptomatic and only a small portion (<10 percent) presents with clinical symptoms such as mononucleosis-like illness. Primary maternal CMV infection is the major risk for congenital disease. Recurrent infection, which quantitatively accounts for most of the congenital infections in highly immune populations worldwide is always asymptomatic and clinical manifestations in the infected fetus or newborn infant are rare.

Infection in pregnancy

EPIDEMIOLOGY OF MATERNAL CMV INFECTION

CMV antibody prevalence differs in various populations according to socioeconomic factors, race, geographic location, and lifestyle. In the USA and western Europe, the antibody prevalence rates in women aged 20–40 years from the higher socioeconomic group ranges from <40–60 percent (mean 45 percent) compared to 85 percent in the lower socioeconomic group. In developing countries more than 90 percent of young women are positive for CMV antibodies (Yow et al. 1988; Istas et al. 1995; Enders et al. 2003).

CMV is not very contagious and requires close or intimate contact with infectious secretions. No data have indicated CMV transmission through respiratory droplets. Infections in adolescent women (aged 14–20) are acquired mainly by sexual/oral contact with saliva, genital secretions, and semen (Shen et al. 1994), particularly in those of lower socioeconomic groups who change sex partners frequently (Istas et al. 1995; Coonrod et al. 1998). Women aged ⩾25 years in the middle and upper socioeconomic classes may acquire infection predominantly by close contact with asymptomatic infants and toddlers excreting CMV in saliva and urine (Stagno and Cloud 1994; Sobaszek et al. 2000).

Primary infection, as well as recurrent or secondary infection, can lead to vertical transmission and congenital infection. The annual rate of primary infection in susceptible pregnant women ranges in British, American, Swedish, and German studies generally from 0.4 to 4.1 percent (Ades 1992; Stagno et al. 1986; Enders et al. 2003). As shown in the US study primary infection is lower (2 percent) in the higher income group as compared to the lower income group with 6 percent (Stagno et al. 1986). Furthermore, it was documented that the annual seroconversion rate increased with the

Table 5 *Serological differentiation between congenital and perinatal infections*

Type of infection	Transmission	Virus-specific antibodies		
		At birth	Neonate <4 weeks	Infant >4 weeks to 1 year
Congenital	Intrauterine	IgM+/–	IgM+	IgM–
		IgG+	IgG+	IgG+
Perinatal/early postnatal	Extrauterine	IgM–	IgM+/–	IgM+
		IgG+	IgG+	IgG+
None	None	IgM–	IgM–	IgM–
		IgG+	IgG+	IgG–

number of pregnancies from about 2 to 3 percent in the first pregnancy to 4 to 7 percent between the second and third pregnancy (Stagno et al. 1986; Yow et al. 1988). It also became evident that seronegative mothers whose children acquired the infection in daycare centers have a 30 percent annual risk for seroconversion. On average these mothers acquired the infection within 4.2 months (range 3–7 months) after their children became infected (Adler 1988). The route of transmission among children in group daycare is caused by horizontal transmission from child to child. This is supported by analysis of the restriction enzyme digestion patterns of CMV-DNA of the virus isolates of the infected children (Adler 1988). The highest risk is posed by toddlers in their second year of life. These children are an important potential source for infection of susceptible parents or caregivers. The risk for seroconversion among seronegative caregivers ($n = 202$) was 11 percent per year in contrast to seronegative women employed in a local hospital ($n = 229$) with 2.0 percent (Adler 1992). Over all, approximately 25 percent of serious congenital infections occurring each year in the USA can be attributed to exposure in daycare centers.

PRIMARY INFECTION AND EFFECTS ON THE FETUS

Primary infection is defined as first contact with the virus. Characteristic symptoms (lymphadenitis with fever and hepatic dysfunction) occur in only 6.5 percent and suspicious symptoms (lymphadenitis with flulike symptoms) in about 19.4 percent (Daiminger et al. 2004). Therefore diagnosis of infection and immune status relies on laboratory tests. The association between primary CMV infection and fetal loss is not clear. In one early study, the number of spontaneous abortions after primary infection in early gestation was higher (4/26; 15 percent) than in the control group (16/744; 2 percent) (Griffiths and Baboonian 1984). A further low numbered study could not confirm an association between primary infection in early gestation and abortion (Yow et al. 1988). Although some studies published in the 1990s detected CMV DNA in abortive or placental tissue, up to now no correlation between active CMV infection and fetal loss was found, supporting the fact that CMV is not a major abortion-related factor (Spano et al. 2002).

Primary infection in pregnancy, regardless of socioeconomic status, accounts for 24–75 percent (mean 40 percent) of congenital infection (Stagno et al. 1986). These data were confirmed by newer studies on prenatal diagnosis in which intrauterine transmission rates varied between 23.5 and 68 percent (Revello et al. 1995; Ruellan-Eugene et al. 1996; Bodus et al. 1999; Lazzarotto et al. 2000; Liesnard et al. 2000; Azam et al. 2001; Enders et al. 2001).

Most studies reported a constant transmission rate throughout pregnancy following maternal primary infection, but some workers found a higher rate in late pregnancy. However all authors agree that the risk for congenital disease is strongly connected with infection in the first 12 weeks of pregnancy (Stagno et al. 1986; Enders et al. 2001; Daiminger et al. 2004). The risk of fetal damage following preconceptional maternal infection (8 to 2 weeks before last menstrual period) appears to be low, but more data are needed to confirm this observation (Revello et al. 2002; Daiminger et al. 2004). In this respect, the study of Fowler et al. (2004) is of interest, reporting that maternal infection up to 2 years before renewed pregnancy may still pose a risk for congenital infection (Plotkin 2004).

RECURRENT INFECTION AND EFFECTS ON THE FETUS

Recurrent (or secondary) infections are defined as either reactivation of endogenous virus or reinfection with a new strain. The most frequent mechanism for recurrent infection during pregnancy seems to be reactivation of latent virus. However, reinfection by CMV strains other than the original infecting strain, particularly in women with multiple sexual partners, has been demonstrated by restriction enzyme analysis (Chou 1990) and indirectly by measuring antibody specificity of glycoprotein H against CMV laboratory strains and isolates (Boppana et al. 2001).

Recurrent infections occur in the presence of both humoral and cellular immunity, but in the absence of a viremic phase. In contrast to primary infection the transmission rate is very low and amounts to only 1 percent (Fowler et al. 2003), however quantitatively recurrent infections account for most of the subclinical infections worldwide (Stagno et al. 1986; Fowler et al. 2003; Griffiths and Baboonian 1984). It is generally recognized by the presence of specific IgG antibodies before conception or by the presence of IgG antibodies in the first 12 weeks of gestation in the absence of IgM antibodies and by detection of congenital infection in the offspring (Fowler et al. 1992).

Recurrent infection occurs most frequently in the late second and third trimester, when a marked transient depression of CMV-specific cellular immunity was observed (Gehrz et al. 1981; Baboonian et al. 1989). With advancing gestational age the rate of viral shedding from the uterine cervix and urine increases (Shen et al. 1993) suggesting that productive CMV infection in nonpregnant women and in women during early gestation is under the control of the cellular immune system. In relation to CMV and pregnancy it is interesting that the rate of viral shedding from urinary or genital secretions of seropositive pregnant women is inversely related to age. For genital secretion, in one study, the high level of 15 percent at the age of 11–14 years falls to undetectable levels in women aged 31 years and older. For urinary excretion, the rate falls from a peak of 8 percent in the younger age group to zero in women

>26 years old. No excretion occurred from either site in postmenopausal women (Knox et al. 1979). Less well investigated is the influence of age in males on CMV excretion in semen (Shen et al. 1994). The relationship between maternal age and congenital infection and disease for maternal primary and recurrent infection in different populations is not yet well defined.

Between 1970 and 1973, it became evident that congenital infection can occur in consecutive pregnancies. In three independent studies, the first infant was severely affected or died and the second born in each case was subclinically infected. Thereafter, several case reports on congenital infection with disease in infants of seropositive mothers with and without immunosuppression have been published (Stagno 2001). Some recent publications indicate that symptomatic infection at birth in infants born to immune mothers may be more frequent than previously recognized (Ahlfors et al. 1999; Boppana et al. 1999; Casteels et al. 1999). However, it should be remembered that, in immune mothers, the rate of vertical transmission is about 1 percent, the rate of defects at birth in newborns less than 1 percent and the risk of late sequelae 5–8 percent (unilateral hearing loss approximately 5 percent or microcephaly 2 percent).

PATHOGENESIS OF FETAL INFECTION

In primary maternal infection, it is assumed that intrauterine infection results from maternal viremia with subsequent placental infection and hematogenous dissemination to the fetus. It is still undefined whether cell-free or leukocyte-associated virus is required for the spread from the mother to the fetus through the placenta. In detail, infected leukocytes may transmit the infection to uterine microvascular endothelial cells which are in direct contact with the cytotrophoblasts of anchoring villi with subsequent infection of underlying tissues of villous cores including fibroblasts, fetal macrophages, and endothelial cells (Sinzger et al. 1993; Gabrielli et al. 2001). Alternatively infected maternal leukocytes may directly spread the infection to the villous stroma through breaches of the syncytiotrophoblast layer (Hemmings et al. 1998). As a further hypothesis, transportation of antibody-coated CMV virions by transcytosis through the intact syncytiotrophoblast has been discussed (Fisher et al. 2000).

Following direct infection of placental and chorionic tissue, the virus may also spread to amniotic cells that are then ingested by the fetus. In this case the virus replicates in the oropharynx and is then carried through the fetal blood circulation to target tissues such as the kidney. The renal tubular epithelium seems to be a major site of replication. By either mechanism of intrauterine infection the fetus would excrete CMV via urine into amniotic fluid, which seems therefore to be the optimal specimen for prenatal diagnosis of CMV fetal infection.

Other modes of intrauterine transmission may include transovarian infection by infected semen (Shen et al. 1994) and in late pregnancy, by ascending infection from the vagina after premature rupture of the membranes (Ohyama et al. 1992).

The pathogenesis of fetal infection in twin pregnancies is not yet systematically evaluated with respect, for example, to type (primary or recurrent) and time of maternal infection. From the literature it appears, that in the case of monozygotic/monoamniotic pregnancies both fetuses are infected, whereas in dizygotic/diamniotic pregnancies one or both fetuses can be infected. The infected fetuses show various degrees of symptoms at birth. Gabrielli et al. (2003) presented the possibility of horizontal (fetus-to-fetus) transmission for a dichoriotic, diamniotic twin pregnancy with fused placentas. They found that only one fetus was infected at WG 21, whereas both fetuses were infected at birth. Altogether, because intrauterine transmission occurs in only 30–40 percent of pregnant women with primary infection, a mechanism that is not understood but is generally referred to as placental barrier must operate to prevent fetal infection.

In recurrent infection, the mode of CMV transmission in immune mothers is not well known. It is unclear how the virus evades the immune system under these circumstances. Latent CMV reactivates from sites that are less accessible to virologic examination, like placental tissue, ovaries, endometrium, or cervix (Mocarski et al. 1990; Reddehase et al. 1994). Reactivation of CMV especially from macrophages during local immunosuppression in the uterus may be a possible mechanism (Revello and Gerna 2004). As shown by dot-blot hybridization of PCR products CMV DNA was detected in 30 percent of placentas of seropositive mothers, localized mostly to the villi, the extravillous trophoblasts, and decidual cells. The frequency of CMV DNA detection in placentas increased from 18.2 percent for deliveries in the second trimester to 32.9 percent in the third trimester (Kumazaki et al. 2002). This is compatible with the increasing rate for cervical and urinary shedding with advancing gestational age.

In the fetus, the fetal cellular and humoral immune responses to infection are reduced compared to that of the adult (Lewis and Wilson 2001). Cellular immunity such as CMV-specific CD8 cells could be detected in congenitally infected fetuses as soon as WG 22, but may not be fully functional as shown by IFN-γ secretion (Elbou Ould et al. 2004). Humoral immune responses are triggered by immunoglobulin-secreting plasma cells, which are detectable by the 15th week of gestation (Toivanen et al. 1969; Gathings et al. 1981).

CONGENITAL DISEASE

Congenital CMV infection, affecting worldwide approximately 0.2–2 percent of all live-born infants (in the USA, mean approximately 1 percent), is one of the leading causes of mental deficiencies. Up to one in ten

newborns has signs at birth commonly associated with congenital CMV disease and about half of these have the classic stigmata of cytomegalic inclusion disease (CID). Another 5 percent present with milder or atypical involvement (e.g. hydrocephalus, hemolytic anemia, pneumonitis, and inguinal hernia) and approximately 90 percent are born with subclinical, but chronic, infection (Demmler 1994). Table 6 presents the clinical manifestations of congenital CMV disease in the newborn period. Most of the data come from the USA National Congenital CMV Disease Registry, the worldwide greatest analysis of congenital disease (n = 786 babies in the 11th year of investigation) (Demmler 2002).

Congenital CMV infection is the leading nongenetic cause of sensorineural hearing loss (SNHL) in childhood, causing 20–30 percent of all deafness cases (Barbi et al. 2003). By universal otoacoustic emission (OAE) screening of neonates as practiced, for example, in the USA, only about half of all SNHL caused by congenital CMV can be detected and late onset hearing loss, which generally occurs up to 6 years of age will pass unnoticed (Fowler et al. 1999). Ocular disease, which manifests principally by chorioretinitis, is detected more frequently in infants symptomatic at birth (Table 6). Because 23 percent of infants with chorioretinitis have either progression of lesions or delayed onset after the first year of life, serial eye examinations are recommended (Anderson et al. 1996; Coats et al. 2000). SNHL usually passes unnoticed for the first 1–2 months of life, as does the less common chorioretinitis. Among the most infected infants mortality ranges between 10 and 12 percent mainly in the neonatal period. More than 90 percent of the survivors have major long-term sequelae. The severity of neurologic impairment is highly variable. In infants with symptomatic infection, normal cranial computer tomographic scan (CT) and normal head circumference proved to be a predictor of favorable cognitive and neurologic outcome (Noyola et al. 2001). However, in symptomatically infected infants presenting with abnormal CT (about 70 percent) and microcephaly, subsequent neurologic abnormalities and mental retardation (IQ <70) may be expected in 90 and 56 percent, respectively (Boppana et al. 1997). Still no factors are identified for predicting progression of hearing loss. Table 7 compares the sequelae in congenital CMV infection in infants symptomatic and asymptomatic at birth. Asymptomatically infected infants have a 10 to 15 percent risk of abnormal development, such as SNHL, chorioretinitis, and microcephaly with varying degrees of mental retardation and neuromuscular defects. Except for SNHL, which may be detected even at school age, these sequelae usually present during the first 2 years of life (Table 7).

Encouraging aspects are that infants with asymptomatic infection at birth seem to have no differences in IQ and other neuropsychological tests compared with a healthy control collective (Temple et al. 2000; Kashden et al. 1998; Demmler 2004). Furthermore, children with congenital CMV infection, including those with systemic signs at birth, are unlikely to be at increased risk of subsequent neurodevelopmental or intellectual impairment if they show normal development at 12 months of age (Ivarsson et al. 1997).

Table 6 *Clinical manifestations and abnormalities in the newborn period with congenital CMV infection*

Abnormalities	Percentage (approx.)
Prematurity (<38 weeks)	34
Small for gestational age	47
Petechiae and purpura	54
Jaundice	36
Hepatomegaly	47
Splenomegaly	44
Pneumonia	11
Thrombocytopenia	54
Hemolytic anemia	13
Elevated liver enzyme values	46
Neurological findings	
One or more of the following	72
Microcephaly	40
Intracranial calcification	43
Lethargy/poor feeding	25
Convulsions	7
Hearing impairment	41
Chorioretinitis	11
Death in the first 6 weeks	12

Table 7 *Sequelae in children with congenital cytomegalovirus infection*

Sequelae	Symptomatic at birth (%)	Asymptomatic at birth (%)
Sensorineural hearing loss	41–58	7.4
Bilateral hearing loss	37	2.7
Speech difficulties	27	1.7
Chorioretinitis with/ without optic atrophy	20	2.5–3.9
Visual impairment	22	1.2
IQ <70	55	3.7
Microcephaly with convulsions or paresis/ paralysis	52	2.7
Microcephaly	37	1.8
Convulsions	23	0.9
Paresis/paralysis	13	0
Death after the newborn period	6	0.3

PERINATAL AND EARLY POSTNATAL INFECTION

Perinatal infection is acquired by passage through the infected birth canal and early postnatal infection mainly by infected breast milk of a CMV-IgG-positive mother as a result of primary or recurrent infection. The source of both types of infection is due to local reactivation of the virus in the cervical and mammary gland.

The correct rate of perinatal infection is more difficult to determine because it can only be assumed in vaginally delivered infants of seropositive mothers with detection of virus in their cervicovaginal secretion at the time of delivery and in throat or ear swabs of the newborns. In an earlier study of this kind, the rate of perinatal infection was found to be 57 percent; in a similar more recent study restricted to preterm infants it was 22 percent (Hamprecht et al. 2001).

The CMV excretion rate in breast milk of seropositive mothers using highly sensitive diagnostic methods for detection of CMV such as DNA with PCR amounts to 88–96 percent (Mosca et al. 2001; Hamprecht et al. 2001). Instead of the less sensitive virus culture detection of CMV pp65 late mRNA was used to indicate replicating virus. Viral shedding in breast milk was seen as early as 2–3 weeks after delivery, peaks in activity by 3–6 weeks, and ending in most individuals by 8–10 weeks (Hamprecht et al. 2001; Numazaki et al. 2001). It is known that there is a considerable variability in perinatal and early postnatal CMV transmission throughout the world, which is due to maternal factors such as age, practice of breast-feeding and socioeconomic, geographic, and ethnic background.

Breast-feeding in premature infants is beneficial. However, breast-feeding of a high-risk group of preterm infants may be associated with symptomatic CMV infection (Hamprecht et al. 2001; Maschmann et al. 2001). This is shown in a 3-year prospective study of 176 preterm infants weighing <1 500 g (<32nd week of gestation) with a high infection rate of 38 percent (33/87 infants). The mean incubation period between positive DNA detection in breast milk and virus or viral DNA detection in the infant was 42 days (range 28–69 days). Half (16 of 33) of the infected infants had symptoms compatible with CMV disease: hepatomegaly, neutropenia, thrombocytopenia, and four infants had sepsis-like deterioration in the early phase of CMV infection. All infants recovered and thus far, no negative effect on neurodevelopment or hearing was found at follow-up of 22 CMV-infected preterm infants at 2–4.5 years of age and matched controls. Besides the relatively favorable outcome of infected preterm infants by breast-feeding, prevention of CMV infection through contaminated breast milk was and still is a challenge. The aim is removing CMV from breast milk without destroying nutritional–immunological factors (Forsgren 2004).

Perinatal and early postnatal CMV infection are as chronic as congenital infection with virus shed into urine up to 6 years (mean 3.9 years) and into saliva up to 2–4 years with the highest quantity excreted during the first 6 months of life. However, the quantity of virus excreted is less than in infants with symptomatic congenital infection.

Transfusion-acquired early postnatal CMV infection and disease is hardly observed due to the use of CMV antibody-negative blood available through more sensitive screening methods and improved pathogen inactivation methods (Roback 2002).

Diagnosis

DIAGNOSIS IN PREGNANCY

Primary CMV infection in pregnancy is usually detected by chance, as primary infection is generally asymptomatic or may cause nonspecific symptoms.

With the basic serological tests, primary infection can best be detected by seroconversion or rising IgG and IgM antibody titers to high level within 2–4 weeks of onset. Medium- to low-level IgM antibodies can be detected in less recent primary infection, as well as in persistent (chronic) and recurrent infection. This makes IgM an insufficient marker for diagnosing and timing primary infection, particularly since the various commercial IgM tests greatly differ in sensitivity and specificity (Landini 1993; Daiminger et al. 1999). Therefore, sera with positive IgM results should be retested in supplementary assays such as the IgG avidity enzyme immunoassay (EIA) (Eggers et al. 2000), the microneutralization assay (Eggers et al. 1998), and the gB/gH recombinant immunoblot (Eggers et al. 2001). Thus, primary maternal infection may be diagnosed with a single serum sample up to WG 20 by negative or low values in the IgG avidity assay and the microneutralization test (Enders et al. 2003, personal communication).

The cellular immune response determined by CMV-specific lymphoproliferative or cytotoxic assays in women with recent primary CMV infection is not routinely assessed, for example, for the prediction of intrauterine transmission. The first study of this kind (Stern et al. 1986) revealed that newborns of women with a good lymphocyte response were not infected ($n = 8$), whereas mothers whose lymphocytes did not respond delivered infected babies (4/6). In a later study there was a fair, but not complete correlation between a strong lymphocyte response and birth of noninfected infants (Fernando et al. 1993).

The detection of virus shedding in cervical secretion and urine in pregnant women is of little value for distinguishing primary from recurrent maternal infection, because CMV may be excreted intermittently in primary as well as recurrent infection.

Breast milk of lactating seropositive mothers of preterm infants may be investigated for presence of CMV DNA by PCR. However, negative results are of minor value for deciding whether or not to breast feed as excretion may be delayed or often intermittent.

Altogether there is presently no serologic or immunologic test that can predict, for example, protection against intrauterine infection and disease in the fetus (Weinberg 2002).

DIAGNOSIS IN THE FETUS

Prenatal invasive diagnosis of fetal CMV infection is increasingly used in pregnant women with serological suspicion of acute or recent primary infection and in those with abnormal findings by ultrasound examination, whose CMV antibody status is mostly unknown. A variety of sonographic findings has been reported from a number of authors: ascites, fetal growth retardation, cerebral ventriculomegaly, microcephaly, hydrocephalus internus, and oligohydramnion are the most common features. A wide range of brain abnormalities (e.g. intracranial calcification) and hyperechogenic fetal bowel has also been documented in addition to cardiomegaly, hepato- and splenomegaly, hydrops fetalis, or placentomegaly as reviewed by Crino (Crino 1999; Enders et al. 2001). In one study, more than two fetal abnormalities were recorded in 46 percent (27/58) and only one sign in 22 percent (13/58). Fetal abnormalities were first observed between WG 18 and 22 in 40 percent and beyond WG 23 to 32 in 60.3 percent at which time termination of pregnancy is a difficult option (Enders et al. 2001 and update 2001–2004). For detection of fetal intracranial abnormalities transvaginal sonography in WG 22–37 (mean gestational age of 27.5 weeks) provided additional information for all fetuses and fetal magnetic resonance imaging (MRI) in one of two cases (Malinger et al. 2003). In counseling the parents it is necessary to mention not only what can be seen of the characteristic manifestations of congenital infection but also what cannot be seen, like hearing defects or chorioretinitis.

Prenatal diagnosis relies on the detection of viral DNA by PCR and infectious virus by the rapid shell vial culture in amniotic fluid and on the detection of DNA and CMV-specific IgM antibodies in fetal blood (Table 3). Detection of CMV in chorionic villi was more rarely attempted. Amniotic fluid is the preferred specimen not only because of the relatively low technical risk of fetal loss with amniocentesis in undamaged fetuses (0.2–1 percent) but also because CMV is excreted into fetal urine, which accumulates in amniotic fluid as pregnancy proceeds. For avoiding false-negative results, amniotic fluid should be obtained after WG 21. In all instances an interval of at least 6 weeks between presumed onset of maternal infection and invasive procedure is recommended (Revello et al. 1995; Bodus et al. 1999; Liesnard et al. 2000; Enders et al. 2001; Gouarin et al. 2001).

In fetal blood obtained after WG 20 CMV DNA detection by PCR was found to be more sensitive (92.6 percent) than detection of IgM antibodies with a sensitivity of approximately 50–80 percent, especially in fetuses with overt infection (Enders et al. 2001 and update 2001–2004; Lipitz et al. 1997; Hagay et al. 1996; Revello et al. 1995; Liesnard et al. 2000).

In one study, the predictive value of prenatal diagnosis on fetal infection, as estimated by the outcome of pregnancy, for positive results (obtained with at least two detection methods) was 100 percent (74/74) and for negative results 96.1 percent (149/155) (Enders et al., 2001 and update 2001–2004). Generally, isolated positive PCR results in only one sample must be considered with caution. Therefore additional cell culture-based methods (shell vial assay or isolation in cell culture) or alternative DNA and RNA detection methods (e.g. nucleic acid sequence based amplification (NASBA), quantitative PCR), PCR in another sample, for example, fetal blood, or in addition a second sampling may be performed for a safe prediction of fetal infection.

The following virological markers may be useful for the prognosis of fetal outcome: viral load in amniotic fluid (Lazzarotto et al. 2000; Guerra et al. 2000; Enders et al. 2001; Gouarin et al. 2002) or fetal blood (Revello et al. 1999b) and presence of CMV-specific IgM antibodies in fetal blood (Revello et al. 1999b; Enders et al. 2001). Also nonspecific biological, biochemical, and immunological markers for fetal function (Azam et al. 2001; Forestier et al. 1988) may provide supportive evidence of congenital disease.

The present experience suggests that prenatal diagnosis carried out with well-controlled serological and virological techniques and ultrasound screening at high level saves a considerable number of pregnancies, since fetal infection can be excluded in about 75 percent of primary maternal infections in pregnancy (Enders et al. 2001 and update 2001–2004, personal communication).

DIAGNOSIS IN INFANTS

The diagnosis of suspected congenital infection in newborns is confirmed by detection of virus in saliva, urine, blood, and by detection of IgM antibodies in cord blood or blood of the neonate.

All the different CMV genotypes (four gB and four gN variants) can be vertically transmitted and produce congenital disease. However, up to now, it seems that the 'potential of infectivity' and ability to produce severe disease is not related to a single polymorphic gene alone (Barbi et al. 2001; Pignatelli et al. 2003).

The virus detection is carried out today mainly by detection of CMV DNA by PCR using commercial and 'in-house' tests of various sensitivities and by detection of infectious virus in the shell vial culture or less frequently in conventional cell culture. Virological tests must be initiated within 2 weeks after birth to distinguish congenital from perinatal or early postnatally

acquired infection. It is of interest that higher CMV DNA levels are detected in serum (Nelson et al. 1995) and peripheral leukocytes (Revello et al. 1999a) of symptomatic infants than in asymptomatic infants and that in the former the mean duration of leuko-DNAemia was longer (156 ± 50 versus 40 ± 8 days).

More recently a simple and reliable diagnosis of congenital infection can be accomplished by demonstration of CMV DNA in dried blood spots (DBS) on Guthrie cards (Barbi et al. 2000). The DBS test could be used as an alternative to viral culture. The main benefit comes from the fact that congenital infection may retrospectively be diagnosed beyond the neonatal period or to link morbid conditions like SNHL or white matter abnormalities in brain MRI to congenital infection. However the sensitivity of the DBS test, especially when used retrospectively has to be further investigated.

Antibody testing for detecting prenatal infection is less informative. After birth, approximately 70 percent of symptomatic newborns are IgM antibody positive in contrast to only 30 percent of asymptomatic infected neonates; IgM antibodies are usually detectable for 3–4 months in declining levels (Revello et al. 1999a; Enders et al. 2001). IgG antibodies measured in the cord blood or in the blood of the newborn are mostly of maternal origin. An initial decrease of IgG antibody is followed by an IgG antibody increase and lifelong persistence at medium to low titers. The presence of IgG antibody in asymptomatic infants ⩾8 months of age can be due to congenital or perinatal/early postnatal infection (see also Table 5). In this respect the IgG avidity test is helpful in identification of the type of infection (G. Enders, personal communication).

Management

MANAGEMENT IN PREGNANCY

Preventing primary CMV infection by hygienic measures and altering their lifestyle is difficult to achieve and only effective in women who want to become pregnant or are pregnant as they may be highly motivated to follow hygienic guidelines (Adler et al. 1996).

Seronegative pregnant women with significant exposure to CMV at home or at work should be serologically controlled in 2–3-weekly intervals up to 12 weeks after first exposure and at delivery to demonstrate that no infection has occurred (Enders 2003).

For passive prophylaxis, several intravenous hyperimmunoglobulin preparations (CMVIG) with known neutralizing antibody titers are available. They may be used for forensic aspects in seronegative pregnant women with close occupational contact to newborns, infants, or toddlers known to excrete CMV with the goal of preventing maternal infection. From our own experience, passive prophylaxis is less important or needed than observing correct hygienic measures. Antenatal care directives for CMV seronegative pregnant caregivers differ from country to country from reinforcement of hygienic measures to (for example, in Germany) removal from the workplace for the whole of the pregnancy or restriction to work with infants more than 3 years of age.

In cases of suspected primary infection in the first and second trimester of pregnancy, ultrasound screening at high level and prenatal diagnosis for assessing fetal infection is recommended up to WG 23. This is a better option than the often unnecessary immediate termination of pregnancy.

Treatment of pregnant women with suspected primary CMV infection with the antiviral drugs ganciclovir, foscarnet, and recently valganciclovir (all of which cross the placenta) is not recommended due to their potential teratogenic and embryonic toxicity according to animal studies. Thus far, ganciclovir was applied only in single pregnancies in which the mother had preceding organ transplantation or suffered from severe disease. Whether CMV-infected fetuses benefit from intravascular administration of ganciclovir or CMVIG preparations cannot be finally assessed since only a few case reports with diverse outcome have been published (Revello et al. 1993; Negishi et al. 1998; Nigro et al. 1999; Matsuda et al. 2004, G. Enders personal communication). New drugs for treatment of CMV, e.g. non-DNA polymerase inhibitors, are in development and some of them will hopefully enter clinical trials for safety and efficiency in the near future (Emery and Hassan-Walker 2002).

Delivery: cesarean section is not recommended in case of presumed maternal primary and fetal congenital CMV infection – unless the fetus is highly damaged.

Breast-feeding of seropositive mothers in uninfected and congenital infected newborns is not contraindicated. Recommendations for breast-feeding of very low birth weight (VLBW) preterm infants (WG <32, body weight <1 500 g) born to IgG-seropositive mothers vary from country to country between breast-feeding after counseling the parents for possible risks and feeding breast milk following various virus inactivation methods (Holder pasteurization or a new procedure for gentle virus inactivation up to corrected WG 34). Other intervention strategies for seronegative women are avoidance of iatrogenic transmission in in vitro fertilization (IVF) programs by using screened semen or screened blood products for seronegative pregnant women in case of emergency or seronegative donors in organ transplantation.

MANAGEMENT OF THE NEONATE

In infants of mothers with suspected CMV infection in pregnancy, screening for CMV congenital infection should be performed by detection of virus in urine or saliva within 14 days after birth or by DBS test on Guthrie cards followed by auditory screening of infected infants up to school age, so that affected infants can receive intervention (e.g. cochlea implants) as promptly as possible (Fowler et al. 1999).

An increasing number of neonates with hearing defects will now be identified due to the more universally practised auditory screening in industrialized countries by otoacustic emissions or auditory brain stem response. It should be remembered that about half of all cases with sensorineural hearing loss caused by CMV will be missed due to the late onset of hearing loss in formerly asymptomatic newborns.

In infants with congenital disease at birth antiviral therapy is an option and its aim is the suppression of virus replication in order to prevent the progression of auditory, visual, and mental impairment and the occurrence of further or late manifestations. From a number of studies it is known that there is a reduction of virus load during therapy, but no complete virus elimination. After cessation of therapy, virus shedding usually returns to preceding or even higher levels especially when treatment was suspended too early (Barbi et al. 1996). According to several studies – using different treatment regimes – i.v. ganciclovir is fairly well tolerated even in preterm infants. Acute symptoms (pneumonia, hepatitis, chorioretinitis) seem to resolve by early treatment (Hocker et al. 1990; Stronati et al. 1995; Nigro et al. 1994; Liberek et al. 2002; Barampouti et al. 2002). In the USA, a large-randomized controlled multicenter clinical trial (with and without 6 mg/kg i.v. twice a day for 6 weeks) was performed in infants with congenital disease at birth and central nervous system (CNS) involvement and showed very promising results with respect to safety and antiviral effects (phase I (Trang et al. 1993); phase II (Whitley et al. 1997)). The results from phase III indicate that i.v. ganciclovir therapy in symptomatically infected neonates prevented hearing deterioration at 6 months and might prevent it thereafter ($\geqslant$1 year) (Kimberlin et al. 2003).

The availability of oral therapy (oral ganciclovir and most recently valganciclovir) would be a great advance in long-term maintenance therapy usually following the initial i.v. treatment. Thus far, there are only few pharmacokinetic studies on oral ganciclovir application in infants (Michaels et al. 2003). In infants dosage should be related to body surface or body weight and controlled by drug monitoring in blood plasma. The effect of oral valganciclovir with a ten times higher bioavailability than oral ganciclovir is still under investigation. Preliminary results in seven infants show that valganciclovir is well tolerated, effective in a transient reduction of the viral load, and effective in resolving acute symptoms (G. Enders, personal communication).

There is good agreement that asymptomatic congenitally infected infants should not be treated with ganciclovir so far, but should be closely surveilled for onset of late manifestations, which may then justify treatment. Early after birth, e.g. via breast milk, infected preterm infants with symptomatic disease seem to benefit from early therapy in preventing severe disease (G. Enders, personal communication).

The overall effectiveness of ganciclovir i.v. treatment is difficult to judge from the multicenter study and from the increasing number of observational studies, due to the erratic natural course of the congenital disease.

With regard to childhood vaccination, it has been observed that the recently used sixfold vaccine combination (DTPa, hepatitis B, poliovirus 1, 2, 3, HiB), measles, mumps, and rubella (MMR), and lately varicella is well tolerated in asymptomatic and symptomatic congenitally infected infants producing satisfactory antibody levels against the various vaccine components (G. Enders, personal communication).

FUTURE MEASURES AND PUBLIC HEALTH ASPECTS

Opinions vary on the value and cost-effectiveness of screening programs for CMV. Universal antenatal CMV antibody screening is not officially recommended or has not been introduced into any prenatal programs in industrialized countries (Revello and Gerna 2002; Enders et al. 2003). Such programs have shown to be helpful for the guidance of pregnant seronegative women in commonsense measures for preventing the acquisition of primary infection and for reassuring IgG-positive/IgM-negative women that they are protected against primary infection. In case of recurrent infection there is only a low risk of the birth of a child with congenital disease. However, to such women a closer surveillance in the following pregnancy by serology and ultrasonography (WG 21–24) should be recommended.

For active prophylaxis, several vaccines are under investigation (Pass and Burke 2002) and currently four of them have reached clinical trials: Towne live-attenuated virus, subunit glycoprotein B (gB/MF59) (Mitchell et al. 2002), canary pox, and an improved Towne (chimeric CMV) vaccine. Further vaccines consisting of plasmid DNA, dense bodies, or synthetic peptides are in development (Plotkin 2001). To be effective, these vaccines should induce persisting titers of serum-neutralizing and mucosal antibodies comparable to those found after natural infection. Induction of cellular immunity (cytotoxic lymphocyte response of importance for protection) would also be beneficial, but will not be achieved with subunit vaccines alone. Potential vaccine recipients would be young boys and girls before puberty. Encouraging aspects come from a study by Griffiths (Griffiths et al. 2001) showing by a mathematic modeling approach that in developed countries a vaccine applied to 1-year old infants with only modest efficiency (60 percent protective effect against primary infection) would nevertheless be sufficient in eradication of CMV from the population.

The public health impact of congenital CMV infection is enormous, especially when the late sequelae of congenital CMV infection are more definitely associated with CMV congenital infection (Istas et al. 1995), which is presently the case (2004). The annual costs of supporting children

with congenital CMV in the USA approaches two billion US dollars (Griffiths 2002; Prober and Enright 2003).

VARICELLA-ZOSTER VIRUS

Varicella-zoster virus (VZV) is an alphaherpesvirus that causes two main clinical syndromes: primary infection gives rise to varicella (chickenpox) and recurrent infection to herpes zoster (shingles). Varicella is highly contagious, whereas herpes zoster is less so. Chickenpox in pregnancy may be associated with severe maternal disease, spontaneous abortion, and infrequently, during the first two trimesters, with congenital varicella syndrome (CVS). Maternal varicella around term carries the risk of serious neonatal disease. Zoster at any time during pregnancy does not result in congenital anomalies or neonatal disease.

Infection in pregnancy

INCIDENCE

Varicella in pregnancy is relatively uncommon because in densely populated areas of the northern hemisphere, approximately 95 percent women of childbearing age are seropositive. However, this figure may be smaller in some populations (e.g. black women in the USA and in countries of the southern hemisphere) (Gray et al. 1990; Dworkin 1996; Seward et al. 2000). Reliable data on the incidence of varicella in pregnancy are not available, but extrapolation from the consultation rates for chickenpox in adults aged 15–44 years in the UK suggest an infection risk of approximately 2–3 per 1 000 with an average mortality rate of 1/1 million pregnancies (Department of Health 1996a; Fairley and Miller 1996). In Germany, the seroprevalence to varicella was studied annually from 1984 to 1997 in more than 26 000 pregnant women aged 20–40 years; the seronegative rate was about 5–6 percent, with no significant change over the period (Enders 1984; Enders and Miller 1994; Enders and Miller 2000, and update 2004). Based on the suggested infection risk of 2 per 1 000 in the UK in all adults aged 15–44 years, the frequency of varicella in pregnancy was calculated to be 8 000 in the USA, 1 600 cases per year in Germany, and 1 400 in England and Wales (Department of Health 1996a; Enders and Miller 2000). Asymptomatic reinfection is possible and second attacks of varicella have also been reported (Martin et al. 1994, Enders et al. personal communication). An upward shift of incidence to adults aged 15–44 years has been recognized in England (Miller et al. 1993a) and in the USA (Gray et al. 1990; Choo et al. 1995). Zoster in pregnancy may have an annual incidence of 2 per 1 000, similar to that in nonpregnant adults aged 15–40 years (Miller et al. 1993b; Schmader 2001). There is no evidence that the incidence in adults has changed over the last few decades.

ADVERSE EFFECTS IN PREGNANCY

Anecdotal evidence suggests that varicella is more severe in pregnant women than in other adults, particularly the risk of varicella pneumonia. However, there are no reliable population-based prospective studies to confirm this impression (Nathwani et al. 1998). Among 1 721 pregnant women with varicella followed up prospectively by the author between 1980 and 1999, no cases of pneumonia nor deaths were recorded (Enders and Miller 1994, 2000). However, outside this study, we investigated three very severe cases of VZV pneumonia between WG 22 and 33 (1992–1997). All three women survived and two of the three infants were born healthy and uninfected. In the third pregnancy, intrauterine death and spontaneous abortion occurred in WG 23. This indicates that varicella pneumonia associated with pregnancy is rare, although mortality data from the UK suggest that the risk of fatal varicella appears to be fivefold higher in pregnant than in nonpregnant immunocompetent adults (Miller et al. 1993b).

VZV pneumonia is the most common serious maternal complication in pregnancy (Haake et al. 1990; Katz et al. 1995). It usually develops within 1 week of the rash. The predominant signs and symptoms are fever, cough, dyspnea, and tachypnea. The outcome is unpredictable and there may be rapid progress to hypoxia and respiratory failure. Pneumonia is regarded as a medical emergency requiring prompt diagnosis and treatment. Studies reporting the outcome of varicella pneumonia in pregnancy show an excess of cases in the third trimester, suggesting that the risk to the mother may be greatest towards term. For example, 28 of 34 cases reported in 1989 and 1991 occurred in the third trimester (Esmonde et al. 1989; Smego and Asperilla 1991). Of the nine deaths reported as due to varicella in pregnancy in England and Wales between 1985 and 1998, seven occurred between 27 and 32 weeks of gestation.

In pregnancies complicated by varicella, spontaneous abortion, stillbirth, and prematurity do not seem to be significantly increased (Paryani and Arvin 1986; Balducci et al. 1992). In a prospective study of a total of 1 721 VZV-complicated pregnancies, the incidence of fetal loss due to spontaneous abortion during the first 20 weeks was 2.9 percent ($n = 49$) and of intrauterine death after the 20th week 0.6 percent ($n = 11$) of 1 612 live-born infants (Enders and Miller 1994, 2000). In pregnancies complicated by localized zoster rarely has dissemination been reported in immune-competent women.

Effects on the fetus

CONGENITAL VARICELLA SYNDROME

The risk of congenital varicella syndrome is an important concern. Since its first description by Laforet and Lynch (1947) more than 112 such cases have been

reported in the English and German medical literature (Sauerbrei and Wutzler 2003). A causal association with maternal infection has been confirmed in only a few cases in live-born infants by isolation of VZV or detection of viral DNA from skin lesions at birth and in some more cases in tissues following therapeutic abortion or intrauterine death (e.g. Da Silva et al. 1990; Scharf et al. 1990; Puchhammer-Stöckl et al. 1994; Sauerbrei et al. 1996; Sauerbrei 1998; Hartung et al. 1999; Schulze-Oechtering et al. 2004).

CLINICAL MANIFESTATIONS

The clinical manifestations of CVS range from severe multisystem involvement, resulting in death in the neonatal period, to dermatomal skin scarring, limb hypoplasia, or both as the only defects. Table 8 shows the clinical features of CVS and their relative frequencies of 48 well-documented cases from the world literature, as well as the 13 prospective and the 12 retrospective cases investigated by Enders and Miller (2000).

PATHOGENESIS OF CVS

The precise mechanism of infection with VZV in utero is unknown. It is generally accepted that transplacental transmission of VZV may take place during the viremic phase, resulting in congenital infection (Trlifojova et al. 1986). The pattern of defects in CVS, particularly the limb hypoplasia and scarring, suggests that they are due to intrauterine zoster. The extremely short period between reactivation and fetal infection may be the result of an inadequate cell-mediated immune response in early gestation (Higa et al. 1987).

The clinical consequences of congenital VZV infections depend on the stage of pregnancy at which maternal infection occurs (Table 9).

Intrauterine varicella infection can, however, occur without clinical sequelae at any stage of pregnancy, the proportion rising from 5–10 percent in the first and second trimester to 25 percent towards WG 36 and reaching approximately 50 percent when maternal varicella occurs 1–4 weeks before delivery (Miller et al. 1989). It seems possible that fetal infection early in pregnancy may result in clinical manifestations with healing of lesions before birth. Localized zoster in pregnancy could theoretically result in fetal infection, if the dermatomes involved were T10 to L1, as sensory nerves to the uterus originate from these segments; but no such cases have yet been documented (Miller et al. 1993b; Enders and Miller 2000).

The risk of zoster in infancy and childhood following maternal varicella in the second and third trimesters is 0.6 percent (4/618) and 1.6 percent (7/431), respectively, and the overall risk 1 percent (Enders and Miller, 1994, 2000, and update 2004). In the prenatal diagnosis study of Mouly et al. (1997) the rate of localized early herpes zoster in infants born to mothers with varicella before the 24th week of pregnancy was 3.8 percent (3/78).

RISK OF CONGENITAL VARICELLA SYNDROME

Several workers undertook prospective studies to estimate the risk of CVS following maternal varicella infection at various stages of pregnancy (Enders 1984; Paryani and Arvin 1986; Balducci et al. 1992; Jones et al. 1994; Pastuszak et al. 1994). In the largest reported prospective study (Enders and Miller, 1994, 2000, and update 2004), including 1 795 pregnant women with acute varicella with known outcome the overall risk during the first 20 weeks of gestation is 1.4 percent, the highest (3.0 percent) being observed between weeks 13 and 20. The latest gestational age at which CVS occurred was WG 19, which is consistent with the findings in one retrospective report (Alkalay et al. 1987). In a recent prospective study in 2002, involving 347 pregnant women with primary VZV infection only one case

Table 8 *Congenital varicella syndrome*

	Number of infants (%)	
Main signs	***n* = 48[a]**	***n* = 25[b]**
Skin: dermatomal cicatricial skin lesions, contractures	39	18
Skeleton: Limb hypoplasia associated with reduction deformaties	21	18
Eye: microphthalmia, chorioretinitis, cataract, Horner syndrome	26	11
CNS: microcephaly, brain atrophy, paralysis, convulsions, encephalitis, mental retardation	26	14
Other organ defects (e.g. gastrointestinal, genitourinary)	5	5
Multiorgan involvement (e.g. hemorrhagic rash and dystrophy)	ND	6
Death postpartum and later	ND	9
Female	ND	13
Male	ND	12

Table 9 *Clinical manifestations of congenital varicella infection following chickenpox in pregnancy*

Stage of maternal infection	Sequelae
First and second trimester	Congenital varicella syndrome
Second and third trimester	Herpes zoster in infancy or childhood
Perinatal	Disseminated neonatal varicella

From Miller et al. (1993b).

of CVS with typical skin scars and left retinal macular lesion occurred, however, after maternal varicella at WG 24 (Harger et al. 2002). In zoster in pregnancy involving 504 women with localized zoster there was no serological evidence of intrauterine infection and no congenital varicella syndrome (CVS) symptoms in the infants (Enders and Miller 1994, 2000, Enders update 2004). Various congenital defects have been reported after maternal zoster (Webster and Smith 1977; Higa et al. 1987), but only one infant with characteristic limb hypoplasia and skin scarring has been described following disseminated maternal zoster at WG 12 with presumed maternal viremia (Higa et al. 1987).

Based on the estimate of risk, together with the incidence of chickenpox in pregnancy and the annual rate of births, the number of CVS cases, which could be expected to occur each year is 44 in the USA, eight in England/Wales (UK), and nine in Germany (Enders and Miller 2000). The incidence of the CVS in Australia has been reported as 1–2 of 100 000 pregnancies per year which is 2.3 cases per year (Forrest et al. 2000). This confirms the low frequency of CVS.

The possibility of reinfection with adverse consequences for the fetus, has been raised (Martin et al. 1994). In our investigation on asymptomatic reinfection in 347 seropositive pregnant women with close exposure a significant rise of IgG antibodies was detected in 203 women and a rise of IgG and IgM antibodies in 144 women. In one case of reinfection at WG 37 varicella-like symptoms were noted together with a very high rise of IgG and IgM antibodies. Reinfection could be recognized by the already high avidity index in the first low-level IgG serum sample. Pregnancy outcome was documented in about 70 percent of the cases. In the newborns, no abnormal serology nor defects or illness consistent with CVS or neonatal varicella were observed (Enders, personal communication).

Re-exposure to VZV also induces a VZV-specific cellular immune response with an expansion of antigen-specific $CD4^+$ T cells and changes in cytotoxic $CD8^+$ T cells and NK cells. This T-cell response of VZV-specific $CD4^+$ memory T cells largely resembles the primary immune response to VZV (Vossen et al. 2004).

Neonatal varicella

Severe neonatal disease is generally attributed to intrauterine infection and lack of maternal antibody. If the mother's rashes appears more than 6 days before delivery, the infant invariably has maternal antibodies. When it is <6 days before delivery, only some infants have significant titers of antibody, whereas those born <3 days after onset of maternal rash, or infants whose mothers develop varicella after delivery are VZV IgG-negative. Infants at greatest risk of severe or fatal illness are those whose mothers' rashes appears 5 days before to 2 days after delivery (Gershon 1975; Miller et al. 1989). The interval between the onset of rash in the mother and infant is usually 12–13 days, but may be as brief as 2 days, suggesting transplacental infection. In one retrospective series, the clinical attack rate was estimated to be 17 percent (Meyers 1974) and the fatality rate 30 percent (Gershon 1975). According to a more recent large prospective study the commonly cited fatality rate of 30 percent seems to be an overestimate due to selective reporting of fatal outcomes (Miller et al. 1989). The annual incidence of neonatal varicella is only known from Australia, which is 5.8 per 100 000 live births or one in 17 000 pregnancies. Of interest is that all these 44 infants recovered without reported sequelae (Forrest et al. 2000).

A severe outcome of neonatal varicella is not limited to transplacentally acquired infection, but occasionally occurs in early postnatally acquired infection (minimum incubation period 8 days after birth) despite the use of varicella immunoglobulin (VZIG) even at high dosage.

Most of the concern surrounding neonatal varicella relates to infants whose mothers develop varicella. But it should be borne in mind that maternal immunity to varicella does not always protect the neonate exposed postnatally at home. There have been occasional reports of varicella in neonates of mothers with a past history of chickenpox (Bendig et al. 1998; Baba et al. 1982). All the cases (two and five) were of moderate severity or mild. Miller et al. (1989) followed up 36 infants who had a home exposure to varicella during the first 4 weeks of life. Six infants (17 percent) were infected, three with symptoms (mild to severe) and three without clinical features. Clearly, passively acquired VZV antibody provides incomplete protection, particularly under conditions of close exposure. Following neonatal varicella reactivation is not uncommon giving rise to zoster within a few months or years of the primary infection. Further zoster episodes have not been reported in these children, suggesting that good cell-mediated immunity develops after reactivation.

Despite the potential for horizontal transmission of VZV from zoster cases, neonates do not seem to be at risk of infection if maternal zoster occurs around the time of delivery (Miller et al. 1993b; Enders and Miller 2000). The reason for this is the lower infectivity of zoster compared to chickenpox; furthermore, if the onset of maternal zoster is $\geqslant$4 days before delivery, the infant passively acquires antibody from the mother, whose own pre-existing immunity is reinforced as a result of her recent reactivation.

Diagnosis

DIAGNOSIS IN PREGNANCY

In typical cases of varicella and zoster a clinical diagnosis is usually sufficient. In pregnancy VZV infection

should be verified serologically. To detect specific IgG, IgM, and IgA antibodies, the enzyme-linked immunosorbent assay (ELISA) with whole virus has become the most widely used method, and for a very rapid determination of the immune status in case of exposure the latex agglutination (LA) test is also employed. Results with both tests correlate well with cell-mediated immunity as determined by lymphoproliferative assays (Weinberg et al. 1996). It should be known that in the majority of adults (e.g. pregnant women) following primary infection VZV IgG antibodies are detected before VZV IgM antibodies due to strong cross-reaction with herpes simplex virus type 1 (Enders and Miller 2000). More recently the IgG avidity test – which is investigated for its diagnostic value since 1990 (Thomas et al. 1990) – proved in our in-house version very useful for assuring protection against VZV disease in persons with low-level IgG antibodies, for diagnosing recent infection in the absence of IgM antibodies and for differentiation of asymptomatic or symptomatic reinfection from primary infection (G. Enders, personal communication).

Virus detection is unnecessary in uncomplicated varicella, but is used in cases complicated by pneumonia or encephalitis to guide antiviral therapy and in prenatal diagnosis. Rapid diagnosis can be achieved in smears of vesicle fluid or respiratory secretion by immunofluorescence applying monoclonal antibodies for identification. Virus detection with the conventional methods such as cell culture is only successful with varicella or zoster vesicular fluid containing free virus, whereas cell-associated virus can, apart from the rapid diagnosis, be demonstrated by detection of VZV DNA. Initially VZV DNA has been detected in amniotic fluid and fetal blood by dot-blot hybridization (Gottard et al. 1991), but now detection by single round and nested PCR is the method of choice. However, positive results with n-PCR only must be judged with caution.

DIAGNOSIS IN THE FETUS

Invasive prenatal diagnosis (PD) to exclude fetal infection with VZV is feasible, but not generally recommended. PD should only be performed in women with varicella up to WG 21–22, since the risk of CVS is limited to this period. In cases where VZV DNA is detected in the amniotic fluid and the ultrasonographic scan is considered normal, the majority of infants have no clinical manifestation at birth (Mouly et al. 1997; G. Enders personal communication 1996–2004). Amniotic fluid taken at WG 18–21 and >4–6 weeks after the onset of maternal varicella is technically easy to obtain and yields the best results. In case of varicella infection and genetic indication for prenatal diagnosis the latter could be done earlier, but not before all vesicles have disappeared in order to avoid iatrogenic infection of the fetus. High-level ultrasound screening is recommended between WG 19 and 23. If the findings are abnormal, both amniotic fluid and fetal blood should be tested for VZV DNA. Tests for fetal VZV-specific IgM are not helpful, because VZV IgM antibodies are usually not detected in fetal blood. Skeletal defects may be evident by ultrasound earlier, but cerebral or ocular abnormalities are seldom recognized before WG 22–23. They may not become evident until much later in pregnancy, when therapeutic abortion is not an option. The combined use of ultrasound and magnetic resonance imaging (MRI) may document earlier the extent of tissue damage, particularly involvement of the CNS (Verstraelen et al. 2003). These findings are substantiated by the author's own prospective series on invasive prenatal diagnosis of 195 women with acute varicella up to WG 24 between 1991 and July 2004. In nine cases, detection of VZV DNA in amniotic fluid and fetal blood was associated with suspicious finding for CVS by high-level ultrasound and in some cases by additional MRI between WG 20 and 27. Following termination of pregnancy in six cases, VZV DNA could also be demonstrated by PCR in fetal blood and various types of fetal tissues and also in fluids and tissues in three cases who died shortly after birth (Enders and Miller 2000; G. Enders personal communication 2000–2004).

DIAGNOSIS IN INFANCY

The criteria for the diagnosis of fetal varicella syndrome in the infant include maternal symptomatic varicella infection during early pregnancy, presence of dermatomal cicatrial skin lesions, limb hypoplasia, and some of the other signs and symptoms associated with CVS recognizable at birth (see Table 8). Laboratory confirmation of intrauterine VZV infection is more important in cases with less typical CVS features. Concerning the immunological evidence of in utero VZV infection, IgM antibody detection, and detection of cellular immune response are unreliable markers, because IgM antibodies are only exceptionally detected with the presently used commercial ELISA IgM tests even in infants with CVS. Also the detection of a positive cellular immune response over the age of 1 month by the standard lymphocyte proliferation (^{3}H-thymidine) test has been rarely accomplished (Paryani and Arvin 1986). Attempts with the newly developed interferon-γ ELISPOT assay have not been made thus far (Smith et al. 2001). Detecting persistent VZV IgG antibodies in the infant seems to be more indicative of congenital VZV as shown in CVS cases assessed prospectively and retrospectively since 1980–2003 (Enders and Miller 1994, 2000). An even later criterion of intrauterine VZV infection is the occurrence of zoster in early infancy. Therefore, attempts to detect VZV DNA by PCR in body fluids or skin biopsies and EDTA blood should be undertaken. Positive results are limited (Mehraein et al. 1991; Puchhammer-Stöckl et al. 1994; Schulze-Oechtering et al. 2004). In contrast, DNA detection in

tissues of various organs obtained postmortem is the method of choice in cases of early death and the demonstration of miliary calcified necrosis by histopathological techniques may further support intrauterine varicella infection (Hartung et al. 1999).

Management

MANAGEMENT IN PREGNANCY

Passive prophylaxis with varicella-zoster immunoglobulin

The value of passive prophylaxis is difficult to assess because of the differences in quality of the various varicella-zoster-immunoglobulin (VZIG) preparations used worldwide. This concerns IgG antibody concentration and the test used for establishing the international units (IU). Passive antibody prophylaxis with a standardized preparation of VZIG for intramuscular application is available in the USA (CDC 1996), in the UK, France, Scandinavian countries, and Australia for exposed susceptible pregnant women to prevent or attenuate varicella.

The English preparations have a relatively low IgG antibody concentration (700 IU per adult dose) and administration of VZIG is recommended within 4–10 days of a close (e.g. home) exposure. Their effect is to attenuate disease rather than to prevent infection (Miller et al. 1993b).

In Germany, two preparations of VZV immunoglobulins with defined antibody concentrations are available for passive prophylaxis, one for intramuscular and the other for intravenous administration, with an IgG antibody concentration of approximately 2 000 IU per adult dose. The dosage for example for a 70-kg woman is 20 ml Varicellon i.m. (2 000 IU) or 70 ml Varitect i.v. (1 750 IU). It should be given within 24–72 (96) hours after exposure. According to the experience of Enders and Miller (2000) in 212 seronegative pregnancies, even if VZIG is given in the recommended dosage and within 24–72 (96) hours of exposure, infection is prevented in only 54 percent. Of the remaining cases VZIG administration results in subclinical infection (5 percent) or in modified to normal disease (41 percent). When VZIG is given 4–5 days after exposure, there is still a mitigating effect in 20 percent of patients.

In the UK and Germany, postexposure prophylaxis with VZIG is recommended only for seronegative pregnant women with significant exposure to an acute case of varicella (e.g. household contact, face-to-face contact, contact indoors with a case of chickenpox for >1 h). As a consequence of the findings in the largest prospective study (Enders and Miller 1994), that no case of CVS occurred in maternal varicella after WG 20, VZIG is no longer recommended for women exposed after WG 21. However, VZIG prophylaxis for women exposed later in pregnancy is officially recommended, also in Germany by the RKI, to reduce the risk of rare maternal complications of varicella such as pneumonia. In the UK, however, VZIG is only issued for women exposed after WG 20 if national supplies permit (Department of Health 1996b). These recommendations differ from the US recommendation, which includes all susceptible pregnant women with close contact throughout pregnancy.

It is clear that seropositive women do not need VZIG. They can be assured that they are protected against clinical disease but not completely against reinfection. In the case of exposure to zoster, passive prophylaxis is only recommended for seronegative women up to WG 21 intimately exposed to persons with extensive zoster lesions.

Whether VZIG has any benefit in preventing intrauterine infection and of CVS is not known. A certain benefit of VZIG administration during pregnancy in case of contact is deduced from the prospective studies of Enders et al. (Enders and Miller 1994 and 2000 with update). There were no CVS cases in 108 pregnancies in which maternal varicella occurred despite VZIG prophylaxis and no persistent IgG antibodies could be detected at the age of 7 months in eight infants tested.

One other study (Pastuszak et al. 1994) indicates that in order to prove such a benefit a prospective study would be needed, which includes the following: a large cohort of VZV-seronegative women with confirmed close contact to VZV who all receive the same in neutralizing units of a standardized preparation of VZIG.

Besides postexposure prophylaxis with VZIG, oral acyclovir (ACV) given at the 9th day of incubation or within 24 h after onset of exanthema (5 × 800 mg/day for 5 days) and vaccination with live-varicella vaccine within 72 h after contact may be effective. In the UK and Australia in contrast to Germany, oral ACV is offered to persons presenting within 24 h of onset of rash and given for 5 days; pregnant women over 20 weeks of gestation with varicella are treated with this regimen. However, the use of oral ACV during the incubation period or vaccination in early pregnancy is not established.

The recommendations in the UK and Germany for postexposure prophylaxis to varicella in early and late pregnancy are summarized in Table 10.

The medical advice for acute varicella at various stages in pregnancy is summarized in Table 11.

Management of exposure to zoster and zoster in pregnancy is presented in Table 12.

Active prophylaxis with vaccine

In the USA, universal vaccination of children, adolescents, and young adults including all nonpregnant women

Table 10 *Recent exposure to* varicella *in pregnancy – high contagiousness*

VZV exposure in pregnancy

Ask for previous varicella:
If yes: no testing
If no or doubtful
↓
Quick antibody test (ELISA, LA test)
AB positive: previous infection
AB low or equivocal: repeat test in 2–3 weeks
AB negative: susceptible

First and second trimester: risk for CVS	**End of third trimester around delivery: risk for severe neonatal varicella**
VZIG: until WG 21 within 24–72 (96 h) after exposure[a]	No VZIG after WG 37, because it may shift onset of exanthem to delivery, better to induce labor
New: >20 WG: ACV oral within 24 h after onset of exanthem	
Check after 2–3 weeks for preventive effect	Check antibody status in 2–3 weeks

AB, varicella-zoster antibodies; ACV, acyclovir; CVS, congenital varicella syndrome; ELISA, enzyme-linked immunosorbent assay; LA test, latex agglutination test; VZIG, varicella immunoglobulin; WG, week of gestation.
a) Personal recommendations by G. Enders; official German recommendations also include women exposed beyond 21 WG.

of childbearing age with no history of varicella has been recommended since 1996 (CDC 1996). The effectiveness of this universal childhood vaccination in the USA is indicated by a significant decline of varicella cases in the total population and, in particular, in the vaccinated age group of 1–4 years. Also the rate of hospitalization in all age groups has decreased within the first 3 years since the beginning of routine childhood vaccination. Furthermore, a reduction in pediatric hospitalizations for VZV-related invasive group A streptococcal infections

Table 11 *Acute varicella throughout pregnancy*

Management for acute varicella throughout pregnancy		
First and second trimester		
1. Counsel		Risk of CVS is low
2. Mention		Prenatal diagnosis possible in case of acute varicella in WG 1–20, ~4 weeks after onset of varicella: VZV-DNA detection with PCR/n-PCR in amniotic fluid (WG >18–21) Advocate: Ultrasound control of high level (MRI) in WG 19–24, if abnormal: PCR/n-PCR in amniotic fluid and fetal blood in WG 23/24; IgM antibodies not detected
3. Observe		VZV pneumoniae occurring mainly late second and third trimester: advice immediate i.v. acyclovir therapy at any stage of pregnancy and intensive medical support
Third trimester		
More than 6 days prior to delivery	→	No VZIG
4–5 days prior to delivery	→	If birth cannot be delayed: VZIG to mother Instead of VZIG – new: ACV oral within 24 h of onset of rash (5 × 800 mg/day for 5 days) not yet practisized VZIG to neonate and ACV i.v. before or at onset of prodromal signs
2–4 days after delivery	→	VZIG to neonate
		No isolation of mother/child (rooming-in). Breast-feeding possible, in case of florid exanthem, pump off breast milk. Observe neonate ⩾12 days in hospital and until age of 28 days at home

ACV, acyclovir; CVS, congenital varicella syndrome; n-PCR, nested polymerase chain reaction; VZIG, varicella immunoglobulin; VZV, varicella zoster virus; WG, week of gestation.

Table 12 *Exposure to zoster and zoster in pregnancy – low contagiousness, no risk for CVS or perinatal infection*

Management for exposure to zoster and zoster in pregnancy		
Recent exposure to zoster lesion		
Determination of VZV IgG antibody status:		
VZV IgG antibody positive	→	no VZIG
VZV IgG antibody negative	→	VZIG only if close contact until WG ±21
Onset of zoster		
1st–3rd trimester	→	No VZIG
(1st), 2nd, 3rd trimester	→	Acyclovir if severe manifestations, i.v., oral
±4 days prior to delivery	→	No VZIG to newborn Cover maternal zoster lesions Breast-feeding: yes, if no vesicles in area of nipples; otherwise pump off breast milk
3–4 days after delivery	→	VZIG for newborn 0.5 ml/kg weight, since maternal antibody level is still low

CVS, congenital varicella syndrome; VZIG, varicella immunoglobulin; VZV, varicella-zoster virus; WG, week of gestation.

parallel to the increase of vaccination rates has been observed. In most European countries, the universal childhood vaccination is still controversial. In July 2004, Germany, however, introduced the US childhood vaccination program encouraged by the favorable US experience (Wagenpfeil et al. 2004). It is hoped that the shift in the proportion of cases to older persons will be minimized by catch-up vaccination of adolescents and adults. Selective vaccination is recommended for seronegative risk-patients, their family contacts, healthcare workers, women who want to become pregnant, and also adolescents at the age of 12–15 years without varicella history. Children aged 1–12 years generally receive one dose of vaccine, whereas from 13 years on two doses of vaccine with an interval of 6 weeks are recommended.

Pregnancy is a contraindication for administration of live-attenuated varicella vaccine. However, the virulence of the vaccine virus is less than wild-type VZV, so the risk to the fetus, if any, is even lower and therefore inadvertent administration is no reason for termination of pregnancy. As a precaution, however, nonpregnant women who are vaccinated should avoid becoming pregnant for 1 month following each injection. A varicella vaccine in the pregnancy registry in the USA has been established, similar to that for rubella vaccine. Between 1995 and 2000, 362 women were inadvertently exposed to varicella during pregnancy or within 3 months of conception. In this group 58, of 92 seronegative women received their first dose of vaccine (Varivax) during the first or second trimester. No cases of congenital varicella syndrome were identified in 56 live-births (Shields et al. 2001). With respect to transmitting vaccine virus from vaccinees, there is one report in which the vaccinated child transmitted vaccine virus to its pregnant mother (Long 1997). Despite this observation recommendation of the German Vaccine Commission (STIKO) does not consider pregnancy of the mother as a contraindication to the vaccination of her own child (Robert Koch Institut 2004).

Furthermore, postpartum vaccination of varicella-susceptible women need not be delayed because of breast-feeding. In a study of 217 postvaccination breast milk specimens, varicella DNA was not detected by PCR. In addition, none of the breast-fed infants became seropositive (Bohlke et al. 2003).

Antiviral therapy

For antiviral chemotherapy of VZV infection, acyclovir (which has an excellent safety record), valacyclovir, brivudin, and famciclovir are available.

The efficacy of intravenous acyclovir in the treatment of chickenpox in immunocompromised people is well established. By oral application, valacyclovir, brivudin, and famciclovir have a higher bioavailability than ACV. All these drugs in intravenous and oral form are not licensed for use in pregnancy. However, in varicella complicated by, for example, pneumonia or signs of dissemination, early treatment with intravenous acyclovir at any stage of pregnancy is essential and life-saving (Haake et al. 1990; Smego and Asperilla 1991). The prospective follow-up of a total of 1 207 women treated by oral and intravenous application during the first, second, and third trimester with ACV did not show an increase in the number of birth defects when compared with those expected in the general population, or any consistent pattern of defects. Similar data have been reported on the outcome of 94 pregnancies in which oral valacyclovir had been given (Enders and Miller 2000). The use of oral ACV following exposure as a postprophylactic measure has already been discussed. For cases of CVS antiviral therapy is recommended, particularly, in those in which VZV DNA in fluids and lesions is detected (ACV 30–60 mg/kg/day i.v., divided into three single doses).

MANAGEMENT OF THE NEONATE

For neonates whose mothers have varicella around the time of delivery, prophylaxis with VZIG is recommended to prevent neonatal infection or to modify the disease. In the USA and Germany, prophylaxis is only recommended for neonates whose mothers develop varicella between 5 days before, to 2 days after, delivery (CDC 1996); while in the UK prophylaxis is recommended for any infant whose mother develops varicella in the 14-day period centered on delivery (Department of Health 1996b). In the UK, VZIG is also recommended for infants with nonmaternal postnatal exposure during the first 7 days of life and who lack VZV antibodies. In the USA and UK, susceptible infants can be identified by testing a stored antenatal blood sample from mothers with a negative history of chickenpox. In the USA and Germany, prophylaxis for postnatal exposure is restricted to premature infants. However, all preterm infants less than 28 weeks or infants weighing less than 1 000 g exposed to acute cases should be given VZIG (0.5 ml/kg i.m.) regardless of a positive maternal history of varicella (Deutsche Gesellschaft für pädiatrische Infektiologie 2003) and regardless of low-level IgG antibodies in the infant.

If severe varicella develops in the infant despite treatment with VZIG, high-dose intravenous acyclovir should be given (Reynolds et al. 1999). Fatal outcomes have been reported despite VZIG prophylaxis and treatment with ACV (Holland et al. 1986; King et al. 1986). All were in infants whose mothers developed varicella within the period 4 days before, to 2 days after, delivery. Early treatment with intravenous ACV of infected neonates in this high-risk period is therefore recommended (Nathwani et al. 1998; Reynolds et al. 1999). Prophylactic use of intravenous ACV in this group has also been advocated (Sills et al. 1987), but there is no evidence of efficacy. For limitation of the existing symptoms and further symptoms by interrupting possibly still ongoing virus replication, ACV therapy is carried out.

At present, there is no convincing information about whether mothers who develop varicella in the high-risk period around the time of delivery should breastfeed or be isolated from their infants. Not unexpectedly, VZV DNA has been detected by PCR in breast milk (Yoshida et al. 1992), but whether VZV was transmitted to the newborn via breast milk could not be determined because the mother was breast-feeding in the 24 h prior to rash onset. Furthermore, neonates whose mothers have varicella shortly before delivery may have already been infected transplacentally at the time of birth.

For those infants whose mothers develop varicella in the puerperium, transmission during the infectious period before rash onset is likely. Therefore isolation of the infant from the mother is questioned (Trompeter et al. 1986; Stephenson 1993).

Management of nosocomial exposure

Despite the concern raised when varicella exposure occurs in an antenatal clinic or neonatal intensive care unit, documented nosocomial transmissions in these groups are rare. This is probably due to the low intensity of exposure, particularly in neonatal units. Furthermore, the majority (approximately 90–95 percent) of the neonates, also premature and low birth weight infants, have low or medium maternal antibody titers which may be protective. The index case is often a healthcare worker or visitor and control measures may require extensive VZV antibody testing of patients and staff contacts. To avoid unnecessary use of VZIG for the newborn only neonates of seronegative mothers should receive VZIG.

Newborns with CVS have to be isolated from other neonates although there is no report of an infection transmitted by the respiratory route or by intimate contact. Asymptomatic newborns whose mothers develop varicella 5 days before to 2 days after delivery do not need to be isolated from other babies.

For more than 20 years it has been stipulated that medical and healthcare workers should know their immunity status and since the availability of live vaccine in 1995, vaccination of susceptible healthcare workers is recommended.

Recommendations for limiting nosocomial spread of varicella are listed in Table 13.

HERPES SIMPLEX VIRUS TYPES 1 AND 2

Maternal herpes simplex virus (HSV), primary and recurrent genital infection, which is frequently asymptomatic, may cause neonatal herpes. Although infrequent, neonatal herpes is a devastating disease with a high rate of morbidity and mortality despite early and appropriate therapy. Because its incidence is significantly higher in the USA than elsewhere, special efforts are being made in that country to establish a reliable and cost-effective strategy for prevention.

Infection in pregnancy

EPIDEMIOLOGY OF MATERNAL HSV INFECTION

In the past, approximately 90 percent of herpetic genital infections were caused by HSV-2, but more recently HSV-1 has been implicated as the cause of up to 40 percent of cases of primary genital herpes in seronegative adults. However, the reactivation rate for genital HSV-2 is at least twice as high as for HSV-1, and so too are the risks of transmission by sexual intercourse and of neonatal herpes infection (Forsgren 1992; Koelle et al. 1992; Corey et al. 1996). This was confirmed in a recent study in the UK. The prevalence of HSV-1 antibodies among attenders of a sexually transmitted disease

Table 13 *Limitation of nosocomial varicella transmission*

Group	Action
For hospital staff	
Test for VZV IgG antibody	In personnel before working in maternity/newborn wards and wards for immunosuppressed patients
In case of exposure, test for IgG antibody if immunity status is unknown	Seropositive staff: remain on ward
	Seronegative staff: removal from work 8–21 days after exposure to a case of varicella or immediate vaccination with live vaccine
	Vaccinees: develop IgG antibody in low titer within 10–12 days. Should avoid close association with susceptible high-risk individuals if they develop some vesicles
For pregnant women	
Exposed to cases with acute varicella shortly before and after delivery	Determine IgG antibody titer Mother antibody-positive → no VZIG to neonate Mother antibody-negative → VZIG to neonate
For infants in neonatal care	
In case of exposure in the first 7 days of life	Determine IgG antibody titer Infants VZV-IgG positive → no VZIG[a] Infants VZV-IgG negative → VZIG
Newborn with CVS	Isolation mother and baby (rooming-in), contagiousness low

VZIG, varicella immune globulin; VZV, varicella-zoster virus.
a) Except premature neonates born before 25 weeks gestational age and/or with birth weight of less than 1 000 g.

(STD) clinic was 60 percent and among the blood donors 46 percent (n = 1 494). The increasing genital herpes infection due to HSV-1 was strongly associated with early age of first sexual intercourse (Cowan et al. 2002).

Seroprevalence studies with HSV type-specific antigens have demonstrated rates of HSV-1 infection of approximately 30 percent in people aged 20–40 years in higher socioeconomic groups and approximately 80 percent in those of lower socioeconomic groups (Corey and Spear 1986a, 1986b; Johnson et al. 1989). Thus people with higher living standards now acquire HSV-1 infection less frequently in childhood than they did in the past. The consequent lack of partial cross-protection may be one of the reasons for the higher frequency and severity of primary HSV-2 and HSV-1 genital infection (Koutsky et al. 1990; Bernstein 1991).

Most surveys of seroprevalence have shown a relatively low but increasing rate of HSV-2 infection during the last decade in the general adult population in the developed world; for example, in the USA from 16 percent in 1976–1980 to approximately 22 percent in 1989–1991 (Johnson et al. 1989, 1994). HSV-2 seroprevalence in women of childbearing age in the USA varied from 10 to 35 percent in white women and from 35 to 60 percent in black women (Johnson et al. 1989; Arvin and Prober 1990). In other surveys, the HSV-2 seroprevalences in pregnant women in various countries ranged between 10 and 33 percent, and in most of the HSV-2-seropositive women, a large proportion (55–87 percent) had asymptomatic infections (Slomka 1996). This finding led to alterations to the preventive strategies previously suggested (Prober et al. 1988; Randolph et al. 1993). A global review of type-specific HSV seroepidemiologic surveys shows that HSV-2 prevalence is higher in Africa and the Americas (South America), lower in western and southern Europe than in northern Europe and north America, and lowest in Asia (Smith and Robinson 2002).

CLASSIFICATION OF GENITAL HERPES INFECTION

Genital herpes infections are defined as primary first episode, nonprimary first episode, or recurrent infections. Primary first episode infections are those with seroconversion for either type 1 or type 2; in nonprimary first episode infection, seroconversion occurs to one type in the presence of antibody to the other type; and in recurrent – also called reactivated – infection, homologous antibodies to the type in question are already present.

Primary infection

Initial genital infection due to herpes may be either asymptomatic or associated with severe symptoms. With

symptomatic primary infection, lesions may occur on the vulva, vagina, or cervix, or on all three between 2 and 14 days following exposure to infectious virus. These lesions are larger in number and size than those observed in patients with recurrent disease and patients who have had prior infection with HSV-1.

When systemic symptoms (malaise, myalgia, and fever) occur (low risk), they are most commonly restricted to presumed primary herpetic infections. These symptoms reflect the viremia that occurs more likely with primary infection. Subclinical cervical and vulvar shedding occur at a rate of approximately 2.3 percent in women with HSV-2 infection and 0.65 percent in women with HSV-1 infection (ACOG, 2000a).

Nonprimary first episode

Prior infection with HSV-1 does not fully protect a patient from initial infection with HSV-2 in the genital tract. There are fewer systemic manifestations, less pain, a briefer duration of viral shedding, and a more rapid resolution of the clinical lesions in the nonprimary infection. These episodes are usually thought to be the result of an initial HSV-2 infection in the presence of partially protective HSV-1 antibodies.

Recurrent infection

Shedding of the virus from the genital tract without symptoms or signs of clinical lesions (subclinical shedding) is episodic and lasts an average of 1.5 days (ACOG 2000b). The clinical signs of genital herpes are present in approximately 25–30 percent of infected women (Table 14).

Table 14 *Classification of genital herpes simplex infection and viral shedding*

Infection	Clinical characteristics
Primary first-episode infection: HSV-2 (HSV-1)	Seroconversion for either type 1 or 2 Characteristic genital lesions, sometimes with systemic illness Low risk of disseminated severe disease Virus shedding in the cervix (ca. 3 weeks) and in high concentration, often continuing after clinical healing
Nonprimary first-episode infection: HSV-2, (HSV-1)	Seroconversion to one type in the presence of antibody to the other type Significant to moderate local symptoms, but little systemic illness Virus shedding often similar to that in primary infection
Recurrent infection: HSV-2 (HSV-1)	Homologous pre-existing antibody Usually minor or no local symptoms Viral shedding in low concentration during the very early phase for 2–5 days

(HSV-1), less common.

EFFECT ON PREGNANCY

The form of genital infection at the time of delivery is of major importance, whereas primary or recurrent oropharyngeal type 1 infections are of little significance. Severe disease after primary oropharyngeal or genital infection in pregnancy is rare. The first case of disseminated HSV infection in pregnancy was reported by Flewett et al. (1969). Since then 25 cases have been described in the English language literature (Kang and Graves 1999; Frederick et al. 2002), which occurred between WG 22 and 38 with an average gestational age of 36 weeks. Both HSV serotypes have been implicated with type 2 more prevalent accounting for 63 percent of cases. HSV hepatitis presents as anicteric hepatic dysfunction with highly elevated transaminases, fever, and abdominal tenderness. Symptoms of central nervous system involvement ranging from lethargy to seizures and coma may be observed in 50 percent of cases. Maternal mortality from 24 reported cases is 39 percent. Three of those received ACV therapy and six were not or inadequately treated. Early diagnosis and early initiation of antiviral therapy with i.v. acyclovir plays a major role in improving survival. Only three patients (20 percent) on antiviral acyclovir died and these three received antivirals late in their clinical course, whereas the mortality rate in patients without antiviral therapy was 67 percent. The overall perinatal mortality, excluding terminated gestations, was 39 percent, but evidence of HSV infections by virus detection in the tissues of these infants was very limited. The review of the reported cases shows that fever and anicteric hepatitis in the third trimester should prompt an investigation for disseminated herpes simplex infection and early treatment with acyclovir will reduce maternal and fetal mortality and morbidity.

Primary genital infections with HSV-2 up to midgestation have been associated with an increased rate of abortion (Nahmias et al. 1971). However, these findings were not confirmed in another study of 94 women with seroconversion during pregnancy (Brown et al. 1997). In the second or third trimester, intrauterine growth retardation and prematurity can occur (Brown et al. 1987). Furthermore, maternal primary, and less often nonprimary first episode infection during the first or second trimester, may lead to congenital infection with severe disease evident at birth (Hutto et al. 1987; Hoppen et al. 2001).

RISK FACTORS IN MOTHER–INFANT TRANSMISSION

Most infants with neonatal herpes acquire infection by passage through an infected birth canal. Mothers with a known history of genital herpes and those with unrecognized genital herpes infection (approximately 70 percent) are at risk of transmitting HSV to their infants. For the intrapartum route of transmission, the risk of neonatal infection depends on the form of maternal genital infection and is directly related to viral shedding into the cervicovaginal secretion at the onset of labor.

Brown and colleagues (Brown et al. 1991) made a prospective study of the very important group of women who are asymptomatic at onset of labor. Viral shedding in the genital tract at the beginning of labor occurred in 56 of 15 923 women (0.35 percent). Of these, 51 shed HSV-2 and five HSV-1. Serological tests revealed that 35 percent of the women with HSV shedding at the onset of labor had recently acquired primary infection or first episode genital infection. Vertical transmission occurred in 12.5 percent in women with positive HSV cultures and in 0.02 percent of those with negative cultures, indicating that viral shedding is not always detectable. Neonatal herpes developed in 33 percent of the babies born to women with recent primary or first episode genital infections, but in only 3 percent of those born to mothers with recurrent asymptomatic infection. The incidence of neonatal herpes in this study population was one per 2 000 live births. In a new prospective study of Brown et al. (2003) the outcome of 58 632 pregnancies with an incidence of neonatal herpes of 1:3 200 per live births. One of the novel finding in this study was that the neonatal HSV infection rate was reduced by cesarean delivery (1.2 percent) versus vaginal delivery (7.7 percent). Only one woman with subclinical nonprimary first-episode HSV-2 infection infected her child after undergoing a cesarean delivery because of failure to progress 19 h after rupture of the membranes. Another novel finding was the high efficiency of transmission of HSV-1 (45 percent) from mother to infant, both from primary infection and reactivation of genital HSV-1, among women with genital shedding.

The results of this study indicate that the risk of virus transmission to vaginally delivered infants is approximately 44 percent (3/3 with HSV-1; 1/6 with HSV-2) in women with primary infection 23 percent (0/1 with HSV-1; 4/16 with HSV-2) in those with nonprimary first-episode HSV genital infection shortly (<2 weeks) before delivery, 1.3 percent (2/11 with HSV-1; 0/140 with HSV-2) in women with recurrent lesions and <3 percent in those with recurrent asymptomatic infection (Brown et al. 2003).

ADDITIONAL RISK FACTORS IN MOTHER–INFANT TRANSMISSION

Additional risk factors for virus transmission and neonatal disease are prolonged ruptured or leaky membranes (>6 h before delivery), increasing the risk of intrauterine infection by the ascending route. Fetal scalp electrode monitoring, forceps delivery, or vacuum extraction may provide portals of virus entry in the newborn (Brown et al. 1991; Malm et al. 1991; Forsgren 1992). Other risk factors for neonatal HSV not statistically proven were younger maternal age (Brown et al. 2003).

Effects on the neonate

INCIDENCE OF NEONATAL DISEASE

Neonatal herpes in the USA occurs at an estimated annual rate of one per 3 500–5 000 deliveries, but may be as high as one per 2 000 in certain population groups with high HSV-2 seroprevalence (e.g. Whitley 1994). For unknown reasons, the annual incidence is much lower in some other countries, for example, the UK (1/40 000–60 000) and Sweden (1/15 000), even though the seroprevalences of HSV-1 and HSV-2 in European countries are comparable with those in the USA. In general, a larger proportion of neonatal infections in these countries, as well as in Germany (where no incidence rates are available) has been predominantly caused between 1993 and 1994 by HSV-2 than HSV-1, thereafter up to now by HSV-1 (1995–2004). A nationwide survey in Japan also indicated that twice as many neonatal infections are due to HSV-1 (Morishima et al. 1996). Similar observations have been reported from the Netherlands, where 73 percent of neonatal herpes cases (2.4 cases per 100 000 neonates) are caused by HSV-1 with a seroprevalence rate for HSV-1 of 61–75 percent and for HSV-2 of 11–35 percent in three different cities (Amsterdam, Nijmegen, Rotterdam) (Gaytant et al. 2002).

PATHOGENESIS OF NEONATAL INFECTION

Of the reported neonatal herpes cases in the USA, approximately 4 percent are acquired in utero, 86 percent intrapartum, and 10 percent postnatally (Whitley 1993; Arvin and Whitley 2001).

Transmission of infection in utero occurs transplacentally in <2 percent of cases, most probably in early to mid-gestation, because physical signs are present at birth and include some unusual stigmata (e.g. hydrocephalus, chorioretinitis); a further 2–3 percent arise late in gestation by the ascending route. In intrapartum transmission, the higher infection rate in infants born to mothers with primary or primary first-episode genital herpes shortly before delivery, causing most cases of neonatal herpes, is related both to viral shedding in high concentration and to the absence of maternal neutralizing antibodies (see, for example, Yeager et al. 1980; Brown et al. 1991; Whitley 1994). This is in contrast to recurrent infection, in which virus is shed for a shorter period in low amounts and maternal antibodies against the infecting type are passed to the newborn. Postnatal infections are acquired from maternal sources (oral, genital, and breast

lesions), or close contact with people with herpetic lesions (e.g. of the mouth or fingers), or by nosocomial spread from other infected babies.

IMMUNE RESPONSE IN THE INFECTED NEWBORN

In infected newborns the cellular immune response is suppressed and delayed as indicated by an absent or delayed T-lymphocyte proliferative response and decreased interferon-α and -γ production in response to herpes simplex antigen (see, for example, Kahlon and Whitley 1988; Cederblad et al. 1989). The IgG antibody response is initially not recognizable because, in the first 6–8 weeks, it cannot be distinguished from maternal antibody. Specific IgM antibodies develop within the first 2–3 weeks of illness and remain detectable for approximately 6–8 weeks. Specific IgG antibodies persist at medium to low titers for life. Transplacentally transferred neutralizing and antibody-dependent cell-mediated cytotoxic (ADCC) antibodies modify the severity of neonatal disease (Kohl et al. 1989).

CLINICAL MANIFESTATIONS

Neonatal herpes is almost invariably overt and frequently lethal. The most severely affected infants are those with in utero infection acquired early in pregnancy (<2 percent) with physical signs apparent at birth. Lesions include skin vesicles or scarring, chorioretinitis, microcephaly, and hydrocephaly (Hutto et al. 1987). So far, more than 30 such cases have been identified but the estimated incidence (one per 200 000 live births) is low. Infants with intrauterine infections acquired late by the ascending route (2–3 percent) usually present only with skin or eye lesions at birth, without multiorgan involvement (Baldwin and Whitley 1989; Whitley 1993; Arvin and Whitley 2001). Yet, there are also reports on disseminated neonatal herpes caused by late maternal ascending infection (Vasileiadis et al. 2003).

In a scheme based on large prospective studies, neonatal herpes cases are classified according to the three general patterns of infection, each occurring in about one third of cases (Forsgren 1992; Whitley 1994; Harrison 1995; Arvin and Whitley 2001) (Table 15).

In general, neonatal disease caused by HSV-1 seemed to have a better prognosis than that caused by HSV-2 (Forsgren 1992). However, in the national Japanese survey on neonatal herpes, although similar patterns of disease were evident, the type of virus had no significant effects on mortality, morbidity, and response to treatment (Morishima et al. 1996). This was also shown by Enders et al. (unpublished).

Diagnosis

DIAGNOSIS IN PREGNANCY

Maternal infection with typical mucocutaneous lesions in the oropharynx and the genital tract is easily diagnosed but less typical, minor genital lesions need laboratory confirmation.

PCR is the most sensitive method for detecting both HSV-1 and HSV-2, and can be used at the onset of labor for a rapid decision on the mode of delivery (Schalasta et al. 2000), high levels of HSV DNA in the maternal secretion increasing the probability of transmission to the infant. Assessment of the type-specific antibodies to both HSV-1 and HSV-2 in late pregnancy is essential for identifying mothers at risk of infecting their infants during delivery. The risk is highest in women with primary or nonprimary first-episode infection who seroconvert during pregnancy. ELISA and immunofluorescence tests with nontype-specific antigens detect seroconversion for IgG and IgM antibodies in primary oropharyngeal and genital infections and rises in specific IgG in genital first episodes; in recurrent infections (symptomatic or asymptomatic), there is no rise in specific IgG level and IgM is not detectable. The more cumbersome neutralization test, although not routinely used, is employed for determining the amount of protective antibodies in maternal and newborn blood.

None of the conventional tests, however, can accurately distinguish between type 1- and type 2-specific antibodies. This is possible only with assays (e.g. immunoblot, immunodot, gG2 indirect ELISA) employing recombinant expressed or native purified glycoprotein G antigen (gG-1 for HSV-1, gG-2 for HSV-2) (Svennerholm et al.

Table 15 *Classification, pattern, and outcome of neonatal HSV disease*

Disease	Onset of signs after birth	Mortality		Prognosis in survivors
		No therapy	With therapy	
Disseminated CNS, lung, liver, adrenals, SEM	6–12 days[a]	>80%	>50%	40% develop normally
CNS encephalitis/meningitis in 37–48% without SEM	16–18 days	>50%	15%	In ca. 56% neurological and ophthalmological impairment and recurrent skin lesions
SEM skin/eye/mouth	7–10 days	ND	0%	In $\geqslant$20% neurological impairment, recurrent skin lesions

ND, no data.
a) Onset at 12 days is less frequent.

1984; Johnson et al. 1989; Forsgren 1992; Slomka 1996; Enders et al. 1998; Ashley 2002). HSV-2 type-specific IgM antibodies may also be detected more easily by such assays (Ho et al. 1993). However, certain problems with immunoblot versus ELISA tests with regard to low values have to be recognized (Cherpes et al. 2003). It should be noted that the interval between onset of a primary or first episode genital infection to the detection of type-specific antibodies may range from 2 to 3 weeks for HSV-1 and from 2 to 4 weeks for HSV-2 (Ashley et al. 1988; Ho et al. 1993). The influence of immediate ACV therapy on prolonging seroconversion has to be considered (Ashley and Corey 1984).

DIAGNOSIS IN NEONATE AND INFANT

Cases with skin vesicles are easily recognized; neonatal herpes should also be considered in the differential diagnosis of severe generalized disease or of encephalitis within the first 6 weeks of life.

The most direct means of laboratory diagnosis is viral detection, especially by PCR, which is particularly useful for tests on cerebrospinal fluid (CSF). Serology is of little help in the first weeks of life. Testing the maternal serum together with acute phase and later sera of the infant is essential. A presumptive retrospective diagnosis of a child damaged by HSV-2 is obtained by demonstrating persistent IgG antibodies to HSV-2 or by isolating the virus from recurrent vesicles, because HSV-2 infections are rare before the onset of sexual activity (Malm et al. 1991).

Management in pregnancy and of the neonate

At the first antenatal visit, a careful history should be taken of genital infections in the woman herself and her sexual partner, together with visual inspection of her genital tract both at this visit and at the onset of labor. If lesions are seen, swabs should be taken for virus detection, but a decision on cesarean section rests mainly on the presence of visible lesions. If serological tests are used, seroconversion to HSV-2 antibody-positive during pregnancy may be an indication for rapid virus detection by PCR and possible treatment; this approach might reduce the need for cesarean section.

Cesarean sections, considered at present as the only effective means of preventing neonatal herpes infection, are performed on up to 70 percent of women in the USA with a history of genital herpes, because of possible fetal infection and of medicolegal considerations. It is recommended generally for women with visible cervicovaginal lesions at onset of labor, irrespective of the antibody status or viral shedding, and is best performed before rupture of the membranes. The procedure will, however, not always prevent neonatal herpes, even if performed before rupture of the membranes, and especially not after they have been ruptured for more than 4 h (Stone et al. 1989; Randolph et al. 1993).

Prenatal diagnosis is not recommended because the fetus is rarely transplacentally infected until mid-gestation. Termination of pregnancy in women with disseminated disease is not an option.

For immunoprophylaxis, specific immunoglobulins, humanized murine and human monoclonal antibodies, and hyperimmunoglobulin with high neutralizing activity (but never commercially available) have been developed for administration to neonates lacking maternal antibodies. Vaccines for prevention and treatment, particularly of HSV-2 genital infections, have also been developed and a candidate subunit vaccine is still on trial (Stanberry et al. 2002; Whitley and Roizman 2002).

Acyclovir or its derivatives are the mainstay of antiviral therapy for both topical and systemic application. Although this drug is not licensed for use in pregnancy, no association has so far been identified between its use in pregnancy and adverse effects in mother or child (Kroon and Whitley 1995). This was shown by a large registry of acyclovir use in pregnancy for both HSV and varicella pneumonia which was established in the USA (1984–1998). Up until its closure in 1998, no evidence of any increase in adverse fetal effects related to drug exposure in any trimester, in comparison with the general population, was reported (Enders and Miller 2000).

In maternal primary disseminated infection, early intravenous treatment with acyclovir (i.v. 10 mg/kg every 8 h for 10–14 days) at any stage of pregnancy is recommended. Oral treatment with acyclovir (400 mg three times daily for 14 days) is considered beneficial for women with recognized primary or non-primary first-episode genital infection in the later stages of pregnancy. This is also the case in maternal primary oral infection (e.g. gingivostomatitis) shortly before term, at delivery, or in the neonatal period and in primary genital herpes in the neonatal period. To suppress viral shedding during labor in women with recurrent lesions in late pregnancy, prophylactic oral use (400 mg three times daily) approximately 10 days before delivery (Stray-Pedersen 1990; Haddad et al. 1993) is still controversial for various reasons, such as potential renal toxicity for the fetus, occasional virus shedding despite suppressive treatment (Katz et al. 1995), and the question of its value. The need for suppressive therapy in the above-mentioned target group is limited, because there is only a low prospective risk to babies born to women with recurrent lesions, in contrast to those born to mothers with unrecognized primary and non-primary first-episode genital infections (Kroon and Whitley 1995; Arvin and Whitley 2001). Hence a recently published double-blind, randomized, placebo-controlled trial of acyclovir in late pregnancy shows that acyclovir significantly reduced, but did not eliminate, herpes simplex virus lesions in the genital tract and detection of HSV

DNA by PCR in genital secretion in late pregnancy (Watts et al. 2003).

The prophylactic administration of acyclovir to vaginally delivered asymptomatic newborns at risk of infection depends mainly on the form of maternal infection and the virus load in the maternal secretion. Follow up for clinical and laboratory signs of infection is recommended up to 4 weeks after delivery (e.g. Forsgren 1992; Whitley 1994; Arvin and Whitley 2001). Opinions on administration of acyclovir to exposed vaginally delivered infants who have no signs of infection are controversial. However, prophylactic treatment should be considered for infants of mothers with high-risk markers for primary or primary first-episode genital infection.

B19 VIRUS (PARVOVIRUS B19)

The *B19 virus* (B19), belonging to the genus *Erythrovirus*, family *Parvoviridae*, was discovered in the plasma of healthy blood donors in 1975, and recognized in 1983 as the cause of erythema infectiosum. In 1984, its causative role in hydrops fetalis and fetal death became evident and in 1993 blood group P antigen (glycolipide-globoside) was identified as the cellular receptor for parvovirus B19 (Brown et al. 1993). Since 1995, parvovirus B19 has become associated with a wide spectrum of hematological and nonhematological complications.

Recently, a second human erythrovirus, the V9 isolate, was detected in the serum and bone marrow of a child with transient aplastic anemia (Nguyen et al. 1999; Servant et al. 2002). The prevalence of V9 and its association with clinical disease and significance for pregnancy remains to be evaluated.

Postnatal infection

Postnatal infection of parvovirus B19 is acquired through aerosol droplets by the respiratory route by close person-to-person contact, but may also occur through blood-derived products administered parenterally. Transmission via respiratory secretions is greatest during viremia and before clinical signs are apparent, complicating efforts to control transmission. The incubation time ranges between 8 and 18 days (Anderson et al. 1985; Joseph 1986), the contagious period lasts from 5 to 7 days before, and until 2 to 4 days after, onset of symptoms. First-phase illness appears approximately 8 days after infection and second-phase illness with typical symptoms about 17/18 days. All immunocompetent people with or without characteristic symptoms develop antibodies to parvovirus B19 and presumably lasting immunity that protect them against infection with the virus in the future. The seroprevalence rate in childbearing age, in adults and in pregnancy ranges from 30 to 60 percent in individual countries and with regional differences (Cohen and Buckley 1988; Enders and Biber 1990; Kelly et al. 2000).

Infections in temperate climates are common in late winter, spring, and the early summer months. Rates of infection may rise to an epidemic level every 3–4 years. During epidemic periods, women of childbearing age show an annual seroconversion rate of 13 percent compared with 1.5 percent in endemic periods (Koch and Adler 1989; Valeur-Jensen et al. 1999; Jensen et al. 2000). During outbreaks, secondary spread to seronegative contacts is very common. The infection rate in susceptible children and adults is up to 50 percent within families and approximately 20 percent for care workers and teachers in primary school being highest for those in contact with younger and greater numbers of infected children (Gillespie et al. 1990). During school outbreaks, 10–60 percent of students may get fifth disease (CDC 2000). A serological study on the occupational risk in employees of hospital and elementary schools during an endemic period revealed that those persons in daily contact with school-age children had a fivefold increased annual occupational risk for infection (Adler et al. 1993).

In pregnancy, approximately 60 percent of infections are asymptomatic or clinically uncharacteristic, for example, without the typical slapped-cheek rash and the lacy red rash on the trunk and limbs, but often associated with joint swelling which lasts usually for 1–2 weeks, and more rarely for several months. Most frequently affected are the joints of the hands, wrists, and knees (Woolf et al. 1989; Enders and Biber 1990).

Effects on the fetus

PATHOGENESIS OF FETAL INFECTION

The main cellular receptor for B19 virus (the blood group P antigen, a glycolipid-globoside), is expressed on mature erythrocytes and erythroid progenitor cells. Abundant productive infection with cell lysis has only been demonstrated in the nucleated, rapidly dividing erythroid progenitors (burst-forming units erythroid (BFU-E) and colony-forming units erythroid (CFU-E)) in bone marrow and fetal liver (Morey and Fleming 1992). The inhibition of fetal erythropoiesis occurs mainly in the late pronormoblast stage in which intranuclear inclusions (Lantern cells) are commonly detected. Direct toxic cell injury, as well as B19-induced apoptosis and cell cycle arrest may be involved in the pathogenesis of erythroid aplasia (Chisaka et al. 2003). The damage of the erythroid progenitor cells, e.g. in the bone marrow, spleen, and liver during the time of a rapidly expanding red-cell volume combined with a shortened fetal red-cell life span of 45–70 days produces a profound aplastic crisis in the fetus with a resultant anemia culminating in cardiovascular decompensation, hydrops, ascites, and fetal death.

P antigen is also presented on nonerythroid cells, for example, megakaryocytes, endothelial cells, placental villous trophoblast cells, and cardiac myocytes. However, none of these cells are fully permissive for B19 replication. Various reasons for the nonpermissiveness are discussed and include incomplete virus replication (Liu et al. 1992), the need for a second receptor for viral entry (Weigel-Kelley et al. 2003) or a viral phospholipase A2 which appears to be necessary for B19 infectivity (Zadori et al. 2001; Heegaard and Brown 2002). Nevertheless, B19 was found to infect fetal myocardial cells and was associated with fetal myocarditis (Soulie 1995; von Kaisenberg et al. 2001). Hence, not only anemia but also myocarditis may be implicated in the pathogenesis of hydrops fetalis.

The presence of the globoside receptor on trophoblast cells may play a role in transmission of the virus across the placenta. It was observed that the immunoreactivity for globoside was strongest in the villous trophoblast cells of first trimester placentas with diminished reactivity in second trimester placentas and a near lack of staining for the antigen in those of third trimester. The observed change found in globoside immunoreactivity correlates well with the fact that fetal outcome is worse when maternal infection occurs during the first or second trimester as compared with an infection occurring near term (Jordan and DeLoia 1999). Furthermore, an enhanced apoptotic activity within placental villous trophoblast cells in pregnancies complicated by B19 infection was described. Damage to the protective trophoblast layer may compromise the integrity of the placenta, and cause fetal loss not necessarily associated with fetal infection (Jordan and Butchko 2002).

FETAL COMPLICATIONS

The virus may cross the placenta at any time during pregnancy and infection is possible as early as 6 weeks of gestation (Nunoue et al. 2002). The overall transplacental transmission rate was estimated to be 33 percent based on an adverse outcome, parvovirus B19 IgM in cord or neonatal blood, and on the persistence of specific IgG antibodies (Miller et al. 1998; Public Health Laboratory Service Working Party on Fifth Disease 1990) and others have reported similar rates (Gratacós et al. 1995; Koch et al. 1998).

The major risks are spontaneous abortion, stillbirth, and hydrops fetalis (HF). The interval between onset of maternal infection and fetal complications may range from 2 to 17 weeks (Miller et al. 1998), 2–6 weeks (Yaegashi et al. 1998), and 2–20 weeks (Nunoue et al. 2002).

Fetal loss

The rates of fetal loss varied in some small numbered prospective studies between 1.66 percent (one of 60 infected mothers) (Gratacós et al. 1995), 5 percent (2/39) (Rodis et al. 1990), 15 percent (7/48) Yaegashi et al. 1999), and 0 percent (0/52) (Harger et al. 1998). In two prospective studies from the UK, 427 pregnant women with acute B19 virus infection were investigated (Public Health Laboratory Service Working Party on Fifth Disease 1990; Miller et al. 1998). The excess rate of fetal loss was confined to the first 20 weeks of gestation and averaged 9 percent. In our prospective study, 1 018 pregnant women with B19 infection were enrolled and the excess rate of fetal loss was also confined to the first 20 WG, but slightly smaller (5.6 percent). The median interval between maternal infection and diagnosis of fetal death was 2 weeks (Enders et al. 2004). Although the majority of B19 infections associated with fetal death occur in the first 20 WG, intrauterine death in late pregnancy without signs of fetal hydrops has been reported by different authors (Skjöldebrand-Sparre et al. 2000; Tolfvenstam et al. 2001; Norbeck et al. 2002). According to our observations and to the findings of other studies (e.g. Miller et al. 1998), there seems to be no such association.

Nonimmune hydrops fetalis

In 1984, the first case of hydrops fetalis associated with confirmed parvovirus B19 infection was reported by Brown et al. (1984). The risk of fetal hydrops in the two English studies (Public Health Laboratory Service Working Party on Fifth Disease 1990; Miller et al. 1998) was diagnosed to be 2.9 percent. In our investigation, hydrops fetalis was diagnosed in 3.9 percent (40/1018) throughout pregnancy with a maximum of 7.1 percent (23/322) when maternal infection occurred between WG 13 and 20. The rate was lower than 1 percent when maternal B19 infection occurred after WG 32. The median interval between maternal infection and diagnosis of hydrops was 21 days. In the rates of hydrops, there were no significant differences between asymptomatic and symptomatic maternal infection (Enders et al. 2004). It should be noted that hydrops can resolve spontaneously without apparent ill-effects on the infant (Morey et al. 1991; Pryde et al. 1992, Sheikh et al. 1992; Zerbini et al. 1993; Tercanli et al. 1996). In the large study of Rodis et al. (1998a) with 539 cases of parvovirus B19 induced hydrops 34 percent resolved spontaneously.

DISEASES POSSIBLY DUE TO FETAL PARVOVIRUS B19 INFECTION

In addition to the fetal complications described above, B19 virus infection has been suspected to lead, if the fetus survives, to specific and permanent organ defects. Most of those findings have been made in aborted fetuses with B19 infection and involvement of myocardial cells (Porter et al. 1988), eye anomalies, and damage to other tissues (Weiland et al. 1987) or with bilateral cleft lip and palate, micrognathia, and webbed joints (Tiessen et al. 1994). Systematic studies, however,

have failed to substantiate congenital malformations caused by parvovirus B19.

Brown and colleagues (1994) described three cases with chronic anemia closely resembling congenital red cell aplasia (Diamond–Blackfan anemia). In all three, the sera lacked B19 DNA, but viral DNA was found in bone marrow. In one instance hepatic disease was associated with intrauterine B19 infection in a premature newborn (Metzman et al. 1989). Furthermore, a case of 'prune belly' after maternal B19 infection and hydrops fetalis has been reported (Walther et al. 1994). There is a more important preliminary report on three live-born infants with severe nervous system anomalies following serologically confirmed maternal B19 infection (Conry et al. 1993), but a follow-up on these children is missing. One report concerns fetal B19 infection and meconium peritonitis (Schild et al. 1998) and another one fetal parvovirus B19 myocarditis with terminal cardiac heart failure and perinatal heart transplantation (von Kaisenberg et al. 2001).

IMMEDIATE AND LONG-TERM OUTCOME OF B19 INFECTION IN PREGNANCY

In the study of Miller et al. (1998), no abnormalities attributable to parvovirus B19 infection were found at birth in surviving infants and no late effects were diagnosed at 7–10 years. The congenital infection rate was estimated with 22 percent based on the detection of IgG antibodies in children at least 1 year of age. It was concluded that the maximum possible risk of congenital abnormality is under 1 percent and the long-term development will be normal (Miller et al. 1998). In another study, the favorable long-term outcome in 108 children exposed in utero to maternal parvovirus B19 infection at the median age of 4 years (range from 6 months to 7 years) was described (Rodis et al. 1998b). Our observations on the outcome of live-born infants of mothers with serological proven B19 infection at birth and at age 8 to 24 months also indicate that there are no parvovirus B19 attributable immediate or long-term clinical consequences (G. Enders, unpublished 2004).

Diagnosis

DIAGNOSIS IN PREGNANCY

B19 virus infection should be excluded in pregnant women who are contacts to patients with erythema infectiosum. In pregnant women with exanthems, lymphadenopathy, or arthralgia, B19 infection as well as rubella must be considered. Anamnestic data about type and time of contact are helpful. In pregnant women with suspected hydrops fetalis or fetal anemia on sonography, parvovirus B19 infection should be confirmed or excluded.

Detection of specific IgM with or without IgG antibodies indicates acute B19 infection. This should be confirmed by testing a second serum. IgG antibodies in the absence of IgM antibodies indicate previous infection ($\geqslant$4 months) or protection (Searle et al. 1997; Ferguson et al. 1997). However, depending on the serological assay used, IgM antibodies may decline to undetectable levels within 4–6 weeks. The significance of detecting NS1-specific IgG has been continuously discussed and contested since it was suggested that this antibody was suggested to be associated with an altered course of disease (von Poblotzki et al. 1995). Conversely, others have found no evidence of NS1 IgG antibodies representing a marker of persistent infection or contributing to pathogenesis. Most of the studies find that, irrespective of the underlying disease, NS1-specific IgG antibodies appear late in infection (>6 weeks), and the NS1 antibody test may, therefore, be used to exclude very recent infections in patients with an otherwise unclear serology (Hemauer et al. 2000; Searle et al. 1998). Neither raised levels of alpha-1 fetoprotein (AFP) nor human chorionic gonadotropin (hCG) levels in maternal serum have been found to be regular prognostic markers for fetal complications in pregnant women with parvovirus B19 infection (Saller et al. 1993; Komischke et al. 1997). However, both markers are frequently elevated when fetal complications were already evident.

Maternal B19 infection can be confirmed by detection of B19 DNA using PCR when diagnostic interpretation of serological results is difficult. Large amounts of B19 DNA are present in the blood shortly before and after onset of symptoms and can persist at low titers for 2–6 months or even longer (Musiani et al. 1995; G. Enders et al. unpublished). This, however, also depends on the sensitivity of the PCR employed with refined PCR-based techniques such as automated sample preparation and real-time quantitative PCR with a detection limit of 234 IU/ml (Schorling et al. 2004).

DIAGNOSIS IN THE FETUS

Fetal infection is suspected most frequently when hydrops is diagnosed by ultrasonography after a serologically confirmed B19 virus infection in the mother or at routine scan without knowledge of maternal serology. The most reliable way to diagnose fetal infection is to detect B19 DNA by PCR in amniotic fluid, body effusions, or fetal blood. The severity of hydrops fetalis has been graded according to the degree of fetal anemia or ascites (Fairley et al. 1995; Schild et al. 1999). Mild hydrops is not usually associated with significant anemia (Hb 7.2–11.5 g/dl), and may resolve spontaneously over time (category I). Moderate hydrops fetalis is associated with Hb values of 5.7–7.2 g/dl (category II). In cases with generalized hydrops, fetal Hb values range between 1.9 and 5.4 g/dl (category III). Without very early intervention, most cases end in intrauterine death (Tercanli et al. 1996). In prenatal diagnostic centers more recently,

Doppler sonography is employed to recognize fetal anemia by measuring the peak systolic velocity (PSV) in the middle cerebral artery (MCA) (Delle Chiaie et al. 2001; Cosmi et al. 2002). According to the work of Cosmi et al., it seems to be a reliable predictor of parvovirus-induced fetal anemia.

In the case of pathologic PSV values, fetal blood sampling should be considered to determine fetal Hb and reticulocyte count, as well as to confirm B19 infection by detecting viral DNA, IgM antibodies, or both. To detect B19 DNA in fetal blood by PCR, it is important that heparin is not used for moistening the needle employed for cordocentesis, because this anticoagulant may inhibit *Taq* polymerase by binding to DNA (Beutler et al. 1990; Schwarz et al. 1992) and can cause false-negative results. Fetal parvovirus B19-IgM antibodies are a less reliable marker for fetal infection than the detection of B19 DNA in fetal blood or amniotic fluid (Schild et al. 1999). This is confirmed by our results performing the laboratory investigation of fetal specimens obtained at prenatal diagnosis in 349 B19-affected pregnancies (G. Enders, personal observation). In addition, B19 can be identified by histopathology, immunohistochemistry, and in situ hybridization in fetal tissues (Wright et al. 1996).

Management in pregnancy and of the neonate

When acute infection is diagnosed in pregnancy, weekly ultrasound monitoring at low level up to 8–12 weeks after onset of maternal infection is recommended to detect signs of fetal infection such as increased volume of amniotic fluid, skin or placental edema, ascites, and pleural and pericardial effusions early in the course of disease. In such cases the patient should be referred immediately to a prenatal tertiary diagnostic center for further tests and, if necessary, for intrauterine therapy (Schild et al. 1999).

In case of late maternal B19 infection after the 32nd week of pregnancy, fetal complications are less likely. If such an exceptional case occurs near term, the induction of labor or cesarean section may be performed. After delivery, no special precautions (e.g. isolation mother/child) are needed and breastfeeding is not contraindicated. No observations have been reported that late intrauterine or perinatally infected newborns pose an occupational risk to medical personnel or care workers.

TREATMENT OF THE HYDROPIC FETUS

Intrauterine transfusion as a new therapy regimen in B19-infected hydropic fetuses was first reported from Germany (Schwarz et al. 1988; Schwarz et al. 1990). Initially, this treatment was controversial, since the case of intrauterine transfusion rests against the spontaneous resolution of fetal hydrops. However, the findings in a study conducted in the UK during the epidemic year of 1993/1994 indicated that timely intrauterine transfusion of fetuses with severe hydrops fetalis reduces the risk of fetal death. In this study, the surviving fetuses had no abnormalities related to B19 infection (Fairley et al. 1995). In the meantime, an increasing number of studies on invasive prenatal diagnostics and intrauterine transfusion in fetuses mainly with hydrops fetalis and their favorable immediate and long-term outcomes were reported worldwide (e.g. Rodis et al. 1998a; Schild et al. 1999; Eis-Hübinger et al. 1998; Swain et al. 1999; Forestier et al. 1999; Grab et al. 2002). From all these studies there is little evidence of damage to fetuses infected with parvovirus B19, treated by intrauterine transfusion, and born alive. This is important for the justification of intrauterine treatment of infected fetuses.

PROPHYLAXIS AND THERAPY

Screening in pregnancy for B19 virus antibodies is not recommended and exclusion from work of pregnant women in, for example, childcare centers and elementary schools during the highest risk period between the 9th and 24th week of pregnancy may be considered, but is not officially recommended (Crowcroft et al. 1999). Efforts to prevent contact with infected individuals are of very limited effect, since people are contagious before they develop the rash (CDC 2000).

Passive prophylaxis with immunoglobulin may be effective, since all immunoglobulin preparations for i.v./i.m. application tested contain parvovirus B19-IgG antibodies which can be measured in international units per milliliter and neutralizing antibodies detectable by using a reverse-transcriptase polymerase chain reaction (Ballou et al. 2003). Postexposure prophylaxis with immunoglobulins in pregnancy is presently not recommended; however, pre-exposure prophylaxis has been proven to be beneficial in patients with chronic parvovirus infection and in nosocomial outbreaks in hospitals.

Antiviral drugs are not available for treatment and a parvovirus B19 vaccine is presently not licensed for use. A recombinant human parvovirus B19 vaccine has been developed and is composed of the VP1 and VP2 capsid proteins and formulated with a special adjuvant has recently been evaluated in a randomized, double-blind phase 1 trial in healthy B19-seronegative adults. The vaccine seems to be safe and immunogenic, since all volunteers developed neutralizing antibody titers that peaked after the third immunization and were sustained thus far through 1 year (Ballou et al. 2003).

It is now evident from all the available information that approximately 94 percent of parvovirus B19-affected pregnancies have a normal outcome, that the risk of fetal damage is low and no malformations were observed, and that in case of moderate to severe fetal anemia intrauterine transfusion(s) reduce the risk of fetal death. Therefore a pregnancy does not need to be terminated when B19 infection occurs. Even so, although studies on

immediate and long-term outcome of surviving infants following maternal infection in pregnancy have increased recently, further such studies are needed.

HUMAN IMMUNODEFICIENCY VIRUS

AIDS is caused by the lentiviruses human immunodeficiency virus 1 and human immunodeficiency virus 2 (HIV-1 and HIV-2). At the end of 2003, more than 40 million people were living worldwide with human immunodeficiency virus (HIV), including about 19 million women (estimated by UNAIDS); 700 000 children under the age of 15 years are infected annually, most of them by mother-to-child transmission. Prenatal care is an important means of detecting HIV infection in pregnancy. Progress in diagnosis, therapy, and interventional measures has drastically reduced the risk of vertical transmission in industrialized countries.

Effects on pregnancy

Pregnancy does not seem to accelerate progression of HIV-1 disease as demonstrated in studies from the USA and Europe (Burns et al. 1998; Weisser et al. 1998; Saada et al. 2000). Data from developing countries suggest a weak association between pregnancy and an adverse maternal outcome related to HIV infection (French and Brocklehurst 1998). Furthermore, a greater frequency of spontaneous abortion, preterm birth, low birth weight, intrauterine growth retardation, stillbirth, and infant death was shown among HIV-infected women (Brocklehurst and French 1998).

Mother–infant transmission

The main factor associated with increased risk of vertical transmission is the maternal plasma HIV-1 RNA level (e.g. Cooper et al. 2002). In former studies a critical threshold for transmission was estimated to be 100 000 RNA copies/ml of plasma (Fang et al. 1995), but later studies could not confirm this threshold (European Collaborative Study 1999). A lower copy number decreases the risk of transmission significantly (Ioannidis et al. 2001), whereas in pregnant women with undetectable virus copies the transmission rate might be reduced completely (Mofenson et al. 1999). Further factors associated with increased risk of vertical transmission as low maternal $CD4^+$ cell counts, advanced clinical HIV disease, increased levels of beta-2-microglobulin and race/ethnicity are also assumed to reflect the viral load (Cunningham et al. 2004). Other factors are, for example, co-existing sexually transmitted diseases, drug abuse, low vitamin A, chorioamnionitis, rupture of the membranes >4 h before birth regardless of the mode of delivery, and premature delivery (e.g. Minkoff et al. 1995; Landesman et al. 1996). Also immunological factors contribute to the risk of vertical transmission. A mother–child HLA class I concordance, several HLA-B alleles, maternal SDF1 chemokine receptor ligand polymorphism, and infant homozygosity in a mutation of the regulatory region of chemokine receptor 5 gene increase the risk of perinatal HIV-1 transmission (Polycarpou et al. 2002; Winchester et al. 2004; John et al. 2000; Kostrikis et al. 1999), whereas the presence of maternal neutralizing antibodies decreases the risk (Scarlatti et al. 1993). Also some MHC class II alleles of the infant are associated with reduced or enhanced risk of vertical HIV infection (Winchester et al. 1995).

ROUTES OF TRANSMISSION

Mother-to-child transmission may occur in utero, intrapartum, or by breast-feeding. Intrauterine infection in early pregnancy seems possible, but is more likely to occur shortly before delivery. It is usually assumed to occur by hematogenous spread across the placenta. However, it may also spread from pelvic organs in which replication is occurring, and in late pregnancy by ascending infection from the vagina after rupture of the membranes.

Intrapartum transmission causes a substantial proportion of the cases of vertical transmission (Chouquet et al. 1999). Possible mechanisms include transfusion of the mother's blood to the fetus during labor contractions, infection after the rupture of membranes, and direct contact of the fetus with infected secretions or blood from the maternal genital tract.

The mainly postnatal route of HIV transmission is by breast-feeding. Breast-feeding is associated with an additional 15 to 20 percent risk of HIV transmission (Nduati et al. 2000). Modifying infant feeding practices with early cessation of breast-feeding at 4–6 months or inactivation of HIV in breast milk reduces the risk of postnatal transmission (Rollins et al. 2004).

RATES OF PERINATAL TRANSMISSION

Transmission rates for HIV-1 range today from <2 up to 40 percent depending on geographic areas, socioeconomic conditions, therapeutic and obstetrical interventions. With optimal management of the mother and the newborn, a transmission rate below 2 percent can be achieved (Buchholz et al. 2002).

HIV-2 infections in pregnant women are still rarely reported. However, in the few studies the perinatal transmission rates range form 0 to 4 percent (Adjorlolo-Johnson et al. 1994; De Cock et al. 1994). The much lower rate of transmission of HIV-2 compared with HIV-1 is possibly due to a 37-fold lower maternal RNA level in HIV-2-infected women (O'Donovan et al. 2000).

Effect on infant

Two patterns of disease have been described for infants vertically infected with HIV-1. In one, infection

progresses rapidly to AIDS within the first year of life in approximately 25 percent. In the remainder it progresses more slowly and, of these, approximately 25 percent remain asymptomatic until pre-adolescence (Grubman et al. 1995). In two European prospective studies an estimated one-fifth of infected children will have been diagnosed with AIDS or have died by 12 months of age, rising to a third by 6 years of age (Blanche et al. 1997). In a study from Malawi, the mortality rate of HIV-infected children up to the age of 3 years was 45 percent, the major causes of death were wasting and respiratory conditions (Taha et al. 1999).

The more rapid progression of disease in vertically infected infants compared with adults is explained by the relative immaturity of the immune system, the infectious dose, the route of infection, and infections with opportunistic organisms. In children infected with HIV-1, the wide range of clinical manifestations includes features of severe immunodeficiency, nonspecific symptoms and AIDS-related diseases. The prospects for survival of children with opportunistic infections, neurological disease, and lymphoma are worse than for those with lymphocytic interstitial pneumonitis or bacterial infections.

Diagnosis

DIAGNOSIS IN PREGNANCY

Prenatal HIV testing offers the best opportunity for the prevention of perinatal HIV infection. Voluntary HIV screening in pregnancy has been implemented in the USA, Canada, and western European countries in gynecological, prenatal, and other obstetric clinics. For instance in Germany, HIV testing has been included since 1987 in routine prenatal care if the pregnant woman gives her consent. Over recent years, substantial increasing prenatal testing rates have been observed in the USA and Canada. Data from the USA indicate that in 2000, 93 percent of HIV-infected women knew their HIV status before delivery. However, an estimated 280–370 perinatal HIV transmissions continue to occur in the USA each year (CDC 2002a). In western countries, pregnant women remain at low risk of acquiring HIV infection. In Germany, from 1987 to 2004, the seroprevalence of HIV has been surveyed in 325 000 pregnant women resulting in a HIV prevalence of 0.03 percent (G. Enders 2004, unpublished results).

HIV screening in pregnancy is performed with sensitive antibody detecting enzyme immunoassays (EIA). Newer assays include the detection of p24 antigen which improves the diagnosis of a primary HIV infection when p24 antigen is present, but antibodies are not yet synthesized. Reactive HIV screening assays have to be confirmed serologically, for example, with western blot or immunofluorescence assays. For the management of HIV-1-infected women, the viral load in the blood is determined by quantifying RNA and the cellular immune status by counting the $CD4^+$ T cells.

DIAGNOSIS IN THE FETUS

Tests on the fetus of an HIV-infected woman are not recommended, because most vertical transmissions of HIV occur intrapartum and only occasionally during late pregnancy. Furthermore, as in the case of hepatitis C virus (HCV) or hepatitis B virus (HBV) infections, contamination with maternal blood during amnio- or cordocentesis may transmit the virus to the fetus (Enders and Braun 2000; Geipel et al. 2001). An invasive prenatal diagnostic, for example, for the detection of chromosomal anomalies should be performed only when strictly indicated and with antiretroviral therapy/prophylaxis (Buchholz et al. 2002; Maiques et al. 2003).

DIAGNOSIS IN NEONATAL AND INFANT

Early diagnosis of HIV infection in infants born to an HIV-positive mother is not recommended by conventional serological tests, because IgG antibodies reflect maternal serology and IgM antibody determination lacks sensitivity and specificity (Schupbach et al. 1994). Although tests for HIV-specific IgA antibodies are less sensitive compared with virological tests especially for early diagnosis of HIV infection in the first 3 months of life, they may be useful in countries without facilities for viral culture or PCR detection (Livingston et al. 1995). In general, HIV infection can be definitively diagnosed in most infected infants by the age of 1 month and in virtually all infected infants by the age of 6 months by using viral diagnostic assays. A positive virological test (i.e. detection of HIV by culture or polymerase chain reaction) indicates possible HIV infection and should be confirmed by a repeat virological test on a second specimen as soon as possible. Pediatric HIV testing is recommended by the age of 48 h, at age 1–2 months, and at age 3–6 months. At birth only about 40 percent of infected children had positive viral assays. Then the sensitivity increases rapidly during the first week, with over 90 percent of infected children testing positive by the age of 1 month (Peckham and Gibb 1995). HIV DNA and/or RNA PCR is the preferred virological method; HIV culture has a sensitivity similar to that of HIV PCR, but HIV culture is more complex, expensive, and time-consuming to perform compared to HIV PCR. The use of HIV p24 antigen testing alone is not recommended for diagnosis, because the sensitivity and specificity of this assay is less compared with other HIV virological tests. HIV infection is diagnosed by two positive HIV virological tests performed on separate blood samples. HIV infection can be reasonably excluded among children with one negative virological test at the age of 1–4 month, and one at age $\geqslant$4 months. Definitively excluded is the HIV infection at the age of 18 months, if HIV IgG antibody is negative in the

absence of hypogammaglobulinemia and if the child has neither clinical symptoms of HIV infection nor negative HIV virological assays (CDC 1998a).

Previously cases of HIV clearance in children were described in several studies (e.g. Newell et al. 1996). Later investigations of 42 suspected transient HIV-1-infected children could not confirm a cleared HIV infection in any of these cases (Frenkel et al. 1998). Most cases suggest mislabeling of specimens or contamination in the laboratory, therefore rare cases of HIV clearance may be possible but have to be proven carefully.

Management

MANAGEMENT IN PREGNANCY

The great progress over the past few years for treatment of HIV infection has also dramatically influenced the management of HIV-infected pregnant women (European Collaborative Study 2001; Friese 2003).

Prevention

Most HIV infections are acquired sexually, the risk of transmission is associated with the viral load in genital secretions which can be different from the viral load in the peripheral blood (Robert Koch Institut 2003). The optimal preventive measure is sexual contact only with a partner known to be uninfected and the avoidance of unprotected sexual intercourse. Despite extensive worldwide research activities, a successful HIV preventive vaccine is not yet available (Stratov et al. 2004). After occupational exposure (e.g. accidental needlestick of healthcare workers), an antiretroviral postexposure therapy reduces the risk of HIV transmission (Cardo et al. 1997). For HIV exposures relating to sexual or drug injection, the post-exposure therapy can be offered under strict indication when the probability of HIV infection is high, therapy can be initiated promptly and adherence to the regime is likely. This therapy should never be considered as a routinely used form of primary HIV prevention (Robert Koch Institut 2002a).

Chemotherapy

In 1996, the ACTG 076 trial demonstrated a reduction of the vertical transmission after administration of zidovudine monotherapy throughout pregnancy and to the newborn for the first 6 weeks of life (Sperling et al. 1996). Shorter courses of therapy and treatment with other drugs, e.g. nevirapine or zidovudine/lamivudine also reduced the rate of vertical transmission. Studies with highly active antiretroviral therapy (HAART) resulted in the lowest transmission rates (Cooper et al. 2002). When combination therapy is administered during pregnancy, zidovudine should be included whenever possible. Maternal indication for therapy is based on the clinical, immunological, or virological status as published in current guidelines for the treatment of nonpregnant women (e.g. NIH 2004). To reduce the risk of vertical transmission, antiretroviral therapy is recommended even for pregnant women with a HIV-1 viral load below 1 000 copies/ml (Ioannidis et al. 2001). The possible risks of teratogenic drug effects of antiretroviral therapy during the first trimester of pregnancy are so far unknown. Exposure to maternal antiretroviral therapy was not associated with prevalence or pattern of congenital abnormalities, but was associated with reversible anemia in the newborn. However, treatment with some drugs, e.g. efavirenz, should be avoided because teratogenic effects occurred among animal species. The data on the teratogenic potential of antiretroviral agents are limited, currently approved agents and selected information regarding their use in pregnancy are available (US Department of Health and Human Services 2002). New antiretroviral agents, e.g. the 36-amino-acid peptide enfuvirtide, which prevents the fusion of the virus with the cell membrane, may improve the therapy response even in pretreated patients (Lazzarin et al. 2003).

Mode of delivery

Cesarean section before onset of labor or rupture of membranes effectively reduces the rate of transmission (European Mode of Delivery Collaboration 1999). In a meta-analysis of 15 prospective cohort studies, the elective cesarean section decreased the risk by approximately 50 percent as compared with other modes of delivery and independently of the effects of treatment with zidovudine (International Perinatal HIV Group 1999). In women with viral loads below 1 000 copies/ml, a benefit of cesarean section has not yet been demonstrated (Minkoff 2001), but generally cesarean section is recommended when possible.

MANAGEMENT OF THE NEONATE

Among the infants of HIV-infected women, no malformations or an increase in birth defects relating to HIV infection was observed (Brocklehurst and French 1998). Breast-feeding is not recommended in countries where appropriate milk substitutes are available. The risk of HIV transmission through breast-feeding is greatest in early infancy (before 6 months of age), and persists as long as breast-feeding continues (Nduati et al. 2000). In developing countries, however, breast-feeding is encouraged because artificial feeding in a poor hygienic environment greatly increases morbidity and mortality from diarrheal diseases and respiratory infections (Van de Perre 1995). In these countries, a threefold higher mortality rate in HIV-infected mothers who breast-fed their infants was reported compared with those who fed their infants with formula (Nduati et al. 2000). However, these limited results did not warrant any change in current policies on breast-feeding nor on infant feeding by HIV-infected women (World Health Organization

2001). After delivery, zidovudine is administered in general to the newborn for up to 6 weeks according to PATCG protocol 076. In developing countries the single dose nevirapine given to pregnant women in labor and to neonates shortly after birth effectively reduced the rate of perinatal HIV transmission and appears to be one of the most cost-effective options for the prevention of perinatal HIV transmission (Jackson et al. 2003). Management of infants and children is rapidly evolving and becoming increasingly complex, for example, considering possible early and late side-effects. Therefore the management of these children should be directed to a specialist wherever possible.

HEPATITIS VIRUSES

The list of hepatitis viruses continues to expand. Of those so far identified, types B, C, and E are of known significance in pregnancy and for the newborn (Table 16).

Hepatitis A virus

Hepatitis A virus (HAV) (enterovirus 72) is acquired by the fecal–oral route, and has an incubation period of approximately 4 weeks.

INFECTION IN PREGNANCY AND IN NEONATES

Hepatitis A virus has no apparent adverse effect on the outcome of pregnancy. Transmission during birth (e.g. by exposure to maternal feces or by breastfeeding) is very rare (e.g. Zhuang 1989; CDC 1990; Ye 1990; Zhang et al. 1990; ACOG 1998). In one investigation, neonatal infection was diagnosed in an infant born to a mother with hepatitis A 10 days after premature labor, the evidence indicating that he was infected by his mother before or during birth. In another case, vertical transmission of HAV resulted in a symptomatic neonatal disease. After a trip to India, the mother developed symptomatic hepatitis A infection during the 4th month of pregnancy (Fagan et al. 1999). HAV may spread within the neonatal intensive care unit, causing asymptomatic infection in neonates, and symptomatic or asymptomatic infection in staff members as a result of lapses in infection control precautions (Watson et al. 1993). Neonates, even when infected parenterally by transfusion with hepatitis A-contaminated blood (a rare event) rarely have biochemical evidence of hepatitis (Azimi et al. 1986). They are, however, a potential source of infection for nonimmune staff members, as the virus is excreted in the stools of infected neonates and infants for up to 5 months (Rosenblum et al. 1991). This is much longer than in older children, except those in whom icteric hepatitis relapses, as has been reported in 3–20 percent of children (Sjogren et al. 1987).

CONTROL MEASURES

Infection can be controlled by adopting simple hygienic measures and by the sanitary disposal of excreta. Strict isolation of cases is not effective, as fecal shedding of the virus peaks during the prodromal phase. For pre- and postexposure prophylaxis, human normal immunoglobulin preparations (HNIG) are in use and may be given to neonates born within 2 weeks of maternal illness, to neonates in an intensive care unit if a case occurs on the ward, and to nonimmune staff members (Zhang et al. 1990). Inactivated vaccines are effective, and will replace immunoglobulin for pre-exposure prophylaxis; they seem also to be useful for post-exposure prophylaxis as documented in a randomized study (Sagliocca et al. 1999). Neither HNIG nor inactivated hepatitis A vaccines are contraindicated in pregnancy.

Hepatitis B virus

Hepatitis B virus (HBV), a hepadnavirus, is transmitted primarily by the parenteral route, by blood, by sexual contact through contaminated secretions from acutely infected patients or carriers, and by vertical transmission. Perinatal infection and infection during the first year of life have important consequences because 90 percent of these infants become chronic carriers, compared with only approximately 5–10 percent of those infected after the age of 12 years. Such chronicity increases the risk of cirrhosis and hepatocellular carcinoma. Since the commencement of the hepatitis B vaccination approximately 20 years ago, the prevalence of chronic HBV infections has been reduced substantially among populations whose infection rates were previously high. CDC estimates that perinatal HBV infections in the USA declined 75 percent during the period 1987–2000 (CDC 2002b).

INFECTION IN PREGNANCY

The annual incidence of acute hepatitis B cases in pregnant women is not known because pregnancy status is not recorded in most countries. Pregnancy does not appear to influence the severity or mortality rates of acute HBV infections in countries under good living conditions (e.g. Shalev and Bassan 1982). No teratogenic effects have been associated with maternal HBV infection.

MOTHER–CHILD TRANSMISSION

About 90 percent of vertical transmission occurs as a consequence of intrapartum exposure to contaminated blood and genital secretions. In approximately 10 percent infection results from hematogenous transplacental transmission.

The main risk factors for intrauterine HBV infection are maternal serum HBeAg positivity (Wang and Zhu

Table 16 *Effects of hepatitis A–G infection on pregnancy, on the fetus, and the newborn*

2000), a history of threatened preterm labor, HBV in the placenta especially in the villous capillary endothelial cells (Xu et al. 2001, 2002), a high HBV viremia level in pregnant women (Zhang et al. 1998) which is particularly elevated in women acutely infected in the third trimester, and transplacental leakage of maternal blood to the fetus (Lin et al. 1987; Ohto et al. 1987). As reported by Xu et al. (2002), the intrauterine infection rate increased linearly and significantly with maternal HBV DNA concentration. Results of the pathology study showed that HBV infection rates decrease gradually from the maternal side to the fetal side in the placental cell layers.

Recently, it has been found that breast-feeding of infants of chronic HBV carriers poses no additional risk for transmission of the hepatitis B virus (Hill et al. 2002). The early postnatal HBV infections result from close contact between infant and the infected parent(s). In hyperendemic areas, most HBV-related complications occur during adulthood, but nearly half of the primary infected persons becoming chronic HBV carriers have acquired their infection during the perinatal period through the transmission from hepatitis B e antigen (HBeAg)-positive mothers. The other half is from horizontal transmission mainly through intrafamilial spread or injection using unsterilized needles (Chang 1998).

RATE OF TRANSMISSION

The transmission rate from asymptomatic carrier mothers who are positive only for HBsAg is approximately 10–20 percent in the absence of immune prophylaxis. Mothers positive for both HBsAg and HBeAg, and thus highly infectious, transmit the virus in 80–90 percent of cases (see, for example, Stevens et al. 1979). For predicting persisting infection in infants and a possible failure of neonatal hepatitis B passive/active vaccination in earlier studies, the HBV DNA viral load in the maternal serum of the HBeAg-positive mothers seemed to be the most important factor (e.g. Burk et al. 1994; Del Canho et al. 1994). In a more recent case–control study conducted to find out why some infants born full-term to HBeAg-seropositive mothers became infected despite full passive-active immunoprophylaxis, allelic base changes in maternal HBV genotype were determined as risk factors (Ngui et al. 1998).

OUTCOMES OF PERINATAL AND POSTNATAL INFECTION

Most infants born to carrier mothers are HBsAg-negative at birth and, without immunoprophylaxis, seroconvert in the first 3 months after delivery. Perinatally and postnatally infected newborns and infants are asymptomatic. Fulminant hepatitis secondary to perinatal HBV infection has been reported in infants aged 2–6 months, particularly if the mother is anti-HBe-positive and the infecting virus has undergone mutations in the pre-core region of its DNA (see for example, Carman et al. 1990; Omata et al. 1991; Terazawa et al. 1991; Waters et al. 1992; Schödel 1994; von Weizsäcker et al. 1995; Hsu et al. 1999; Ogata et al. 1999; Zuckerman 2000). A recent publication, however, indicates that HBV genomic heterogeneity is not primarily involved either in the initiation of infection nor the failure of neonatal HBV immunoprophylaxis (Cacciola et al. 2002). The risk of chronicity in perinatally and early postnatally infected infants and the rate of progression to liver disease or hepatocellular carcinoma are currently under observation. In earlier studies of almost 350 Chinese and Italian children followed from 1 to 10 years, no progression of liver disease was noted, although almost 50 percent had histological findings of chronic active hepatitis or cirrhosis at presentation (Bortolotti et al. 1986; Lok and Lai 1988). Some more recent observations (Chang 1998) confirm that children with chronic hepatitis B virus infection are mostly asymptomatic. They are generally active and growing well with very rare exceptions. Even with acute exacerbation of liver function and active inflammation, jaundice, or growth failure is uncommon. However, hepatocellular carcinoma may also follow perinatal or childhood HBV infection (Hsu et al. 1987). This is demonstrated in a Japanese long-term follow-up study of 3 to 22 years (mean, 11 years) in 52 adolescents with perinatally acquired HBV infection where hepatocellular carcinoma has been diagnosed in two cases (a 21-year-old and a 16-year-old). All children carrying hepatitis B surface antigen should be observed carefully to monitor the possible development of hepatocellular carcinoma, especially in the anti-HBe-positive phase after spontaneous seroconversion or even after interferon treatment (Fujisawa et al. 2000). It is known that hepatitis B pathology is a dynamic process between the virus, the infected cell, and the host's immune response. In this context, more studies are needed to clear the function of the soluble core gene product (HBeAg) of hepatitis B virus. It has been proposed that transplacentally passed HBeAg might induce fetal immunotolerance to HBeAg (Milich et al. 1990; Wang and Zhu 2000).

DIAGNOSIS IN PREGNANCY

Screening in pregnancy for HBsAg detects both acutely infected and asymptomatic carrier women whose babies are at risk of perinatal infection. Since the beginning of the late 1980s, in most European countries, universal antenatal screening is carried out and is advocated in the USA and in Canada (CDC 1991; ACOG 1993) because selective screening has been of low efficiency (Boxall 1995). Antenatal screening is usually done early in pregnancy together with screening tests for blood group and syphilis (Grosheide et al. 1995). In Germany, selective HBsAg screening was introduced in 1987, but since 1994 has formed part of the obligatory prenatal care program. Testing is performed in the third trimester with the same

blood sample as provided for the second obligatory indirect Coombs' test (Kassenärztliche Bundesvereinigung 1994).

The screening procedures in pregnancy are as follows. If the test for HBsAg is negative, no further testing is done unless there is a clinical indication of hepatitis or suspicion of behavioral risk factors (then testing anti-HBc is carried out). If the HBsAg result is positive, anti-HBc IgM testing and, if this test is positive, quantification of HBV DNA may also be carried out. For results notification requirement to healthy authorities exists. The HBsAg result is documented in the prenatal care notes and, if positive, the obstetrician is advised to administer active/passive hepatitis B immunization to the neonate within 12 h after birth. If antenatal HBsAg screening is not documented, it will be done at delivery. In Germany, universal antenatal HBsAg screening was estimated to be cost-effective over a wide range of assumption (Kassenärztliche Bundesvereinigung 1994). Tests for anti-HBc only in the case of negative results for HBsAg have not been included in the German strategy of antenatal screening. Although an anti-HBc prevalence of 8.71 percent was calculated in the middle-aged adult German population, 1.40 percent of the individuals had anti-HBc, only 7.7 percent of them or 0.1 percent of the whole population were DNA positive in the absence of HBsAg indicating infectiousness (Jilg et al. 2001). However, some countries, e.g. Switzerland, include anti-HBc testing in the antenatal screening algorithm. As a consequence, newborns of the solely anti-HBc-positive mothers also obtain active-passive hepatitis B immune prophylaxis shortly after delivery (personal communication, Professor Zimmermann, Universitätsspital Zürich, Department für Frauenheilkunde und Geburtshilfe, Switzerland).

MANAGEMENT IN PREGNANCY

Preventive measures are designed to prevent transmission by transfusion, transplantation, syringe-borne infection, frequent changes of sex partner, and nosocomial infection between patients. Pregnant women in sexual or household contact with HBV-infected individuals should be offered active/passive immunization after their HBsAg, anti-HBc, and anti-HBs seronegativity is established. The specific antiviral drugs lamivudine, adefovir, entecavir, and pegylated interferon-α are not recommended for pregnant women (Balfour 1999; Anonymous 2002; Schalm et al. 2002). During pregnancy, acute HBV infection is treated by supportive measures as in nonpregnant patients.

Invasive prenatal diagnosis in the second and third trimester is not indicated since transmission occurs primarily during delivery. If genetic reasons are the indication for prenatal diagnosis, a potential risk of iatrogenic infection of the fetus in viremic mothers has to be considered (Enders and Braun 2000; Delamare et al. 1999).

Termination of pregnancy is contraindicated.

Cesarean section is not usually recommended, but may be performed in women with high serum levels of HBV DNA and HBeAg and with acute infection in late pregnancy (Schalm and Pit-Grosheide 1989; Del Canho et al. 1994; Wang et al. 2002).

MANAGEMENT OF NEONATES

In the USA, all newborns are vaccinated at birth regardless of the maternal HBsAg status, with anti-HBs testing of infants at age of 7 months born to HBsAg-positive mothers (Committee on Infectious Diseases 1994). The detailed vaccination procedure is given by the Advisory Committee on Immunization (www.cdc.gov/nip/acip). In most western European countries (term and preterm) babies of mothers with positive HBsAg test or unknown HBsAg status are immunized within 12 hours after birth simultaneously with hepatitis B immunoglobulin (HBIG) and a hepatitis B low-dose vaccine, and again with hepatitis B vaccine only at 1 and 6 months of age; 1 month later, a test for anti-HBs is recommended (Robert Koch Institut 2002b). Infants of mothers with negative HBsAg status are vaccinated within the routine infant program starting at age of 2 months (Robert Koch Institut 2002b).

Perinatal immune prophylaxis has been effective in western populations, protecting 93–95 percent of infants 1 month after the third dose (antibody levels $\geqslant$10 mIU/ml). This was confirmed by a recent study carried out in a population at high risk of infection by examining 522 children in southern Italy born to HBsAg-positive mothers 5–14 years after postpartum immunization. Four hundred of 505 (79.2 percent) children had protective anti-HBsAg titers $\geqslant$10 mIU/ml. Thus, HBV vaccination of children born to HBsAg carrier mothers seems to provide immediate and long-term protection against HBV infection. There was no evidence that the emergence of HBV escape mutants secondary to the immune pressure against wild-type HBV is of concern (Mele et al. 2001). In areas with low HBV endemicity, for vaccination of infants low-dose vaccine (5 μg) is used, whereas in areas with high HBV endemicity, normal dose of vaccine (10 μg) seems to be more effective in perinatal and infant vaccination (Lee 1995; Milne et al. 1995).

In 1991, recognizing the difficulty of vaccinating high-risk adults and the substantial burden of HBV-related disease acquired from infections in childhood, a comprehensive strategy to eliminate HBV transmission in the USA was recommended (CDC 1991, 1995, 2002b). It includes universal childhood vaccination, antenatal screening, vaccination of all nonvaccinated young adults, and vaccination of groups at risk because of their occupation, behavior, contacts, travel, etc. This strategy was taken up by the majority of western countries, including Germany (Robert Koch Institut 1995) and various Asian (Ruff et al. 1995) and African countries.

For elimination of HBV transmission, it is important to sustain high vaccine-coverage rates among infants, children, adolescents, and adults at increased risk for HBV infection. However, if the efforts to vaccinate the latter group are not greatly expanded, complete elimination of HBV transmission might take another 20 years to achieve (CDC 2002b; Robert Koch Institut 2002b).

Hepatitis C virus

Hepatitis C virus (HCV), with >6 genotypes and >70 subtypes, is the etiological agent of most cases of non-A, non-B post-transfusion and sporadic hepatitis (Simmonds 1995; Maertens and Stuyver 1997). Acute HCV infections are asymptomatic in 75 percent of cases and in the remainder symptoms are mild, but >50 percent of infected adults develop chronic liver disease. Information on the perinatal implications of HCV is still constantly expanding. Based on observational data of more than 77 studies carried out in approximately 18 countries, vertical transmission has been confirmed to occur generally at a low rate (1–5 percent) and is favored mainly by a high maternal virus load in the blood. Maternal risk factors such as coinfection with HIV increase the vertical transmission rate to more than 20 percent (Roberts and Yeung 2002).

INFECTION IN PREGNANCY

The important risk factors for infection in pregnancy are intravenous drug abuse, sexual contact with intravenous drug users, high promiscuity, and infection with other sexually transmitted diseases. Other risk factors are previous transfusions, transplantation, and administration of blood products.

In pregnant women at normal risk, antibody prevalence is 0.7–2.5 percent, being higher than in blood donors (approximately 0.2–0.5 percent) in the same geographical area (Bohman et al. 1992; Marranconi et al. 1994; Pipan et al. 1996). In a UK study, the HCV seroprevalence in mothers born in the UK was 0.13–0.15 percent and 0.81 percent in mothers born elsewhere in Europe (Ades et al. 2000). In pregnant women from high-risk populations, antibody prevalence rates are >2.5 percent, irrespective of the geographic region.

It appears that pregnancy has no impact on the viral load and the clinical course of acute hepatitis C or the activity of chronic infection (Reth et al. 1995). In addition, abortions or intrauterine deaths are not increased in acute or chronic HCV infection (Dinsmoor 2001).

MOTHER–INFANT TRANSMISSION

Routes of transmission

Hepatitis C can be transmitted in utero and during parturition. Intrauterine transmission is suggested in some reports because viral RNA was detected in cord or neonatal blood (e.g. Kurauchi et al. 1993; Kojima and Yamanaka 1994), but not always in follow-up sera of the infants. As in HBV infection, intrauterine transmission may occur late in pregnancy due to placental leakage in cases of threatened abortion and preterm labor (e.g. Lin et al. 1987). The major route, however, is intrapartum transmission, which probably occurs by contact with contaminated blood. This route is verified by detection of viral RNA in nonbreast-fed infants >1 month old (e.g. Resti et al. 1995; Zanetti et al. 1995). Several studies of mother–infant pairs with follow-up of the infants show that the risk of vertical transmission is higher in mothers with acute infection in late pregnancy (Kuroki et al. 1991; Lynch-Salamon and Combs 1992) or chronic hepatitis (Degos et al. 1991); in high-risk mothers co-infected with HIV-1, but not with HBV; and particularly if a high level of HCV RNA is present in maternal blood, with (Zanetti et al. 1995) or without (e.g. Ohto et al. 1994; Tajiri et al. 2001) behavioral risk cofactors.

There is no evidence of transmission by breast milk in asymptomatic carrier mothers, but it cannot be fully excluded in symptomatic mothers (Kumar and Shahul 1998; Mast 2004).

Rates of vertical transmission and infection

In low risk groups In prospective studies of the world literature from 1994 to 2001 on vertical HCV transmission in low-risk, HIV-negative mothers a mean transmission rate of 5.5 percent (range, 0–11.1 percent) was reported (Ohto et al. 1994; Moriya et al. 1995; Giacchino et al. 1995; Meisel et al. 1995; Pipan et al. 1996; Kumar et al. 1997; Resti et al. 1998; Xiong et al. 1998; Conte et al. 2000; Ceci et al. 2001; Tajiri et al. 2001; Lima et al. 2004). All these studies indicate that infants are infected only by HCV-RNA-positive mothers, particularly those with a high viral load. One investigation reports that vertical transmission of HCV can occur irrespective of the maternal viral load (Pipan et al. 1996).

Older studies from 1990–1992 on vertical transmission in anti-HCV-positive and HIV-1-negative mothers indicate that, on the basis of antibody persistence the infection rate in infants followed up for 10–12 months was 4.5 percent (4/88) (Lynch and Ghidini 1993). In one of these older studies, in which both HCV RNA detection and antibody persistence were used as markers of infection of infants, RNA was found not only in infants who seroconverted or who had persisting antibody, but also in those who became and remained antibody negative (Thaler et al. 1991). This puzzling observation was also made in later studies (e.g. Giacchino et al. 1995; Paccagnini et al. 1995) and may indicate false-positive PCR results or seroreversion with clearance of infection, as has been found in a few infants born to HIV-1-positive mothers (Newell et al. 1996).

In high risk groups Several studies tried to establish the rate of vertical transmission of HCV in mothers

of high-risk groups with and without HIV-1 coinfection. In studies (1995–2002) from various countries, vertical transmission rates in children born to HCV-RNA-positive mothers with HIV infection ranged from 44 to 8 percent, whereas the transmission rate in children born to HCV-RNA-positive mothers without HIV infection range from 10 to 0 percent (Zanetti et al. 1995; Zuccotti et al. 1995; Paccagnini et al. 1995; Tovo et al. 1997; Mazza et al. 1998; Thomas et al. 1998; Papaevanegelou 1998; Zanetti et al. 1998; Gibb et al. 2000; Resti et al. 2002).

The investigations of Zanetti and colleagues (1995, 1998) and Zuccotti and co-workers (1995) show clearly a higher maternal HCV RNA positivity in HIV-1 coinfected mothers than in those with HCV RNA alone, and a higher rate of vertical transmission in the group positive for HIV-1 and HCV RNA. The study of Paccagnini et al. (1995) further indicates that HCV and HIV transmission, alone or in combination, can occur in infants born to coinfected mothers.

Some authors (Kudesia et al. 1995; Fischler et al. 1996; Spencer et al. 1997) recorded no vertical transmission in HCV-infected pregnant women engaged in injection drug use (IDU). In contrast to these studies, Resti et al. (1998) have shown that intravenous drug use itself and post-transfusional hepatitis is an important risk factor for transmission of hepatitis C virus (Resti et al. 1998). In their more recent study Resti et al. (2002) have postulated that transmission occurs mainly in those women who are former or current injection drug users and not in HIV-coinfected women. However, it has been questioned why transmission would be associated with a history of IDU in women who do not currently engage in IDU (Armstrong et al. 2003). Furthermore, Yeung et al. (2001) have examined the results of prior studies and have confirmed that transmission is more strongly associated with HIV coinfection than with IDU.

The outcomes of HCV-infected children in four studies of maternal low risk groups and in five studies of maternal high risk groups are summarized in Table 17. Nearly all the infected infants showed signs of liver involvement during the follow-up period. Increased, but fluctuating, values of alanine aminotransferase (ALT) were usually detected as well as histological evidence of liver disease. Tests for HCV RNA were repeatedly positive in all children aged ⩾6 months; HCV antibodies persisted beyond 14 months of age in 12 infants; there was temporary seroreversion in nine infants and loss of HCV antibodies in six infants aged 6–9 months despite persistence of HCV RNA.

These studies in high- and low-risk groups which have already been discussed above and some further studies reflect various courses of the infection in apparently vertically infected infants (especially in the first year of life), e.g. transient viremia without real infection, acute self-limited clinically inapparent infection, or clearance of HCV-RNA (Bortolotti et al. 1997; Sasaki et al. 1997; Ketzinel-Gilad et al. 2000). Long-term observations are needed to clarify if chronic hepatitis in infants will spontaneously resolve or progress to chronic liver disease.

Although transmission via breast milk has been suggested in one study (Gürakan et al. 1994), the majority of studies that have examined transmission rates with breastfeeding have not noted any significant increase in transmission in infants who were breast-fed, compared with those who were bottle-fed (Kumar and Shahul 1998; Lin et al. 1995; Zanetti et al. 1995; Zimmermann et al. 1995; Tovo et al. 1997; Resti et al. 2002; European Paediatric Hepatitis C Virus Network

2001). In recent studies, the authors were unable to find HCV RNA in any breast milk samples tested (Kage et al. 1997; Polywka et al. 1997).

According to the knowledge that vertical HCV transmission occurs like HIV transmission around the time of delivery, the effect of the mode of delivery on transmission was of interest. Of the various studies (Paccagnini et al. 1995; Spencer et al. 1997; Tovo et al. 1997; Resti et al. 1998; Thomas et al. 1998; Conte et al. 2000; European Paediatric Hepatitis C Virus Network 2001) only two reported significantly lower transmission rates with elective cesarean section. One study reported that in mothers with high viral load, vaginal delivery resulted in a vertical transmission rate of 44 percent (7/16) (Okamoto et al. 2000). In contrast, the eight patients with a high viral load who underwent elective cesarean section (prior to labor) did not transmit HCV to their ten neonates. In the study of Gibb et al. (2000) in 441 HCV-infected women in the UK, there were no cases of neonatal HCV following elective cesarean delivery in 31 patients. This transmission rate was significantly lower than that for vaginal delivery and emergency cesarean section combined. Unfortunately, data on maternal HCV RNA levels were not available for the patients in this study.

A viral factor which influence the risk of mother-to-infant transmission may be the HCV genotype (e.g. Zuccotti et al. 1995), but this could not be substantiated in a number of further investigations (e.g. Mazza et al. 1998).

At present, the guidelines from the American Academy of Pediatrics, the Centers for Disease Control and Prevention (CDC), and the American College of Obstetricians and Gynecologists (ACOG) do not prohibit breast-feeding in infants of HCV-positive mothers (CDC 1998b; American Academy of Pediatrics 1998; ACOG 2000c). It is likely that most of the individual studies done thus far lack the statistical power to detect differences in transmission following interventions such as cesarean section or formula feeding. The current guidelines from the CDC and ACOG recommend cesarean section only for obstetric indications in patients who are infected with hepatitis C (CDC 1998b).

It might be of interest that mothers who have already delivered an HCV-infected child can be advised that this event does not increase the probability of infecting the second child (Resti et al. 2000).

The contribution of vertical transmission to community-acquired HCV infection in western populations seems to be low (e.g. Alter et al. 1992; Goto et al. 1994; Yoshii et al. 1999), but may be important among children living in areas of high HCV prevalence (Chang et al. 1994).

DIAGNOSIS IN PREGNANCY

Laboratory tests for HCV infection in pregnancy are the same as for nonpregnant people. With regard to vertical transmission, a maternal viral load of more than 10^{6-7} IU/ml is considered high, 10^{4-6} as moderate and $<10^4$ as low or negative values. Commercially available qualitative and quantitative HCV RNA assays provide good sensitive, specific, and reproducible results today.

DIAGNOSIS IN INFANCY

Infants born to anti-HCV-positive and, particularly, to HCV-RNA-positive mothers should be tested at birth, at 6–8 weeks and at the age of 10–12 months for HCV RNA and, facultatively, for anti-HCV persistence. Liver function tests should be performed on HCV-RNA-positive infants at 2–3-monthly intervals and also on infants with antibodies persisting beyond 12 months of age.

MANAGEMENT IN PREGNANCY

Screening tests

Universal screening of pregnant women with anti-HCV antibodies is not recommended (CDC 1991). Selective screening should be performed in women with behavioral risk factors, with known positive HIV or HBsAg status, in those with signs of hepatitis or with a history of transfusion or transplantation and in nonpregnant and pregnant women with an HCV-positive partner. In cases of anti-HCV positivity, PCR for HCV RNA should be performed; if positive, the viral load should be determined toward the end of pregnancy.

Avoiding infection

The possibility of sexual transmission exists, predominantly in cases of high promiscuity. In contrast to previous findings, HCV RNA has been detected recently in seminal plasma by using highly sensitive PCR techniques (Hsu et al. 1991; Terada et al. 1992; Levy et al. 2000; Bourlet et al. 2003).

Although the risk of virus transmission is low, the presence of HCV RNA in seminal plasma suggest a possible risk of sexual transmission. It is noteworthy that French legislation has introduced a screening for HCV RNA in seminal fluids of HCV-infected men who are involved in programs of assisted reproductive techniques (Bourlet et al. 2003).

At present there is no contraindication to pregnancy for HCV-positive women or for anti-HCV-negative women with an HCV-positive partner.

Invasive prenatal diagnosis in the second and third trimester is not indicated since transmission occurs primarily during delivery and since, for example, genetic reasons for prenatal diagnosis, a potential risk of iatrogenic infection of the fetus in viremic mothers has to be considered (Enders and Braun 2000; Delamare et al. 1999).

Termination of pregnancy is not indicated.

Passive/active prophylaxis and therapy

The efficacy of passive prophylaxis for HCV by intravenous immunoglobulin seems limited (e.g. Krawczynski et al. 1996), and a vaccine is not yet available (Choo et al. 1994; Zanetti et al. 2003). Treatment with IFN-α or pegylated IFN-α alone or in combination with ribavirin (Di Bisceglie et al. 1995; Collier and Chapman 2001) is not indicated in pregnancy (McDonnell and Lucey 1995). However, more recently some reports suggest continuing pregnancy if they were exposed inadvertently at the beginning of pregnancy to interferon (Hiratsuka et al. 2000; Trotter and Zygmunt 2001; Ozaslan et al. 2002), but less so in case of therapy with ribavirin (Mishkin and Deschenes 2001; Hegenbarth et al. 2001).

Mode of delivery

If the viral load in the maternal serum is high, elective cesarean section has been suggested, to reduce the rate of vertical transmission (Paccagnini et al. 1995; Gibb et al. 2000), but should rather be reserved for cases acquiring acute infection during the second and third trimester (Lin et al. 1996). After delivery no special precautions (e.g. isolation) are needed.

Breast-feeding

Breast-feeding by HCV-positive mothers is not contraindicated, because of the generally low risk of early postnatal transmission, unless they have a high viral load in the serum. In this case, breast milk may be quickly assessed for HCV RNA before routine breast-feeding is recommended (Pipan et al. 1996).

MANAGEMENT OF THE NEONATE

Prolonged follow-up of infants (up to 24 months) born to anti-HCV and HCV-RNA-positive mothers is of great importance. Treatment of chronic hepatitis C in infants and children is usually started not before the age of more than 2 years. Treatment with interferon-α alone yielded poor results, but the combination therapy of interferon-α 2b with ribavirin is an important advance (Wirth et al. 2002).

Hepatitis D virus

Hepatitis D virus (HDV) is also known as delta agent. HDV is a defective single-stranded RNA virus that requires the helper function of HBV for viral replication since the envelope of HDV consists of HbsAg and a unique internal antigen, the delta antigen. HDV is transmitted principally by blood and blood products, but also by sexual contact or injecting drug use. There is considerable regional variation in its prevalence. The prevalence of HDV is generally low among both asymptomatic HBV carriers and among patients with chronic HBV-related liver disease in countries with low prevalence of chronic HBV infection. In countries with moderate and high levels of chronic HBV prevalence, the prevalence of HDV infection is highly variable (CDC 2001a). Vertical transmission is rare.

INFECTION IN PREGNANCY AND IN THE NEONATE

A study in northern Italy demonstrated an incidence of anti-HDV antibody among HBsAg-positive pregnant patients lower than that in a group of HBsAg-positive patients with chronic liver disease (7 versus 20 percent) (Zanetti et al. 1982). Exacerbation of HDV infection during pregnancy has not been reported. Vertical transmission seems possible either during late pregnancy or intrapartum (Ramia and Bahakim 1988; Riongeard et al. 1992). Perinatal infection has been described in an infant born to a mother positive for both HBeAg and anti-HDV, but in none whose mothers were anti-HBe-positive (Smedile et al. 1981). Prevalence rates of HDV as estimated by HDAg or anti-HDV antibody in hepatitis B-infected children range from 1.6 percent in Taiwan to 12.5 percent in parts of Italy, China, and the Balkans, and up to 25 percent in the Amazon basin in Brazil (e.g. Chen et al. 1990; Torres and Mondolfi 1991).

PROPHYLAXIS

Measures to control the spread of HBV are also effective in preventing transmission of HDV infection to the infant. Administration of HBIG and HBV vaccine within 12–24 h after birth to newborns of HBsAg-positive mothers seems to prevent both HBV and HDV infection (Silverman et al. 1991). Zanetti and colleagues (1982) reported serological evidence of HDV infection only in newborns who did not receive HBV immunoprophylaxis.

Hepatitis E virus

Hepatitis E virus (HEV) a currently unclassified probably zoonotic RNA-virus (HEV-like viruses) is transmitted enterically and is responsible for waterborne epidemics and for sporadic outbreaks in tropical and subtropical countries (Mast and Alter 1993; Emerson and Purcell 2003).

In contrast to hepatitis A, HEV affects mainly young adults (15–40 years old) and has considerable implications in pregnancy. The death rate due to hepatitis E in the general population is 0.5–3 percent, in pregnant women as high as 15–25 percent (Mast and Krawczynski 1996).

INFECTION IN PREGNANCY AND IN THE NEONATE

During epidemics, the incidence of HEV infection in pregnant women is nine times higher than in nonpregnant women or in men (Khuroo et al. 1981; Khuroo and Kamili 2003). Both in epidemic and in sporadic outbreaks, HEV causes fulminant hepatitis and maternal

death, especially among women in the third trimester (Nanda et al. 1995). Mortality in pregnant women is as high as 25 percent compared with the overall mortality of 0.5–3 percent (Krawczynski 1993; Purdy and Krawczynski 1994; Kumar et al. 2004). The reasons remain unknown, but it seems unlikely that HEV is the sole cause of liver failure in pregnant women (Fagan et al. 1994).

According to the early observations of Khuroo and co-workers (1981), even mild HEV infection during pregnancy seems to cause a high rate of abortion and intrauterine death and increased perinatal mortality in babies born to women with fulminant hepatitis. Another report suggests that, unlike other hepatitis viruses, HEV often causes intrauterine infection, as well as substantial perinatal morbidity and mortality (Khuroo et al. 1995) and a more recent report suggests significant vertical transmission of HEV among HEV-RNA-positive mothers with appreciable perinatal morbidity and mortality (Kumar et al. 2001, 2004). Excluding mothers with acute hepatic disease, breast-feeding appears to be safe in HEV seropositive mothers (Kumar et al. 2001).

PROPHYLAXIS

Fecally contaminated drinking water is the most common vehicle of transmission. Hygienic precautions (e.g. adequate heating of drinking water and food) are necessary in areas where HEV is endemic. Immunoglobulin prepared from plasma collected in industrialized countries does not prevent HEV infection, immunoglobulin prepared from donors in endemic areas is of unknown efficacy (CDC 2001b). Until now, no effective antiviral drugs exist. A recombinant capsid vaccine is under evaluation in Nepal with adult volunteers receiving three doses of HEV vaccine or placebo over 6 months (Purcell et al. 2003).

Hepatitis G virus

An additional agent that may be responsible for as yet unexplained liver disease was discovered in 1995–1996 by molecular amplification and named hepatitis G virus (HGV) also known as GB virus C (Simons et al. 1995; Linnen et al. 1996). At present, HGV infection is mainly detected by reverse-transcriptase polymerase chain reaction (RT-PCR), but serological assays are now also in use. The clinical importance of this agent is as yet unclear. No causal relationship between HGV and hepatitis has been established (Alter 1996; Alter et al. 1997). Mother-to-infant transmission has been demonstrated without evidence of disease manifestations.

INFECTION IN PREGNANCY AND IN THE NEONATE

Few data are yet available on vertical mother-to-child transmission and infection of the infant. Feucht and colleagues (1996) studied mothers belonging to a behavioral-risk group; 61 mother–infant pairs were investigated. In six of 30 mothers coinfected with HCV and three of 17 coinfected with HIV-1, HGV viremia was detected by RT-PCR. Vertical transmission of HGV occurred in three of the nine infants, but co-transmission with HIV-1 or HCV could not be demonstrated. The rate of vertical transmission for HIV-1 was 11.8 percent (2/17) and for HCV 6.7 percent (2/30), corresponding with the reported vertical transmission rates of these viruses.

During follow-up of all 61 infants for vertical transmission of HGV, HCV, and HIV-1 every 3 months for >1 year, none of the three HGV-infected infants or the two with HCV infection became icteric or showed other biochemical or clinical signs of hepatitis.

In another report on vertical transmission of HGV, three HGV-positive pregnant women (one coinfected with HCV, but all three negative for HIV-1) and their three infants were studied. All three women had elective cesarean delivery because of obstetric indications, and their infants were not infected with HGV or HCV during the 12 months of observation. These negative results may indicate that mother-to-infant transmission does not occur in women from low-risk populations or that cesarean delivery minimizes infection because there is less microtransfusion from mother to fetus compared with other modes of delivery (Lin et al. 1996). Viazov et al. demonstrated a mother-to-infant transmission of 56 percent. During follow-up studies, none of the GBV-C/HGV-infected infants had elevated levels of ALT or clinical signs of liver disease. Prospective epidemiological and clinical studies are further needed to determine the long-term outcome of this infection (Viazov et al. 1997).

ENTEROVIRUSES

There is no convincing evidence that maternal infection in early pregnancy with any of the picornaviruses is associated with teratogenic defects. Maternal poliomyelitis caused by wild-type poliovirus is now largely of historical interest. In the prevaccination era, poliovirus infections in pregnancy could result in abortion, stillbirth, and, rarely, in neonatal disease. Transplacental transmission of the virus to the fetus was demonstrated especially in maternal poliomyelitis in late pregnancy, but seldom in early pregnancy (Bates 1955; Carter 1956).

Coxsackie virus and ECHO viruses

Maternal enterovirus infections with various coxsackie and ECHO viruses may be followed by spontaneous abortion, intrauterine death, placentitis, and multiorgan fetal infection, as demonstrated in various prospective studies (Basso et al. 1990; Garcia et al. 1991; Frisk and

Diderholm 1992; Dommergues et al. 1994). In our investigations, during the past 14 years on the untoward effects of coxsackie/ECHO virus in pregnancy, involving 288 women with serologically suspected or virologically proven coxsackie/ECHO virus infections during pregnancy, fetal loss of 6.5 percent, but no teratogenic defects in the newborns were reported. In addition, no enterovirus RNA (virus culture was not attempted) could be detected in amniotic fluid of 30 women with symptomatic infection, who underwent prenatal diagnosis (18–24 WG) (G. Enders 2004, unpublished). A recent case report shows that a late intrauterine enterovirus infection (coxsackie virus B3) could be diagnosed antenatally in amniotic fluid by virus culture, but surprisingly not by enterovirus RNA detection (Ouellet et al. 2004). Late intrauterine, intrapartum, or early postnatally acquired infections are of importance for the newborns.

CONGENITAL AND PERINATAL INFECTION

Clinical manifestations in the neonate or infant often include sepsis, meningoencephalitis, hepatitis, myocarditis, and coagulation disorders (Kulhanjian 1992; Bendig et al. 2003). Meningitis is a common manifestation of neonatal enterovirus infection, and enteroviruses seem to be responsible as often as bacteria for meningitis in the first month of life (Shattuck and Chonmaitree 1992). Onset 1–2 days after birth suggests intrauterine or intrapartum transmission and disease is severe in approximately 80 percent of cases. Onset 5–6 days after birth suggests that the infant has acquired infection by contact with infected mothers, siblings, or an infected neonate in the maternity unit. The course of illness is less severe in such cases (Simoes and Abzug 1993).

More recently it was described, that in utero coxsackie virus infection of the placenta was associated with the development of severe respiratory failure and central nervous system sequelae in the newborn (Euscher et al. 2001). This underscores the importance of detailed pathologic and viral examination of the placenta in cases of systemic illness in the newborn. Data on the long-term prognosis of neonates with enteroviral meningitis are still incomplete and contradictory. Children <2 years of age with enteroviral meningitis do not have long-term sequelae (Rorabough et al. 1992). Encephalitis occasionally occurs and in young infants may have neurological sequelae. Furthermore, it was reported that varicella-like congenital skin lesions in the newborn may be one of the leading manifestations of intrauterine infection with coxsackie B viruses (e.g. CVB3) (Sauerbrei et al. 2000).

MANAGEMENT IN PREGNANCY AND OF THE NEONATE

Enterovirus infections in early pregnancy occasionally cause abortion but are not teratogenic, and the mother should be reassured accordingly. Prenatal diagnosis should be considered in the differential diagnosis of nonimmune *hydrops fetalis* with pericardial effusion and fetal tachycardia, particularly in women with suspicion of recent enterovirus infection. Acute symptomatic or asymptomatic infections towards the end of pregnancy carry the risk of intrauterine infection causing severe neonatal disease. In case of known infection of the mother, the child should be isolated at delivery and the baby should be fed with expressed maternal breast milk. The use of intravenous immunoglobulin up to the age of 14 days as a preventive measure for neonates exposed to infected infants did not confer significant benefit (Abzug et al. 1993). Pleconaril may be used as an emergency medication (Ouellet et al. 2004). In hospitals, adequate hygienic measures must be observed because of the ready spread of these viruses in neonatal units.

LYMPHOCYTIC CHORIOMENINGITIS VIRUS

Lymphocytic choriomeningitis virus (LCMV) is a rodent-borne *Arenavirus*. The infected animals may be asymptomatic, but may excrete the virus for months. The illness in infected people is influenza-like and accompanied by fever, headache, nausea, and myalgia lasting 5–10 days; a small proportion develop meningitis or choriomeningitis, which in adults usually resolves without sequelae.

LCM virus infection is an often undiagnosed cause of congenital disease with features similar to those of cytomegalovirus or *Toxoplasma gondii*. Infection with LCMV in the first trimester of pregnancy may cause abortion (Ackermann et al. 1975; Biggar et al. 1975; Deibel et al. 1975), and infection of the fetus can result in congenital hydrocephalus, chorioretinitis, severe hyperbilirubinemia, and myopia (Sheinbergas 1975; Sheinbergas 1976; Enders et al. 1999). Although the number of published studies on intrauterine and perinatal infections is limited, the incidence of serious sequelae in infants seems to be high (Barton et al. 1995; Enders et al. 1999; Barton and Mets 2001).

Because healthy mice and hamsters shed LCMV chronically, pregnant women should avoid direct contact with these animals and their excreta.

HUMAN PAPILLOMAVIRUSES

Juvenile laryngeal papillomatosis (JLP) is associated most often with human papillomavirus (HPV) types 6 and 11; it is an uncommon but potentially serious problem, which is best treated by prevention if possible.

Infection in pregnancy

Growth of HPV warts is stimulated by several factors, including pregnancy. Some of the lesions may grow markedly during pregnancy, only to recede postpartum.

This phenomenon is thought to be related to hormonal influences or to changes in local cellular immunity. Rarely, the lesions become so large as to obstruct the birth canal and extensive formation of HPV condylomata may lead to premature rupture of the membranes, chorioamnionitis, and intrapartum infection of the fetus (Young et al. 1973).

Effects on the fetus and the neonate

Overall, the risk of perinatal transmission seems to be low, and it is still unclear how frequent it progresses to clinical lesions (Watts et al. 1996; Syrjanen and Puranen 2000). Nevertheless, transmission from mother to fetus and to the newborn may occur both in clinically apparent and subclinical maternal infection, and may lead to intrauterine infections, perinatal infections, or both. Approximately 50 percent of children with JLP are born to mothers with genital HPV (Quick et al. 1980; Nikolaidis et al. 1985), and HPV types 6 and 11, which are the most common in anogenital tract infections (Ferenczy 1989), are identified in >80 percent of JLP cases. Gastric and nasopharyngeal aspirates of babies born to mothers with genital tract HPV have been reported to contain HPV DNA (Ferenczy 1989; Sedlacek et al. 1989). The possibility of perinatal transmission is supported by the detection of DNA from HPV types 6, 11, 16, and 18 in foreskin specimens from neonates (Roman and Fife 1986).

Association with JLP

The long latent period from birth to development of JLP (>7 years) and the observation that HPV types found in newborns often differs from those detected in their mothers make association with intrauterine or perinatal infection difficult. Postnatally acquired infection from a variety of sources may account for numerous cases of JLP. For example, HPV may be transmitted on fomites after contact with individuals with warts (Patsner et al. 1990) and sexual abuse may also result in postnatal infection (Fleming et al. 1987). Recent data from Scandinavia indicate that despite the increasing rate of genital HPV infections in pregnant women, the incidence of JLP remains very low (Lindbergh and Elbrond 1990).

Diagnosis

The HPV infection may be latent without evident warts or manifest with warts. The diagnostic methodology extends from gynecological examinations, PAP smear tests, and colposcopy to the direct detection of the viral nucleic acids with molecular biology techniques such as PCR or hybrid capture (Arena et al. 2002). HPV antibodies are detectable in children of infected mothers, but there is generally no correlation between seropositivity and the detection of DNA in either the oral or the genital mucosa (Syrjanen and Puranen 2000; Burd 2003). Women under treatment for cytologically and virologically proven HPV infection should be examined at intervals until lesions and HPV DNA are no longer detectable. Testing their partners is recommended.

Management

The treatment of pregnant women with HPV-induced genital warts should be started as early as possible and directed at elimination of the virus near term to diminish risk of the infant's acquiring HPV infection by passage through an infected birth canal. Laser vaporization is proposed as an effective invasive technique for treatment of warts in pregnant women (Arena et al. 2001). As noninvasive methods, topically applicable immune modifiers have been reported. Prophylactic cesarean section in pregnant women with genital HPV infection is not advocated except in the rare event of large condylomata obstructing the birth canal.

Preventive and therapeutic vaccines, usually composed of recombinant viruslike particles directed against HPV, are under development (Hines et al. 1995; Borysiewicz et al. 1996). Beside this more classical technology, a new strategy based on genetic immunization with naked HPV DNA is now evaluated (Moniz et al. 2003; Burd 2003; Roden et al. 2004).

Virus infections in immunocompromised patients

ANTHONY SIMMONS

HIV-infected adults	1	Immune deficiencies not caused by HIV	9
HIV-infected children	7	References	13

Perturbations of immunity can influence the pathogenesis of viral infections in several ways. Prominent among these is increased frequency or severity of disease, exemplified par excellence by the debilitating manifestations of many herpesvirus infections in immunocompromised hosts. However, not all viral infections are exacerbated by immunosuppression and the acute stages of some diseases, such as hepatitis B, may be unusually mild. This is presumably because immunologically mediated lysis of infected cells contributes more than virally induced cell damage to the pathogenesis of some diseases in normal hosts.

Diagnosis of viral infections in immunocompromised patients can be difficult. Total and differential leukocyte counts tend to be unhelpful, clinical signs and symptoms of infection are often atypical, and symptoms produced by the host's immune response (e.g. the rash of measles) may be absent. Serology has little role in diagnosis because patients with dysfunctional immunity do not usually mount appropriate immune responses rapidly enough to influence decisions about management. The mainstay of diagnosis is detection of virus in appropriate clinical specimens: rapid procedures, such as direct antigen detection, nucleic acid detection and culture amplified enzyme immunoassays, have increased the usefulness of laboratory diagnosis enormously (Simmons 1996). In some situations (e.g. post-transplantation), regular surveillance cultures may be helpful: virus shedding may precede the onset of symptoms, and initiation of therapy as soon as virus is detected may prevent extensive tissue damage.

The AIDS pandemic has created an explosive increase in the number of profoundly immunocompromised people worldwide. The clinical manifestations of viral infections in human immunodeficiency virus (HIV)-infected individuals often differ significantly from the signs and symptoms caused by the same viruses in patients with other types of immune deficiency. Accordingly, a significant part of this chapter is devoted specifically to patients infected with HIV.

HIV-INFECTED ADULTS

The progressive decline in immunological function associated with HIV infection is usually monitored by measuring the absolute $CD4^+$ T-cell count. In general, significant opportunistic viral infections (Table 1) are not seen until $CD4^+$ T cells fall below $200/mm^3$ and the most severe problems are associated with $CD4^+$ T-cell counts of $<100/mm^3$. Herpesviruses, particularly cytomegalovirus (CMV) and herpes simplex viruses types 1 and 2 (HSV-1 and HSV-2), are common causes of serious disease in profoundly immunosuppressed HIV-infected individuals and therefore herpesviruses receive particular attention here. Infections caused by papillomaviruses and enteric viruses are also given special consideration. Importantly, in locations where highly active antiretroviral therapy (HAART) is available, the prevalence in patients with AIDS of severe complications caused by viruses has been reduced considerably. Where appropriate, the discussion includes diagnosis and treatment of first-episode disease, prophylaxis against recurrence and, finally, measures to prevent acquisition of infection in previously unexposed individuals.

Herpesvirus infections

Several genetically distinct herpesviruses have been isolated from humans. Some, namely HSV-1 and HSV-2, varicella-zoster virus (VZV), Epstein–Barr virus (EBV) and CMV have been recognized for decades. By contrast, human herpesviruses types 6 and 7 (HHV-6 and HHV-7) are relatively recent discoveries and the latest addition to the list, referred to here as *Human herpesvirus 8* HHV-8, is of particular interest in the present context because it is found in Kaposi's sarcoma (KS) cells (Chang et al. 1994).

Most well-characterized herpesviruses establish latent infections from which disease can periodically reactivate. In some cases, there are prolonged periods of asymptomatic virus shedding. Human herpesvirus (HHV) infections are generally acquired in early childhood and therefore most of the clinical problems associated with herpesviruses in adults are the result of reactivations. With the exception of varicella and herpes zoster, primary and recurrent HHV infections are often clinically unapparent and transmission of infection commonly occurs during periods of asymptomatic virus shedding.

The herpesviruses that cause greatest morbidity among HIV-infected people are HSV, CMV, VZV, and EBV. Occasional disease has been associated with HHV-6 and HHV-8 is thought to have a causal relationship with KS.

HERPESVIRUSES AS COFACTORS IN PROGRESSION OF HIV-RELATED DISEASE

Aside from their direct clinical impact, it has been suggested that herpesviruses could be cofactors in the development of AIDS, i.e. herpesviruses might accelerate progression toward immunodeficiency and death by influencing the pathogenesis of HIV infection at the molecular or cellular level. Epidemiologic data supporting this hypothesis are limited. A study of HIV-infected hemophiliacs suggested more rapid progression to AIDS in CMV-seropositive compared with CMV-seronegative patients (Webster et al. 1989), but this result could not be confirmed in a similar study elsewhere (Rabkin et al. 1993). Probably the best way to address the hypothesis is to study the effect of herpesvirus-specific antiviral drugs on HIV progression. There have been several clinical trials in which patients have been treated prophylactically with the anti-herpes compound aciclovir, in addition to zidovudine. Two groups (Cooper et al. 1993; Youle et al. 1994) showed, independently, that combination therapy increased survival time compared with zidovudine alone. However, neither study showed a decrease in deaths related to any of the known human herpesviruses and

the explanation for the apparent benefit of combination therapy remains obscure.

Although the proposal that herpesviruses promote the development of AIDS is in the realms of speculation, several molecular mechanisms can be envisaged by which HIV replication, or reactivation of latent provirus, could be enhanced.

For instance; all HHVs encode proteins called transactivators, which up-regulate viral gene expression during replication. Some herpesvirus transactivators are 'promiscuous,' i.e. they can upregulate expression not only of herpesvirus genes but also of genes belonging to other viruses or host cells. In vitro, several herpesvirus transactivators have been shown to interact with the HIV long terminal repeat, which is the main region of the HIV genome responsible for controlling gene expression. Thus, co-infection of a cell with a herpesvirus and HIV could, in principle, result in enhanced HIV replication. Alternatively, reactivation of latent HIV might be stimulated by superinfection with a herpesvirus. The best candidates for herpesviruses that might enhance HIV replication are CMV and HHV-6 because these viruses are commonly found in the same tissues as HIV in autopsy specimens (Emery et al. 1999). Therefore, coinfection of, for example, lymphocytes with HIV and either CMV or HHV-6 is a theoretical possibility. Furthermore, HHV-6 infection has been shown to transactivate the HIV *tat* gene in vitro (Garzino-Demo et al. 1996).

Promiscuous transactivation of various cellular genes could also, in principle, promote the spread of HIV. For example, virus induced up-regulation of CD4, the main cell surface receptor for HIV, might facilitate the spread of HIV from cell to cell. Similarly, up-regulation of cell surface Fc receptors, a property of most herpesviruses, could enable antibody-coated HIV particles to enter $CD4^+$ cell types, thereby expanding the pool of HIV-infected cells.

Coinfection of a cell with more than one type of virus raises the possibility of phenotypic mixing and the formulation of virus pseudotypes. This phenomenon is well established in vitro and can be manipulated to the extent that HIV genomes can be packaged into the capsids of vesicular stomatitis viruses. Formation of pseudotypes comprising HIV genomes packaged into particles containing herpesvirus glycoproteins has not been documented in vivo, but nevertheless, pseudotype formation remains a theoretical way in which HIV genomes could gain entry into a wide variety of otherwise resistant cell types.

HERPES SIMPLEX VIRUSES TYPES 1 AND 2

Herpes simplex is one of the commonest infections of humans. HSV-2 is transmitted almost exclusively by sexual contact; consequently, HSV-2 seropositivity is rare before the onset of sexual activity. The epidemiology of HSV-1 is more diverse; infection is commonly acquired during infancy or childhood from infected oral secretions, but sexual transmission of HSV-1 is becoming increasingly common. HSV latently infects primary sensory neurons innervating the portal of entry, creating a reservoir of infection that can periodically give rise to recrudescent disease. The generally early acquisition of HSV means that most episodes of herpes simplex seen in the clinic are recrudescences.

In the context of HIV infection, HSV causes a wide spectrum of disease, including genital herpes, perioral and facial herpes, perianal lesions, proctitis, conjunctivitis and keratitis, aseptic meningoencephalitis, herpetic Whitlow, autonomic nervous system dysfunction and acute necrotizing retinitis. In profoundly immunocompromised patients, with $CD4^+$ T-cell counts of $<100/mm^3$, extensive and chronic mucocutaneous ulceration is a frequently encountered and troublesome clinical problem, particularly in the genital and perianal regions (Safrin et al. 1991). In the absence of a normal inflammatory response, the lesions tend to respond slowly or poorly to antiviral therapy and they are often indolent or atypical in appearance.

In addition to prolonged mucocutaneous ulceration, there are several other severe manifestations of HSV infections in AIDS patients that merit further consideration. HSV may invade the esophagus or other parts of the gastrointestinal tract, giving rise to symptoms that reflect the region of the gut that is infected. Disseminated infection is rare but life-threatening. Many organs may be involved, including the lungs, liver, and adrenals. Prolonged ulcerative lesions and visceral disease are AIDS-defining illnesses.

There is evidence to suggest that genital ulceration facilitates sexual transmission of HIV and, in industrialized nations, the commonest cause of genital ulceration is HSV. By extrapolation, it has been proposed that genital herpes promotes the spread of HIV and there is some evidence that indirectly supports this contention (Holmberg et al. 1988; Stamm et al. 1988; Keet et al. 1990; Hook et al. 1992; Gwanzura et al. 1998).

Prevention of exposure

Strictly speaking, strategies designed to prevent exposure to HSV apply only to those rare individuals who are HSV-seronegative. However, first episode genital infections caused by HSV-2 in people previously exposed only orally to HSV-1 may be symptomatic; i.e. prior HSV-1 infection is, at best, only partially cross-protective against HSV-2 (Xu et al. 2002). Furthermore, in HIV-infected people, exogenous reinfection of the genital tract with different strains of HSV-2 is a possibility. With these considerations in mind, it is recommended that all HIV-infected people use latex condoms during every sexual contact. Condom usage is essential irrespective of whether the sexual partner has noticeable

herpetic lesions, because HSV is frequently shed from the genital tract asymptomatically.

Treatment and suppression of symptoms

HSV replication is inhibited by aciclovir, its pro-drug valaciclovir, and famciclovir. Aciclovir is available in oral and intravenous formulations; the appropriate route of administration and dose depend on the severity of lesions and the degree of immunological impairment. Primary genital herpes can be managed with oral aciclovir or valaciclovir unless immune function is profoundly impaired or lesions are unusually severe, in which case intravenous aciclovir is required. Recurrent genital herpes in patients with early HIV infection generally resolves spontaneously. In this group of patients, the approach to management is the same as for immunocompetent people: symptomatic relief of mild, infrequent outbreaks or, in selected patients who experience clear prodromal symptoms, episodic valaciclovir (Bodsworth et al. 1997) or famciclovir. Continuous administration of valaciclovir should be considered for patients with frequent episodes (Patel et al. 1997) or when lesions tend to heal slowly. In advanced HIV infection, when immune suppression is profound, herpetic lesions often require prolonged therapy with high doses of an antiviral compound; treatment failure is not uncommon, even when the drug is administered intravenously (Whitley and Gnann 1992). In this patient population, emergence of aciclovir-resistant viral strains, which are also resistant to the related nucleoside analogue ganciclovir is an increasingly recognized problem (Chatis and Crumpacker 1992). There are few avenues available for the treatment of recalcitrant lesions caused by aciclovir-resistant virus, the main option being intravenous foscarnet or perhaps cidofovir (Kopp et al. 2002).

Aciclovir resistance

Aciclovir is a nucleoside analogue which, when phosphorylated, inhibits DNA replication. The drug is phosphorylated by an HSV-encoded enzyme, thymidine kinase (TK), hence it is active only in HSV-infected cells. Emergence of HSV strains resistant to aciclovir is rare in immunocompetent hosts, even after long-term suppressive therapy. The situation is different in immunocompromised hosts, particularly patients with advanced HIV infection, in whom aciclovir resistance is a significant clinical problem.

HSV becomes resistant to aciclovir by way of viral TK mutations that decrease the ability of the virus to phosphorylate the drug. Such mutations can also affect the ability of TK to phosphorylate nucleosides required for virus replication. However, TK-altered HSV strains are able to grow in most cell types, because cellular kinases substitute for viral TK. Consequently, aciclovir-resistant viruses may cause aggressive mucocutaneous lesions, However, non-dividing cells, notably neurons, express unusually low amounts of endogenous kinases and, in these cells, replication of aciclovir-resistant HSV strains is, fortuitously, inhibited. This has important practical consequences: HSV must replicate in neurons in order to reactivate from latency and, therefore, the latency/reactivation cycle is interrupted for aciclovir-resistant viruses. The subtle influence of viral TK on the pathogenesis of herpes simplex may explain, in part, why aciclovir resistance is largely confined to patients treated over long periods for recalcitrant cutaneous lesions.

VARICELLA-ZOSTER VIRUS

Varicella is a common disease of childhood that is generally benign in immunocompetent hosts. In industrialized nations, seropositivity to VZV is >90 percent by the age of 15 years and therefore varicella is uncommon in adults. In the USA varicella vaccination is commonplace, further enhancing immunity among the young. This is fortunate, because the clinical impact of varicella in adults with impaired cellular immunity is high. Clinical manifestations include extensive, often hemorrhagic, cutaneous lesions and pneumonitis.

VZV establishes latency in sensory ganglia in much the same way as herpes simplex, although it has been suggested that the virus may be dormant in satellite glia rather than in neurons (Croen et al. 1988). However, despite controversy about the cell specificity of latent VZV for over a decade, it is now widely accepted that the virus is latent mainly in neurons, with only a small proportion of glia infected (Kennedy 2002). Recurrent VZV infection (herpes zoster, or shingles) is characterized by a blistering dermatomal rash and pain. HIV infection has a substantial impact on the incidence of VZV recurrence. HIV-infected adults are nine times more likely than the general population to develop herpes zoster (Holmberg et al. 1995) and the annual incidence of the disease is seven times higher in HIV-infected adults than in the general population. HIV-positive homosexual men are 17 times more likely to develop zoster than demographically matched HIV-negative subjects (Buchbinder et al. 1992).

The clinical manifestations of recurrent VZV infections in HIV-infected patients depend on the degree of immunological impairment. In the early stages of HIV infection, the signs and symptoms resemble herpes zoster in immunologically normal hosts. By contrast, repeated episodes of severe, prolonged, and sometimes atypical disease (Nikkels et al. 1999) are characteristic of advanced HIV infection. A few patients develop VZV retinitis, which has a particularly poor prognosis if the $CD4^+$ T-cell count is $<50/mm^3$. In some cases, atypical herpes zoster may require laboratory tests for confirmation of the diagnosis, in which case material from a recently erupted lesion should be sent for virus culture,

rapid antigen detection or, if available, culture amplified enzyme immunoassay. Antemortem diagnosis of herpes zoster is particularly difficult when atypical manifestations of the disease, such as retinitis, meningoencephalitis, optic neuritis, and visceral involvement, occur in the absence of cutaneous lesions.

Prophylaxis and treatment

Most adults with no history of chickenpox have antibodies to VZV, and serological tests are useful for determining whether an HIV-infected patient is truly at risk of acquiring primary VZV infection. Seronegative patients should avoid contact with varicella- and herpes zoster; if contact is documented, they should receive varicella-zoster immunoglobulin (VZIG) within 96 hours of exposure. In addition, household contacts should be vaccinated against VZV if they have no history of chickenpox or are known to be seronegative provided they themselves do not have advanced HIV infection. The prophylactic effect of varicella vaccine, administered to susceptible HIV-infected people before $CD4^+$ T cells become depleted, has yet to be fully evaluated. However, varicella is not a cofactor for progression to AIDS (Aronson et al. 1992) and is a generally benign illness early in the course of HIV. As a consequence, varicella vaccine (Oka strain) should be considered for non-immunocompromised HIV-positive children.

Most cases of herpes zoster respond well to valaciclovir, famciclovir, or high-dose oral aciclovir. Disseminated, recurrent, or unusually severe cases should be treated intravenously. Aciclovir-resistant VZV strains have been isolated from severely immunocompromised people on long-term suppressive therapy (Lyall et al. 1994). The usual cause of resistance is mutation of the viral TK gene; aciclovir-resistant VZV remains sensitive to intravenous foscarnet (Balfour et al. 1994).

CYTOMEGALOVIRUS

CMV infection is extremely common among men who have sex with men (MSM) and intravenous drug users (IVDU) and in these populations it is generally acquired before HIV. Therefore primary CMV infections are rare among HIV-infected MSM and IVDU. Other HIV-infected people should be informed that CMV is shed in body fluids including semen, saliva, and cervical secretions and advised to use latex condoms during sexual contact. Reactivation of CMV does not cause illness in immunocompetent adults. By contrast, when cellular immunity is impaired, reactivation has many potential clinical manifestations, including retinitis, esophagitis, colitis, pneumonitis, and CNS disease. The spectrum of disease caused by recurrent CMV infection is significantly different in HIV-infected people compared with transplant recipients. For instance, necrotizing retinitis and CNS disease, common complications of CMV infection in advanced AIDS (Drew 1988; Jacobson and Mills 1988), are very unusual in the transplant setting. Conversely, CMV pneumonitis is unusual in HIV-infected adults but is not uncommon in transplant recipients.

CMV is frequently present in body fluids of AIDS patients and it is often difficult to establish a causal relationship between CMV and disease. Detection of CMV in affected organs provides circumstantial evidence that disease is CMV-related, but this approach frequently fails. CMV is often detected in bronchoalveolar lavage specimens from AIDS patients but this alone is not predictive of CMV pneumonitis; histological examination of cells or tissue for characteristic cytomegaly is required to establish the diagnosis.

Prevention, pre-emptive therapy, and treatment

HAART has had a profound impact on the previously high incidence of CMV disease in HIV-infected persons. However, not all patients are able or ready to take HAART and in some cases HAART may have failed. CMV remains therefore a significant problem. Unfortunately, immunization is not an option currently available for protection against primary CMV infection in the immunocompromised but general prophylactic measures are appropriate, including counseling about the risks of sexual transmission and the increased risk of CMV acquisition in the child care setting. In the latter situation, good hygienic practices including hand washing can reduce the risk of acquisition. In reality, measures to prevent exposure apply to only a small proportion of HIV-infected adults but it is essential that patients understand that CMV is present in genital secretions. Finally, if CMV-seronegative patients require transfusion, blood products should be obtained from CMV-seronegative donors.

Many adults are already infected with CMV when HIV infection is diagnosed and reconstituting immunity with HAART is the most effective way of preventing CMV disease from developing in seropositive persons. Ways to predict and prevent development of CMV disease (primary prophylaxis) are being explored, allowing pre-emptive therapy to be commenced before irreversible damage has been done. CMV viremia per se is no more predictive of CMV disease than $CD4^+$ T-cell counts (Salmon-Ceron et al. 2000); most patients who develop CMV disease have <200 $CD4^+$ T cells/mm^3, and the risk increases as the $CD4^+$ T-cell count falls. The greatest risk is in patients with <50 $CD4^+$ T cells/mm^3, in whom the median time to development of retinitis is 6 months. Anti-CMV drugs are generally too toxic for continuous administration to profoundly immunocompromised persons ($CD4^+$ T-cell count <50/mm^3) and therefore true prophylaxis in AIDS patients awaits the development of safer, orally active compounds. Oral ganciclovir has been investigated for

primary prophylaxis of CMV in AIDS but neutropenia, anemia, cost, and lack of proven efficacy have made its use a generally unpopular option.

The mainstays of treatment for established disease are intravenous ganciclovir, foscarnet, cidofovir, and fomivirsen, given intravitreally for retinitis. These drugs are toxic and treatment is not curative, so it is usual to reduce the dosage to maintenance levels after an initial period of induction. Without maintenance, relapse is inevitable; even on maintenance, relapse is common, necessitating periods of reinduction.

EPSTEIN–BARR VIRUS

HIV infection promotes the development of a variety of EBV-related diseases. Oral hairy leukoplakia is an EBV-associated hyperkeratotic disease of the tongue that is very common in HIV-infected patients but very rare otherwise. It responds to aciclovir but relapses if therapy is stopped. Lymphomas occur with greatly increased frequency in HIV-positive individuals, and a high proportion of the tumors, which tend to be monoclonal, contain cells expressing EBV antigens. Despite intensive chemotherapy, the prognosis is poor, especially in patients with low $CD4^+$ T-cell counts.

HUMAN HERPESVIRUSES 6 AND 7

HHV-6 and HHV-7 are ubiquitous, closely related betaherpesviruses, and most humans are infected with these agents in early childhood. Primary infection may be asymptomatic or cause roseola infantum. It is probable that both viruses establish latent infections in lymphoid tissues; in immunocompromised people, latent infection may reactivate and disseminate. HHV-6 is also known to be resident in the brain. In AIDS patients, HHV-6 has been detected in a wide variety of tissues postmortem and may cause fatal pneumonitis (Knox and Carrigan 1994). Further work is required to clarify its clinical impact.

HUMAN HERPESVIRUS 8 (KAPOSI'S SARCOMA-ASSOCIATED HERPESVIRUS)

HHV-8 is found in KS but not in normal skin. It is also associated with primary effusion lymphomas and some cases of multicentric Castelman's disease. On the basis of nucleotide sequence analysis, this agent is a gamma-2 herpesvirus, related to herpesvirus saimiri of squirrel monkeys and newly identified viruses of chimps and gorillas (Lacoste et al. 2000). Several lines of evidence suggest that HHV-8 plays an etiologic role in KS. First, antibodies against the virus are found in the sera of virtually all KS patients. Second, HHV-8 encodes several homologs of human proteins that could modulate cellular behavior, including a variety of cytokines (IL-6, MIPs, IRFs), cyclin D and a G-protein-coupled receptor (GPCR). Retinoblastoma protein and p53 are inhibited by viral cyclin D and the latency-associated nuclear antigen respectively and mice transgenic for GPCR have Kaposi-like regions in the skin. Finally, HHV-8 viral load in lymphocytes (Campbell et al. 2000) and skin lesions (Boivin et al. 2000) have been shown to increase with increasing disease burden.

Prevention and treatment

There is evidence to suggest that acquisition of HHV-8 after being infected with HIV may be associated with accelerated progression to KS, making prophylaxis against HHV-8 a priority. Counseling can be based on the three known routes of transmission, which are kissing (virus in saliva), sexual (virus in semen), bloodborne, and mother to child (Plancoulaine et al. 2000). Avoidance of deep kissing with persons with KS is currently accepted as advisable to reduce the risk of oral transmission. There is no evidence to support the supposition that latex condoms reduce the transmission of HHV-8 but their use is advisable for protection against not only HHV-8 but many other sexually transmissible infections. Owing to the lack of routine serological tests for HHV-8, screening of blood has not been possible and finally, there are no current recommendations for preventing mother-to-child transmission.

The prevalence of KS is lower among AIDS patients treated for retinitis with either ganciclovir or foscarnet, both of which inhibit HHV-8 replication in vitro, suggesting that these compounds might be useful for prevention or treatment of KS. However, the efficacies of antiviral therapies for HHV-8 infection have not been established and this remains a research priority. Finally, restoration of immune function with HAART, where it is available, has greatly reduced the prevalence of KS.

Human papillomavirus infections

Of the 70 or so known Human papillomavirus (HPV) infections, more than 25 have been detected in the genital region. Some HPVs, notably types 16 and 18, are associated with precancerous intraepithelial neoplasias of the cervix, vagina, vulva, penis, and anus. HIV-induced immune dysfunction increases the prevalence of detectable genital HPV infection and HPV-associated intraepithelial neoplasia (Northfelt and Palefsky 1992), as does iatrogenic immunosuppression (Penn 1986). However, the association between HIV and HPV is not explicable solely on the basis of immunosuppression, because HPV DNA is detectable with increased frequency in the genital tracts of women with early HIV infection, before there is a measurable decline in the $CD4^+$ T-cell count. Both direct interaction between HIV and HPV and the common risk factors for their acquisition may contribute to the association between HIV infection and HPV-related disease.

In HIV-infected women, cervical intraepithelial neoplasia (CIN) recurs more frequently than expected after treatment (Maiman et al. 1990), and recurrence is

related to severity of immunosuppression. Although CIN does not seem to progress unusually rapidly to invasive cancer, the latter is an AIDS-defining condition according to the Centers for Disease Control and Prevention guidelines. It is recommended that women have a pelvic examination and Papanicolaou (Pap) smear twice during the first year after HIV diagnosis and once per year thereafter. The usefulness of cytological screening of HPV-positive MSM for early detection of anal high-grade intraepithelial neoplasia is currently unclear (Piketty et al. 2003).

Hepatitis C

HIV infection and hepatitis C share some common risk factors (primarily injecting drug use and hemophilia) and therefore it is prudent to screen all HIV-positive patients for hepatitis C virus (HCV). This is important for helping in the interpretation of abnormal liver function tests and also because in patients with HIV infection the course of hepatitis C may be accelerated (Thomas et al. 1996). The safety of treatment for hepatitis C in HIV-infected patients is currently under investigation.

Enteric infections

Diarrhea is very common among HIV-infected patients. Potential viral causes include astroviruses, adenoviruses, picobirnavirus, and caliciviruses (Grohmann et al. 1993), on the basis that they are detected more frequently in patients with diarrhea than in patients without diarrhea. CMV is also associated with gastrointestinal disease in HIV-infected adults (Laughon et al. 1988).

PICOBIRNAVIRUSES

Picobirnaviruses are small, bisegmented, double-stranded RNA viruses that have been detected in a wide variety of vertebrates, including pigs, in which they are associated with diarrhea (Gatti et al. 1989). They can be grown in mammalian cell cultures, suggesting that they are vertebrate viruses rather than viruses of other intestinal organisms such as protozoa. It is not known with certainty whether picobirnaviruses cause diarrhea in humans (Glass et al. 2001) but their detection in a significant proportion of fecal specimens from HIV-infected patients with diarrhea raises this possibility (Giordano et al. 1998, 1999). Development of serological tests might help to determine the prevalence of picobirnavirus infections in the human population.

ENTERIC ADENOVIRUSES

Reported rates of faecal carriage of adenoviruses among patients with advanced HIV infection are very high (Cunningham et al. 1988). Adenovirus infections of the gastrointestinal tract are frequently asymptomatic, and when symptoms are noted they are often mild. In immunocompetent people, adenoviruses associated with diarrhea (Liste et al. 2000; Pollok 2001; Trevino et al. 2001) usually belong to subgenera A, C, or F, but in HIV-antibody-positive patients at least one report suggests that the most predominant fecal isolates belong to subgenus D (Khoo et al. 1995). There is some suggestion that prolonged infections in patients with $CD4^+$ T-cell counts $<200/mm^3$ may allow antigenic drift and genetic recombination between different serotypes (Hierholzer et al. 1988).

JC polyoma virus and progressive multifocal leukoencephalopathy

Progressive multifocal leukoencephalopathy (PML) is a neurological disease caused by JC polyoma virus (JCV). It is characterized by multiple foci of demyelination throughout the CNS. PML has a global distribution and, in patients who do not have AIDS, it is most common in people over the age of 50. The disease is seen in patients with a wide variety of disorders associated with impaired immune function but very rarely in immunocompetent hosts. JCV is found in the nuclei of oligodendrocytes in affected areas of the brain, and viral DNA is present in the cerebrospinal fluid (Gibson et al. 1993). The clinical features of PML are gradual deterioration of cerebral function, progressing to dementia, blindness, paralysis, and eventual coma and death, usually within 6 months of onset.

No treatment is curative and currently, the best initial approach to therapy for PML is improving the underlying immunodeficiency. Addition of cidofovir to HAART has been reported to improve clinical outcome in PML patients and reduce JCV DNA load in cerebrospinal fluid, indicating control of JCV replication (De Luca et al. 2000).

HIV-INFECTED CHILDREN

The impact of opportunistic viral infections on HIV-infected children has yet to be fully determined. However, as in adults, herpesviruses are a major problem.

Herpesvirus infections

There are marked differences in the clinical manifestations of herpesvirus infections in HIV-infected children compared with adults. In part, the differences depend on whether HIV infection precedes primary infections with herpesviruses.

HERPES SIMPLEX VIRUSES

In children, herpes simplex is almost always limited to the oropharynx. Esophagitis is rare, as is dissemination

or invasion of the CNS. Furthermore, there is no evidence suggesting that neonatal herpes is more common among the offspring of HIV-infected mothers. The diagnostic method of choice is detection of virus or viral antigens in material collected from newly erupted lesions. Treatment follows guidelines similar to those applied to herpes simplex in adults: oral or intravenous aciclovir according to the severity of disease and suppressive therapy with oral aciclovir for frequently recurrent episodes.

VARICELLA-ZOSTER VIRUS

A small number of cases of varicella in HIV-positive children have been reported in the literature, including a recent outbreak at a summer camp for infected children. Some cases run an uneventful course whereas others may be prolonged or complicated by sepsis, pneumonia, or cerebral vasculitis/aneurism. Recurrent varicella- and herpes zoster have been documented. The severity of complications seems to be inversely related to the $CD4^+$ T-cell count (Jura et al. 1989). Diagnosis is usually possible on clinical grounds. Atypical disease may require laboratory confirmation by detection of VZV in material collected from a freshly erupted vesicle.

Prophylaxis and treatment

Serological tests may be required to identify children who are susceptible to primary infection with VZV. Seronegative children should avoid contact with chickenpox and herpes zoster; when exposure is documented, VZIG may be useful. However, even when VZIG is given within 96 hours of exposure, protection is not guaranteed (Srugo et al. 1993). Varicella vaccine has recently been reported to be beneficial and safe in mildly immunocompromised HIV-infected children (ACIP 1999).

Aciclovir is effective in the treatment of varicella in HIV-infected children (Jura et al. 1989). Intravenous therapy is recommended, particularly for children with poor immune function.

CYTOMEGALOVIRUS

CMV infection is very common among infants whose mothers are HIV-antibody-positive. Furthermore, maternal HIV infection seems to increase the prevalence of congenital CMV. CMV-related disease is an important AIDS indicator event in HIV-infected children, and dissemination of CMV in children with advanced HIV infection carries a high mortality. There is evidence to suggest that HIV-related disease develops up to three times more rapidly in CMV-infected infants compared with uninfected infants. Therefore prophylaxis is a desirable but currently unattainable goal.

There are differences in the clinical manifestations of CMV infection in HIV-infected children and adults that most probably represent the different outcomes of primary and recurrent infections, respectively. Pneumonitis and hepatitis, the commonest diseases caused by CMV in HIV-infected children, are probably the result of primary infection. By contrast, CMV retinitis, which is common in adults and rare in children, is thought to follow reactivation of latent virus in the immune host.

Diagnosis of CMV disease is notoriously difficult, owing to the high prevalence of asymptomatic infection by the age of 2 years. Detection of CMV in urine is common and not indicative of CMV disease. Detection of CMV in the diseased organ [by culture, viral antigen detection, culture amplified antigen detection or polymerase chain reaction (PCR)] is currently the best diagnostic approach but the predictive value of a positive result is not absolute.

Prophylaxis and treatment

Ganciclovir, foscarnet, and cidofovir have all been used to treat CMV disease in children. Toxicity is less of a problem in children compared with adults but the drugs must be given intravenously, creating problems with compliance. Realistically, neither drug is suitable for prophylactic use.

EPSTEIN–BARR VIRUS

EBV DNA has been detected in the lungs of HIV-infected patients with lymphoid interstitial pneumonitis (LIP). LIP is rare in HIV-infected adults but is one of the commonest complications of HIV infection in infants under the age of 2 years. Clinical manifestations of LIP include lymphadenopathy, parotitis, bronchospasm, tachypnea, and sleep apnea. Serum immunoglobulin levels may be unusually high, with an associated hyperviscosity syndrome. Chest infections may complicate the disease and therefore immunization against bacterial pathogens is recommended. Diagnosis rests on sequential clinical assessments and chest X-ray changes over a period of 2 months, together with lung biopsy if necessary. Further work is merited to determine whether EBV, the host response to it, or other viruses, plays an etiologic role in LIP because, if this is the case, specific therapy may be possible. Corticosteroids and zidovudine have been reported to be useful in the management of the disease.

Respiratory syncytial virus infections

Pneumonitis, rather than bronchiolitis or wheezing, seems to be a prominent clinical manifestation of respiratory syncytial virus (RSV) in HIV-infected children (Chandwani et al. 1990). Bronchiolitis is thought to be the result of immune-mediated damage to the lung, which might explain its rarity in immunocompromised hosts. In infants with low $CD4^+$ T-cell counts, RSV pneumonia may be life-threatening as a result of

secondary bacterial infection (Chandwani et al. 1990). Pre-emptive antibacterial therapy may therefore be worthwhile in severely immunocompromised children who fail to respond promptly to ribavirin.

IMMUNE DEFICIENCIES NOT CAUSED BY HIV

Malignant tumors, cytotoxic chemotherapy or radiotherapy, and congenital disorders may all profoundly compromise the immune system, predisposing patients to unusually severe or prolonged infections with a wide range of viruses.

Herpesvirus infections

It has been known for a long time that herpesviruses are important opportunistic pathogens in patients with disorders of cellular immunity. The potential manifestations of infection are diverse and sometimes life-threatening.

HERPES SIMPLEX

The frequency and severity of recurrent episodes of herpes simplex are increased in patients with dysfunctional immunity, particularly allograft recipients (Naraqi et al. 1977; Rand et al. 1977; Meyers et al. 1980), those with malignancy or those receiving anti-tumor chemotherapy (Muller et al. 1972) and patients with Wiskott–Aldrich syndrome (St Geme et al. 1965). In allograft recipients, herpes simplex most commonly presents in the second week after transplantation.

Shedding of HSV may be asymptomatic or may present as vesicles or ulcers. Lesions may be widespread and persistent, and may involve the esophagus or rectum, causing pain and gastrointestinal disturbances. Ulcers may become indolent and, in immobile patients, perianal ulcers may be confused with pressure sores. Major manifestations of visceral infection are pneumonia and hepatitis.

Virus detection is the mainstay of laboratory diagnosis. In the case of a superficial infection, the specimen required is material collected from the base of the lesion. To diagnose HSV pneumonia, bronchoalveolar lavage fluid or, preferably, a lung biopsy specimen is necessary. Virus culture is probably the most sensitive diagnostic procedure in routine use but it can take up to 7 days before a characteristic cytopathic effect (CPE) develops. More rapid procedures include direct detection of viral antigens and culture-amplified enzyme immunoassays, in which inoculated cell cultures are tested for the presence of viral antigens after 24–48 hours, in order to prevent the development of cytopathology.

Prophylaxis and treatment

To control reactivation of HSV caused by iatrogenic immunosuppression, bone marrow recipients are often given aciclovir prophylactically, commencing at the start of induction chemotherapy. However, some transplant units believe it is more cost effective to treat episodes as they arise.

Intravenous aciclovir is recommended for the treatment of all HSV disease in profoundly immunocompromised patients, irrespective of whether the infection is localized or disseminated at the time of diagnosis. Oral aciclovir or valaciclovir may be appropriate for localized herpes simplex in patients who are not severely immunocompromised, with the caveat that intestinal absorption of the drug may be reduced by irradiation of the gut or systemic chemotherapy.

VARICELLA

Varicella is an aggressive and potentially fatal disease in people with severe cellular immune defects. The rash may be florid or hemorrhagic, and visceral manifestations include hepatitis, pneumonitis, and encephalitis. Most cases of varicella can be diagnosed on clinical grounds but, occasionally, virus culture or antigen detection tests are required, particularly to distinguish the disease from disseminated herpes simplex.

Treatment and prophylaxis

Intravenous aciclovir is of proven efficacy for the treatment of visceral disease caused by VZV in children with malignant disease (Schulmann 1985). The drug is beneficial in immunocompromised children presenting at the time of emergence of rash (Nyerges et al. 1988) and treatment should begin as soon as possible after rash eruption to be effective in reducing the incidence of visceral complications.

For prevention of varicella, live-attenuated varicella vaccine (Oka strain) is safe and effective when given to children with leukemia (in remission) or other malignancies, provided that anticancer chemotherapy is suspended from 1 week before to 1 week after vaccination. Passive immunization with VZIG is useful for seronegative people known to have been exposed to varicella. VZIG is potentially beneficial when given within 96 hours of exposure but protection is not a certainty (Kavaliotis et al. 1998).

HERPES ZOSTER

Herpes zoster (recrudescent VZV infection) is common in VZV-seropositive immunocompromised children and adults and, unlike zoster in immunocompetent people, episodes may be recurrent. After bone marrow transplantation, 30 percent of patients develop herpes zoster within a year, with a peak incidence in the fourth month (Locksley et al. 1985). The disease is also common in renal transplant recipients (Naraqi et al. 1977) and in patients with Hodgkin's disease (Schulmann 1985).

Infection may be confined to a single dermatome or may involve overlapping or noncontiguous dermatomes. Cutaneous dissemination of infection is not uncommon and, in severely immunocompromised patients, life-threatening visceral dissemination may occur.

Treatment and prophylaxis

Oral aciclovir, valaciclovir, or famciclovir may be used to treat localized herpes zoster in patients who are not severely immunocompromised (e.g. those on maintenance chemotherapy). Treatment should be commenced as soon as possible after eruption of the rash. In profoundly immunocompromised patients and in patients with signs of disseminated disease, intravenous aciclovir is currently the treatment of choice.

At the present time it is not feasible or cost effective to prevent herpes zoster in immunocompromised patients by continuous administration of antiviral compounds. This situation might change in the future if safe and inexpensive oral compounds with high activity against VZV become available. There is interest in determining whether herpes zoster can be prevented in immunocompetent adults by vaccination with the Oka strain of VZV. If this approach proves to be effective, it may be applicable to some immunocompromised patients, given that vaccination of leukemic children during periods of remission safely protects them against varicella.

CYTOMEGALOVIRUS INFECTIONS

CMV infection is usually asymptomatic in the immunocompetent host. Primary infection is acquired at any time throughout life; by 40 years of age, 50–70 percent of the general population are infected, with the lower prevalence correlated with higher socioeconomic class. Primary infection or reinfection of an immune host may be acquired as a result of transfusion of CMV-seropositive blood or blood products, or receipt of a kidney from a seropositive donor. However, reactivation of latent virus is the cause of most CMV infections in immunocompromised hosts. CMV is a major cause of morbidity and mortality in allograft recipients (Peterson et al. 1980; Meyers et al. 1982). Characteristically, reactivation is detected in the second and third months after bone marrow transplantation.

CMV causes a wide range of clinical syndromes in people with dysfunctional immunity, prominent among which are hepatitis, gastrointestinal disease, and pneumonitis. The last is thought to be immunologically mediated (Grundy et al. 1987) and responds poorly to specific antiviral therapy. In bone marrow recipients, graft-versus-host disease is a risk factor for development of CMV pneumonitis. Reactivation of CMV may be manifest as fever without localizing signs of infection, creating considerable difficulty in diagnosis. Surveillance cultures of urine, saliva, and blood, taken twice weekly, are useful in this respect, because virological evidence of active infection precedes disease. In addition, quantification of CMV load in whole blood or plasma has been shown to be a useful predictor of CMV disease in solid organ transplant recipients.

Diagnosis of CMV disease requires detection of virus in material from the affected organ. For diagnosis of CMV pneumonitis, a transbronchial biopsy is a suitable specimen. Detection of virus in buffy coat cells may be a useful adjunct to diagnosis when material cannot be obtained from the affected organ. In order to be useful in patient management, virus detection must be rapid. On average, 16 days are required to identify CMV in conventional cell cultures, making virus culture impractical when decisions have to be made about therapy. Rapid diagnosis depends on direct immunohistochemical detection of viral antigen in biopsy material (Volpi et al. 1983) or culture amplified antigen detection methods. The latter approach is both rapid and sensitive and is based on the principle that a few cells in an inoculated monolayer express immediate early CMV antigens, which can be detected, for instance, by enzyme immunoassay, within 24–48 hours of infection.

Quantification of CMV in plasma or leukocytes by PCR is a rapid and potentially useful diagnostic tool in solid organ transplant recipients (Ferreira-Gonzalez et al. 1999).

EPSTEIN–BARR VIRUS INFECTIONS

Primary EBV infection is very common in early childhood and adolescence, and more than 90 percent of the adult population is EBV-seropositive. EBV replicates in B lymphocytes and pharyngeal epithelial cells and the virus is transmitted in saliva. In the normal host, lytic infection is kept under control by cytotoxic T lymphocytes (CTL) with specificity for virally encoded antigens. After recovery from primary infection, EBV persists in a latent form in B lymphocytes. In renal allograft recipients and other profoundly immunocompromised patients, lytic infection is not adequately controlled, leading to frequently recurrent or persistent virus shedding and an unusually high virus load in the blood. In one report, EBV was detected in throat washings from more than 80 percent of seropositive renal transplant patients (Chang et al. 1978).

There has been considerable debate as to whether EBV can persist in epithelial cells in addition to lymphoid tissue. Current evidence suggests that lymphocytes are the only true reservoir of EBV in vivo. Carriage of EBV is lost following ablation of lymphoid tissue in EBV-seropositive patients undergoing bone marrow transplantation (Gratama et al. 1990). Furthermore, the characteristic pattern of viral gene expression associated with latency is not evident in epithelial cells at sites of oral hairy leukoplakia (Sandvej et al. 1992).

Primary EBV infections may be asymptomatic or cause infectious mononucleosis (IM). The clinical

features of reactivated infection are poorly characterized: fever and hepatitis have been implicated as potential manifestations of recrudescent disease but undoubtedly most reactivations must be asymptomatic. Primary and recurrent infections are associated with B-cell lymphomas in transplant recipients (Hanto et al. 1982; Ho et al. 1985), and EBV nuclear antigen and EBV DNA can be detected in the tumor cells. The incidence of lymphomas in transplant patients has increased substantially with the use of more aggressive immunosuppressive regimens, and recipients of bone marrow, heart, and liver grafts are most at risk. Rapidly progressive lymphomas that develop early after transplantation are most commonly the result of primary rather than recurrent EBV infections, acquired either from the graft or from transfused blood. Lymphoma tends to be a late complication of recurrent EBV infection. Post-transplant lymphomas are resistant to standard antitumor chemotherapies, and aciclovir is not beneficial.

All post-transplantation lymphomas contain EBV DNA. The higher the virus load in the blood, the greater is the risk of developing lymphoma (Riddler et al. 1994; Savoie et al. 1994), consistent with the hypothesis that failure to control lytic infection predisposes to the outgrowth of malignant cells. Tumors are often multifocal and particularly affect the gastrointestinal tract, liver, and CNS. They may progress from a polyclonal to a monoclonal phenotype, presumably representing dominance by the most rapidly growing cell in the original tumor. Different tumors in the same patient commonly have different clonal origins.

The lymphoma cells have several properties in common with EBV-transformed lymphoblastoid cell lines, suggesting that EBV may be the only factor underlying tumor development in vivo. Chromosomal translocations of the Burkitt's lymphoma type and c-*myc* rearrangements have been reported but are rare. Tumors may regress with improved immune function (Starzl et al. 1984), suggesting that they remain sensitive to attack by EBV-specific CTLs. The possibility of treating post-transplant lymphomas by adoptive transfer of CTL is being explored.

X-linked lymphoproliferative syndrome

X-linked lymphoproliferative syndrome (XLPS) is a rare form of immunodeficiency that selectively predisposes affected males to life-threatening EBV-related disease (Purtilo et al. 1975). About 75 percent of those affected die within a few weeks of primary EBV infection. The remainder has a greatly increased risk of developing lymphomas or hypogammaglobulinemia.

Many patients with XLPS fail to control the initial proliferation of EBV-transformed B cells associated with acute IM, despite the presence of reactive T cells. This may result in a disease resembling immunoblastic lymphoma in transplant patients. Infiltration of organs by lymphocytes is a common cause of death in these individuals. Alternatively, the initial proliferation of B cells and reactive T cells may abate, to be followed by widespread infiltration and destruction of lymphoid tissues and bone marrow by phagocytic cells (Sullivan and Woda 1989). This type of pathology is indistinguishable from the virus-associated hemophagocytic syndrome.

The genetic defect responsible for XLPS is closely linked to two X-chromosome markers, DXS42 and 37. Several phenotypic defects have been identified in XLPS patients and carriers, including failure to develop antibodies to EBV nuclear antigens. IgM to IgG switching is defective and the ability of T cells to produce interferon-gamma (IFN-γ) is reduced. It has been postulated that patients with XLPS have a critical defect in their ability to support the activity of EBV-specific CTLs.

Papillomavirus infections

Warts are common in patients with dysfunctional cellular immunity, including those with leukemia or lymphoma and renal transplant recipients (Koranda et al. 1974). Most infections probably represent reactivations of latent virus.

EPIDERMODYSPLASIA VERRUCIFORMIS

Epidermodysplasia verruciformis (EV) is a rare disease that is first manifest in infancy or childhood by the development of multiple warts that do not regress spontaneously. Patients with EV have a poorly understood immunological defect that predisposes them, apparently quite specifically, to papillomavirus disease. There is often a family history of the disease but its pattern of inheritance is not clear. Parental consanguinity is common, suggesting that the trait is recessive.

A mixture of typical flat warts and reddish-brown plaques is characteristic. The lesions are caused by a wide variety of papillomavirus types, most of which rarely cause warts in the general population. Some of the warts, particularly those in areas of the body exposed to the sun, progress to intraepithelial or invasive squamous carcinomas (Jablonska and Majewski 1994).

Enteric viruses

Many viruses have been associated with gastroenteritis. In immunocompetent hosts, illness is usually mild and shedding of virus in the feces is transient. By contrast, enteric viruses cause significant morbidity in immunocompromised patients. Rotaviruses, adenoviruses, astroviruses, caliciviruses, and small round viruses have all been associated with severe or persistent diarrhea in patients with perturbed immune function (Chrystie et al. 1982; Pedley et al. 1984; Oishi et al. 1991; Cox et al.

1994; Romberg 1994), bone marrow recipients being particularly at risk. A nosocomial outbreak of rotavirus infection, with severe diarrhea, has been documented in renal transplant recipients (Peigue-Lafeuille et al. 1991). Although enteroviruses are not usually associated with gastrointestinal disease, coxsackie A viruses have been implicated as causes of diarrhea in the contexts of hypogammaglobulinemia (Johnson et al. 1982) and bone marrow transplantation (Townsend et al. 1982).

ENTEROVIRAL MENINGOENCEPHALITIS

Severe and persistent enterovirus infections are seen in patients with congenital hypogammaglobulinemia, despite regular immunoglobulin replacement therapy. This finding is unusual in that hypogammaglobulinemic patients respond normally to other viral infections. The most frequent complication is chronic, often fatal, meningoencephalitis. Patients may present with neck stiffness, headache, lethargy, weakness or seizures, with or without fever. These features are often associated with a dermatomyositis-like syndrome, characterized by edema of the extremities, sometimes with an erythematous or violaceous rash overlying groups of muscles. Echovirus types 2, 3, 5, 9, 11, 17, 19, 24, 25, 30, and 33, and coxsackie virus B3 have been isolated from the cerebrospinal fluid or brain tissue, and occasionally from muscle, in these patients (Mease et al. 1981: Cooper et al. 1983). Respiratory illness caused by enteroviruses has also been described, and evidence of disseminated infection has been found in fatal cases.

Measles

Dysfunctional cellular immunity predisposes to persistence of measles virus with potentially lethal consequences. Two complications, namely giant cell pneumonia and measles inclusion body encephalitis (MIBE), are recognized, neither of which is seen in immunocompetent hosts. Giant cell pneumonia usually presents 2–3 weeks after exposure to measles. The characteristic measles rash may be absent, in which case the diagnosis may remain obscure until postmortem. Laboratory approaches to diagnosis include detection of virus or viral antigens in nasopharyngeal fluid, bronchoalveolar lavage fluid or lung tissue, and demonstration of multinucleated giant cells with characteristic inclusion bodies in histological sections of lung.

MIBE usually arises within 6 months of exposure to measles virus and is occasionally accompanied by giant cell pneumonia or retinopathy. The disease may be rapidly progressive and has a poor prognosis; rapid deterioration leads to death within a few weeks of onset. The underlying pathology is one of gliosis. Intracytoplasmic and intranuclear inclusion bodies are present in glial cells and neurons, and inflammatory cell infiltration of the brain is minimal. Defective measles virus has been detected in the brains of MIBE patients and it is possible that the disease is an accelerated version of subacute sclerosing panencephalitis (Ohuchi et al. 1987).

Measles vaccine contains live attenuated virus and is not generally recommended for administration to immunocompromised patients. The current vaccination program for normal children reduces the number of susceptible patients among those who subsequently develop dysfunctional immunity, and may reduce the chance of exposure in non-immune individuals. Measles in previously vaccinated hosts has, however, been reported. Administration of normal human immunoglobulin after exposure to measles virus has some beneficial effect, but may not prevent complications, particularly MIBE (Kay and Rankin 1984). There is as yet no specific antiviral therapy with proven efficacy for the treatment of measles or its complications in immunocompromised hosts, but sporadic case reports suggest that aerosolized ribavirin might be of some benefit to patients with pneumonitis.

Polyomavirus infections

BK virus (BKV) and JCV are human polyomaviruses which, according to serological studies, are ubiquitous. It was thought that active, persistent infections were rare in immunocompetent hosts, but recent data suggest that urinary excretion of JCV is common in older people and pregnant women.

About half of renal transplant recipients have serological or other evidence of prior exposure to *Polyomavirus* (Hogan et al. 1980; Gardner et al. 1984), in keeping with the high seropositivity rate in the general population. BKV and JCV are commonly detected in the urine of transplant patients, suggesting that immunosuppression allows latent infections to reactivate. Primary and reactivated infections are usually asymptomatic, although ureteric stenosis has been reported and there may be an association with impaired graft function. Infections are frequent in the second month after renal transplantation, but late infections, occurring several months or even years later, are not unusual.

Urinary excretion of BKV and JCV is also common after bone marrow transplantation (O'Reilly et al. 1981) and has been reported in association with leukemia, lymphoma, solid tumors and Wiskott–Aldrich syndrome. Infection is generally asymptomatic, although deterioration in renal and hepatic function has been observed; BK viruria following bone marrow transplantation may be associated with hemorrhagic cystitis (Rice et al. 1985).

Polyomavirus infections of the urinary tract may be diagnosed by electron microscopy or by demonstrating characteristic intranuclear inclusions in exfoliated urinary epithelial cells. The presence of Polyomavirus antigens within these cells can be confirmed by immunofluorescence. BKV can be isolated in cell cultures, such as human embryo lung fibroblasts.

A minority of non-AIDS immunocompromised patients infected with JCV may develop PML. The factors predisposing to PML are unclear and virus has been detected in the brains of normal individuals. It has been suggested that JCV may adapt itself for growth in the nervous system during the course of infection. In support of this hypothesis, structural alterations in the archetypal regulatory region of the JCV genome have been found in JCV DNA from PML brains. Structural variations in the regulatory region have also been reported among viral DNAs from different organs in the same infected patient (Loeber and Dorries 1988). However, the issue of virus adaptation to different tissues is controversial because different organs have been shown to be infected with the same JCV subtype and PML isolates can be the same subtype as urinary isolates (Myers et al. 1989).

Diagnosis of PML is based on the characteristic clinical picture, and should be confirmed by brain biopsy. The histological appearances are typical and polyomavirus particles can be demonstrated by electron microscopy. Immunofluorescence microscopy of acetone-fixed brain tissue may reveal the presence of polyomavirus antigens. Virus may also be isolated in primary cultures of human fetal glial cells.

No agent has proven efficacy for the treatment of polyomavirus infections; reduction of immunosuppressive therapy, when practicable is, however, beneficial.

INTRODUCTION

Both the emergence and re-emergence of new virological agents and the perceived threats associated with bioterrorism are requiring scientists, engineers, and biosafety professionals to design safe working environments and ensure the protection of the community. In addition, disease eradication programs, such as the World Health Organization (2003) plan for the elimination of wild polioviruses, calls for the establishment of limited holdings and inventories of the agent, possibly raising future containment requirements. Most current safety legislation is based on the principles laid down in a variety of government regulations, which may differ slightly from country to country. Examples of such regulations include the Health and Safety at Work Act 1974 and Heath and Safety Control of Substances Hazardous to Health 2002 (Health and Safety Executive 2002) in the UK, the occupational safety and health laws in the USA, European Directive 1993, and Labour Canada regulations, all of which place a duty of care on employers in relation to the safety of their employees and others. International and national legislation increasingly demand employees to co-operate with employers and place a duty on them to avoid putting themselves, colleagues, or others at potential risk. Therefore, overall safety in the virology, or any other, laboratory is the responsibility of all laboratory workers. People in a supervisory or managerial position are responsible and increasingly accountable for the health, safety, and welfare of all staff and visitors in laboratories under their jurisdiction (Health and Safety Executive, 2000). The emphasis in this chapter, though, is the unique subset of safety issues resulting from the operation of a microbiology laboratory using pathogenic or potentially pathogenic agents. The ability to perform accurate risk assessments (job hazard analysis), based on our understanding of science, is of key importance.

In his review of laboratory-acquired infections, Pike (1979) concluded 'the knowledge, the techniques, and the equipment to prevent most laboratory infections are available.' Over the last decade safety-related technology has advanced significantly, developing biosafety systems that provide a safer working environment. Despite these advances, laboratory accidents still occur at a disturbing rate; unfortunately, as in the past, the most common cause of such accidents is human error. New, sophisticated biosafety systems and improved training methods are still necessary to cope with the increased challenges raised by the emergence and re-emergence of significant pathogenic viruses such as arenaviruses, dengue viruses, Ebola virus, hantavirus, the new hepatitis viruses, severe acute respiratory syndrome (SARS), influenza strains (H5N1), and human immunodeficiency virus (HIV). The fundamental concepts on which to construct a laboratory safety

program must therefore ensure minimal risk to both laboratory workers and the community. These concepts include both the proper use and maintenance of new safety equipment and, especially, a greater appreciation of good laboratory practice and proper risk assessment.

A safety program must be based on a sound understanding of the microbiological properties of the agent to be manipulated; a microbiological risk assessment programme (Advisory Committee on Dangerous Pathogens 1996); an understanding of the protective potential of scientific equipment and facilities; comprehensive personnel training and development appropriate to the studies to be undertaken; and use of guidelines and protocols, with the understanding that both must be flexible and dynamic. Any understanding of the properties of a micro-organism must include its virulence, means of spread, tropism, infectious dose, and environmental stability. For a safety program to be effective, it must have the support of laboratory workers and managers. Laboratory management have the ultimate responsibility of providing a safe working environment as described above.

This chapter discusses the typical components of a prudent virology laboratory safety programme. Topics include facilities, containment criteria, work practices, biohazard surveillance, waste management, and training. It must be repeated, though, that the cornerstone of any worthwhile safety program is accurate risk assessment and management that is based on full understanding of the infectious and pathogenic potential of the agents under investigation.

Information on laboratory safety and biosafety may be found in a variety of national and international guidelines or codes of practice (National Institute of Health 1987 (Japan); Ministry of Health 1988 (Sweden); Association Française de Normalisation 1990; Standards Australia/Standards New Zealand 2002, US Department of Health and Human Services 1999 (being updated); World Health Organization 2004; UK Advisory Committee on Dangerous Pathogens 1995a, b, 2001; Health Canada 2004.

HISTORICAL PERSPECTIVE – LABORATORY-ACQUIRED INFECTIONS

The risk of infection is higher in virology laboratories than in the general population, although the risk of exposure to infectious agents is somewhat less than among other groups of healthcare workers.

To determine the essential components of a laboratory safety program, it is first necessary to assess the 'risk' of infection associated with working in a virus laboratory. Pike (1979) compiled the best collection of data to date dealing with accidental infections of laboratory workers with pathogenic micro-organisms. The analysis was based on global data relating to laboratory-acquired infections recorded from the beginning of the century. Although much of the data covers the period before the age of chemotherapy and biosafety cabinets, it still gives some idea of the potential risk to people working in laboratories. The study concluded that most of the reported infections occurred mainly in research rather than clinical laboratories. However, the data did not provide any information about the changing pattern of laboratory techniques or the relative importance of different groups of infectious agents responsible for the infections.

Examination of these data, as well as analyzing more recent anecdotal and unpublished information, has demonstrated a major shift away from bacteria and rickettsiae as the chief causes of laboratory-acquired infections. Most such infections reported since the 1970s have been of viral origin especially in research environments working with high threat or newly emerged viruses (see Table 1). The trend is generally a decrease in aerosol infections and an increase in bloodborne diseases associated with technique failures and work associated with animal studies.

The overall decrease in aerosol infections in the laboratory is probably due to the development and introduction of engineering controls (i.e. microbiological safety cabinets); increased awareness of the routes of infection and of the need for safe working practices in the laboratory. The increasing availability of antiviral drugs, as well as the increase in the number of vaccines available, has also played a role in the decrease in illness due to laboratory infections. Despite these general trends, though, laboratory-acquired infections still occur regularly; however, because of the lack of a worldwide reporting system and the absence of adequate medical surveillance, their true extent may never be known. In some countries, for example the UK (Health and Safety Executive 1986), microbiological accidents must be reported.

Table 1 lists some of the ongoing concerns relating to laboratory-acquired infections in virology laboratories reported since 1970. Unfortunately, these are merely examples that emphasize the need for a strong and continuing biosafety program in all virus laboratories. The Subcommittee of Arbovirus Laboratory Safety (1980) collated a number of reports relating to arbovirus incidents involving laboratory workers: Crimean-Congo hemorrhagic fever virus (eight cases, one death); Chikungunya virus (39 cases); Japanese encephalitis virus (22 cases); Argentinian hemorrhagic fever virus (21 cases); Kyasanur Forest disease virus (133 cases); Marburg virus (31 cases, five deaths); Rift Valley fever virus (47 cases); West Nile virus (18 cases); western equine encephalitis virus (seven cases, two deaths); yellow fever virus (38 cases, eight deaths); and numerous others.

The use of vaccinia virus in laboratories has increased in recent years, partly as a consequence of international concerns about the potential use of variola virus (smallpox) as a bioterrorist weapon. Although the vaccine is considered safe, it can produce mild to

Table 1 *Examples of laboratory acquired viral infections*

Agent	References	Country/Date	Laboratory type	Exposure details
Marburg virus	Martini et al. (1969)	Germany 1968 Yugoslavia 1968	Tissue culture	Direct

Severe acute respiratory syndrome (SARS)	Taiwan Department of Health (2003)	Taiwan 2003	Research	Researcher working on SARS in P4 laboratory. Source of infection unknown
Severe acute respiratory syndrome (SARS)	World Health Organization, (2004)	China 2004	Research	2 research workers (7 associated, 1 fatal) in BSL3 laboratory, exposure incident/s not identified
Ebola virus	(International Society for Infectious Disease 2004a)	USA 2004	Research	Needlestick
Ebola virus	(International Society for Infectious Disease 2004b)	Russian Federation 2004	Research	Needlestick during guinea pig inoculation at BSL4, fatal

moderate disease in vaccines and can be disseminated to their close contacts (Fenner et al. 1988; Spencer and Lightfoot 2001; Centers for Disease Control and Prevention 2002) or through auto-inoculation causing vaccinia keratouveitis (Lee et al. 1994). There have been 18 previously reported cases of laboratory-related vaccinia infection, of which at least three were accidental infections of laboratory workers with recombinant vaccinia (Jones et al. 1986; Openshaw et al. 1991; Mempel et al. 2003) and through the manipulation of vaccinia virus-infected cells (Moussatche et al. 2003). This re-emphasizes the potential risks of human infection associated with the increasing volume of recombinant work.

It should be noted that most of the incidents could have been prevented by the use of common, readily available, biosafety practices and validated training schemes. An example of this was seen during the investigation into the cause of several laboratory-acquired dengue virus infections which occurred over a brief period in the late 1980s. It was determined that each infection was due to entry of the virus through a skin abrasion or wound and that these infections could have been prevented by the use of common safety practices such as covering exposed skin or by wearing gloves and greater appreciation of infectious disease transmission.

COMPONENTS OF A BIOSAFETY PROGRAM

Rules and regulations about the use, management, and disposal of hazardous and carcinogenic chemicals in the laboratory have been in place for some time. The US Fire Protection Agency, US Occupational Safety and Health Administration (OSHA) regulations, UK Health and Safety Executive, and Labour Canada are agencies that enforce the regulations which are backed by law. Before 1989, the criteria for working safely with biological materials consisted of a series of guidelines and recommendations issued by such organizations as the US Centers for Disease Control and Prevention (CDC) and the National Institutes of Health (NIH), the UK Public Health Laboratory Service (PHLS) or professional groups. The Canadian MRC/HWC guidelines were published in 1990.

The recent concern for laboratory safety was generated by the appearance of HIV, as well as the continuing problem of hepatitis B infections among healthcare workers. In addition potential infections from emergent and re-emergent pathogens have led to the adoption of regulations to reduce occupational exposure to bloodborne pathogens. These regulations have taken various forms, such as the UK Management of Health and Safety at Work Regulations 1992, Control of Substances Hazardous to Health Regulations (COSHH) 2002, Categorisation of Biological Agents According to Hazard and Categories of Containment 1995 and 2000, Workplace (Health, Safety and Welfare) Regulations 1992, Safe Working and the Prevention of Infection in Clinical Laboratories 2003; the European Directives to Member States, relating to the protection and exposure of workers to biological agents 1990; the US OSHA Bloodborne Pathogens Standard (29 CFR part 1910.1030); and the Canadian WHIMIS Biosafety Guidelines. They include most of the information in earlier guidelines with recommendations that stress the importance of employee training and education, the use of safety equipment and the duty of care to be provided by an employer ensuring a safe working environment. Although the new regulations cover many areas relating to laboratory safety, they should be viewed only as a starting point. A comprehensive laboratory safety program relating to work with biological agents should ensure that:

- Senior management actively support and resource it.
- Full and proper risk assessment policies and procedures are in place, and take into account the agent (virulence, transmissibility, routes of infection); the work being considered; and the codes of practice needed to prevent exposure.
- Laboratories, their equipment, and other facilities are properly maintained for the safe conduct of the work.
- Laboratories undergo regular safety audits to ensure compliance with agreed protocols and the identification of new hazards.
- Laboratory workers are provided with suitable safety information, safety instruction, and training as part of their continuing professional development.
- An effective infection control program, including monitoring of exposure, health surveillance, and listing of employees working with class 3 and 4 organisms, is developed and implemented.

All staff, regardless of their position, have a duty to protect themselves, their colleagues, and the community from any hazard arising from their work.

Developing a laboratory safety program

Each safety program, while having similar objectives, will vary according to the type of institution involved and any unique features present in the local regulations. Factors to be considered include the scope of the work being undertaken, the level of technical expertise of laboratory staff, the availability of personal protective equipment (laboratory coats and gowns, gloves, eye protection, respiratory protective equipment, ear defenders), and laboratory hardware designed to ensure a safe work environment. Of equal importance is engineering support to ensure the proper installation and maintenance of biosafety cabinets and fume hoods, eye washes, and the proper air balance. Equally important is the establishment of a continually defined program of facility and equipment validation undertaken after the maintenance program that ensures equipment safety standards are being maintained. It is also crucial that staff understand, and use, the correct procedures for operating laboratory equipment.

MICROBIOLOGICAL RISK ASSESSMENT AND INFECTION CONTROL

The exact incidence of occupational infection among laboratory workers is unknown. A number of published reports detail individual or small group outbreaks of laboratory-acquired infections, retrospective studies, and anecdotal information but there has been no report that has succeeded in determining the population at risk for any of these incidents. The overall mortality of reported cases is approximately 4 percent, but this number is probably very high considering the unknown denominator and the great number of unreported illnesses.

All virology laboratories should provide safe working conditions for all staff. In order to accomplish this goal it is essential to understand and determine the possible risks involved in the manipulation and propagation of viruses (including genetically manipulated viruses), the

propagation of viruses in cell cultures, and undertaking viral immunoassays. In addition, the potential hazards of chemicals and radiological products used must be taken into account during the risk assessment to reduce exposure to nonmicrobiological hazards.

It is increasingly recognized that a structured microbiological risk assessment (MRA) is necessary to identify and characterize microbiological hazards associated with laboratory working practices. Such formal risk assessments underpin current legislation in the UK (Advisory Committee on Dangerous Pathogens 1996, Health and Safety Executive 1986); Europe (EC Directive 89/391 2000); Canada (Workplace Hazardous Materials Information System (WHIMIS), 1987), and the USA (OSHA). Although such legislation requires employees to make suitable assessments of risk, they do not offer any formal guidelines on conducting risk analysis. Several agencies have begun to produce risk assessment guidelines on specific viruses: for example, HIV ((UK) Department of Health 1990); hepatitis ((UK) Public Health Service 1992); and bovine spongiform encephalitis ((UK) Health and Safety Executive 1996). For the process to be meaningful, it is important that formal risk analysis be undertaken on laboratory work practices, including the following:

- Risk assessment that identifies the source(s) of the hazard(s) and quantifies the risk of each hazard within the conditions examined.
- Identification of the gravity of the risk, to guide the management of that risk.
- A formal record of the assessment and recommendation of working practice that is communicated to all staff.
- A regular review and corrective action process.
- A corrective action plan.

For any risk assessment to be acceptable, some attempt at measurement or quantification of the risk(s) must be made. This relies on available experimental data, case and epidemiological information, and population studies including mathematical modeling, all of which relate to different aspects of risk.

It is important when establishing an infection control/medical surveillance program that the institution's authorities understand the relative risks that their employees face. This requires information about infectious agents and other potential sources of risk that are likely to be found at their institution. Laboratories should be especially alert if dealing with large numbers and wide varieties of clinical, environmental, or veterinary materials received for laboratory diagnosis or research.

Knowledge of infectious disease processes is the cornerstone of an infection control program. People must be identified whose duties include routine and anticipated tasks involving or potentially involving exposure to infectious material. Particular duties must be evaluated for their 'infectious potential.' It is the job that is rated and not the individual, although anyone who is highly susceptible to infection should be excluded from duties that are not a risk to the normal population. Especially vulnerable are people whose immune system has been compromised, for whatever reason. The infectious potential of any job is usually determined by asking a series of questions about the work involved. For example, does the individual routinely come in contact with virus-containing blood or blood products? Does the individual routinely handle incoming shipments of potentially infectious material? What is the level of experimental animal handling? Other information required may include the type of laboratory equipment that is used, the nature of the materials used, and whether test samples are inactivated.

Once it has been determined that a worker is at risk, a written infection control plan for that position must be considered. This plan should contain an exposure determination (the criteria used to evaluate the position), a schedule, and method for meeting any relevant safety standards and the content of any training to be undertaken. A well-structured and recorded training programme is vitally important to overall laboratory safety. Training should include familiarization with the nature of laboratory pathogens, and proper and safe use of laboratory equipment. A laboratory safety manual (or code of laboratory practice) must be developed and made available to all employees and should include all approved laboratory protocols, as well as a list of duties and responsibilities. One of the responsibilities of any laboratory worker should be to report any incident that might have the potential for an occupational exposure, according to a defined incidence policy.

Any infection control policy should include medical surveillance. This should incorporate a medical evaluation including an occupational/medical history and a physical examination covering conditions that a physician feels might interfere with a worker's ability to use personal protective equipment. It is also essential to ensure that all workers are adequately immunized.

A major goal of an effective medical surveillance policy is to educate workers of the need, and indeed the requirement, to report an occupational exposure. Employees should also have the right to a confidential medical evaluation and follow-up after reporting such an incident. Elements of such a follow-up include documentation of the events surrounding the exposure, the source (if known), and the route of exposure. For incidents involving possible exposure to HIV or Lassa virus, a quick decision may be necessary as to whether to begin azidothymidine (AZT) or other treatment regimen, or ribavirin treatment. It is therefore prudent to have an established policy covering the various possibilities within any establishment handling viruses. Continuing follow-up, including counseling and illness reporting, should also be part of the program.

A surveillance policy designed for reporting illnesses away from the work site should also be developed.

A typical plan should include employees carrying an information card that will notify treating physicians that the patient may be at risk of certain diseases because of his or her occupation. The card would also contain a means for contacting the employee's institution if it is deemed necessary, such as a physician noting symptoms compatible with a disease related to that person's work. The system is important for two reasons:

1. It is essential for an employer to know if more than one employee has contracted a similar disease, because this may be an indication of a common occupational source.
2. Maintenance of a good reporting system helps to determine any source of infection. Experience has taught us that examination of most laboratory accident reports seldom pinpoints the source of occupationally acquired illnesses.

It is evident that a good infection control/medical surveillance program requires well designed and clearly written procedures and policies. It is also essential that the policy be made known to all employees at their induction and any modifications circulated as part of a continuing process of awareness. Results of investigations of laboratory incidents, with a guarantee of anonymity, should be widely published for educational purposes. Laboratory workers should be made to appreciate the ultimate goal and benefit of policy and not be made to fear it.

All workers in microbiology laboratories should provide a baseline serum sample; consideration should be given to establishing a system whereby employees are tested at quarterly intervals for evidence of infection by any agents used in the laboratory, the purpose being to detect silent infections. Although this policy has not been adopted in all parts of the world, knowledge of such subclinical infections can lead to examination of safety procedures, which may result in changes that will eliminate the potential for infections with clinical, and therefore possibly political, consequences. A major laboratory has recently been able to detect silent infections with a virus with known pathogenic relatives that were being studied there. Procedural and protocol changes have eliminated the potential for what could have been a very serious incident.

Definition of hazard groups

The classification of microbial pathogens is based on the inherent hazard of the organism. The corresponding minimum levels of containment set out in Tables 2 and 3 are intended to compensate for microbial risks encountered when working with pathogens as defined in the various hazard groups. 'Hazard' is taken as expressing the level of danger associated with the nature of the organism and 'risk' as the probability that in some circumstances the dangers will be manifested as an infection. The more inherently infectious the microbe, the higher the risk. In reality there are different levels of risk arising from work with viruses, depending on such factors as the immune status of the individual, the dose, the route, and the site of infection.

Categorizing any virus into the currently recognized four hazard groups depends on whether the organism is:

- infectious for people
- hazardous to laboratory workers
- transmissible to the community; and
- susceptible to effective prophylaxis or treatment.

All pathogenic viruses (and other microorganisms) are assigned to one of the higher hazard groups according to the infective hazard they pose for healthy workers (Table 3). The categorization does not allow for any additional risks that an organism can present to people who may be more severely affected for other reasons, such as pre-existing disease, compromised immunity, pregnancy, or the effects of medication.

The hazard group assigned to a particular organism indicates the minimum level of containment under which it must be handled. It should be noted that viruses listed under one category may require a containment level different from that normally assigned. The decision may be influenced by the techniques used (animal infection, virus concentration procedures, or production of an aerosol). It should also be noted that some organisms are subject to monitoring by national departments of agriculture and fisheries.

STANDARD MICROBIOLOGICAL CODE OF SAFETY PRACTICES

The importance of establishing good laboratory practices cannot be overstated. Previous investigations of laboratory accidents indicate that failures in good laboratory practice are frequently the direct cause of accidents. Information derived from the investigation of laboratory accidents, practical experience obtained from working in microbiological laboratories and the application of informed risk assessment have contributed to the development of a list of good working practices.

- Management practice should ensure that all laboratory personnel are competent and understand the biological and other hazards found in a laboratory, and are fully trained to the biohazard level required before undertaking any work.
- The laboratory director should be the individual responsible for granting or limiting access to the laboratory. In general, people who are at increased risk of infection or for whom infection may be particularly dangerous should be excluded from the laboratory. Some other situations, such as a pregnancy, will have to be considered on an individual basis. Children under the age of 16 years should not

Table 2 *Comparative categorization of biological agents and categories of containment*

be allowed in the laboratory. Animals not involved in laboratory procedures should never be allowed in the laboratory.

- A laboratory code of practice should be available, read, and signed before a new member of staff commences work.
- Laboratories should have a designated biological safety officer and/or a safety committee whose responsibilities include ensuring that all work is carried out in accordance with established safety practices.
- Laboratories must be kept clean, neat, and orderly, and all materials or equipment not pertinent to the work should be kept to the minimum.
- Access to the laboratory must be strictly limited to authorized personnel especially biosafety level

Table 3 *Summary of agent hazard category and associated basis risk assessment*

Hazard group	Agent risk categorization
1	Biological agent unlikely to cause human disease
2	Biological agent that may cause disease and which may be a hazard to laboratory workers, but is unlikely to spread to community. Laboratory exposure rarely produces infection and effective prophylaxis or treatment is usually available. Examples: herpes viruses, paramyxoviruses, picornaviruses, adenoviruses
3	Biological agent can cause severe human disease, and presents a serious hazard to employees. It may present a threat of community spread. Usually an effective prophylaxis or treatment available. Examples include hepatitis B virus (HBV), hantaviruses, Japanese B encephalitis, Rift Valley fever virus, yellow fever virus, rabies virus
4	Biological agent causes severe human infections, serious threat to employees, high risk of community spread, no effective prophylaxis or treatment available. Examples Lassa virus, Ebola virus, smallpox virus, Crimean-Congo hemorrhagic fever virus, Russian spring–summer encephalitis virus

3 (BL3) and 4 laboratories. The laboratory door should remain closed and an international biohazard sign should be prominently displayed on the door, indicating that the room contains potentially infectious material. When an infectious agent (or agents) used in the laboratory requires special provisions for entry (e.g. vaccination), the relevant information must be included in the sign, together with the name of the individual responsible for the laboratory.

- A disinfection policy should be available, regularly reviewed, and displayed.
- Work surfaces should be decontaminated daily, and immediately following any spill involving potentially infectious material.
- All procedures should minimize the production of aerosols. This usually requires the development of standard operating practice and risk assessments for all laboratory procedures, and the timely review of these procedures to ensure that they are abreast of current technology and take advantage of the latest innovations in safety.
- Procedures that have the potential for producing an infectious aerosol should be undertaken within a biosafety cabinet. It is essential that all people who use such cabinets understand the principles of their operation.
- Laboratory coats, gowns, smocks, or uniforms should be worn in the laboratory, and removed before leaving the laboratory for other areas. Although a regular laboratory coat is sufficient for most clinical/diagnostic laboratory situations, a rear-closing, solid-front gown is required when practicing BL3 procedures.
- Face and eye protection or other such devices must be worn when it is necessary to protect from splashes, impacting objects, harmful substances, especially if the work is carried out on the open bench.
- Gloves must be worn for all procedures that might involve contact between broken skin or mucous membranes and potentially infectious material, toxins, or infected animals. This usually means wearing gloves for most laboratory work, including drawing blood. Gloves used in the laboratory are generally made of latex or a vinyl compound (usually polvinylchloride (PVC)), and there seems to be no difference in barrier effectiveness between gloves made of either material. When choosing gloves, consideration should be given to the toxic products (e.g. vinyl chloride and hydrochloric acid) produced when PVC gloves are incinerated.
- Mechanical pipetting devices should be used; mouth pipetting should never be permitted. Modern mechanical pipetting devices are available for almost any laboratory situation.
- Eating, drinking, smoking, application of cosmetics, or storage of food should be strictly prohibited in laboratory work areas.
- Staff must wash their hands immediately after handling any infectious materials or animals and when leaving the laboratory. For this purpose sinks, preferably with foot or elbow controls and located near the exit door, should be provided in each laboratory. Because of the number of times hands are washed it is probably best to use a mild soap with a lanolin base; although these soaps are not disinfectants, their use should remove most surface microbes from the skin.
- All contaminated or infectious liquid or solid materials must be decontaminated before disposal or cleaning for reuse. Contaminated materials that are autoclaved or incinerated at a site away from the laboratory must be packaged and labeled properly for transport and have the outside of the container disinfected chemically.
- Accidents and incidents should be immediately reported to and recorded by the person responsible for the work and to the proper safety and occupational health authorities.
- Appropriate medical surveillance and treatment should be provided.
- Hypodermic needles, syringes and needles, and scalpels, collectively referred as 'sharps,' are the main source of accidents. It is therefore especially important that laboratory workers, as well as others, use and dispose of these items with extreme caution. Needles and syringes should be restricted to parenteral injection and aspiration of fluids from laboratory animals. Only needle-locking syringes or disposable syringe–needle units should be used. Needles should not be recapped or removed by hand; attempts to perform these procedures are a major cause of needlestick injuries. Whenever a person's free hand is near a syringe and there is a needle in the other hand, the potential for an accident is very high. Several recent needlestick injuries have occurred when used syringes, capped or uncapped, were placed in the pocket of a laboratory coat and either the individual wearing the coat or a colleague was subsequently stuck. Hypodermic needles and syringes should not be used as substitutes for pipetting devices in the manipulation of infectious fluids. Once used, needles should be promptly placed in a puncture-proof container and decontaminated, preferably by incineration or autoclaving, before disposal.
- Any soiled 'sharp,' except nondisposable items, should be placed in a sharps disposal container. The sharps container itself must be of rigid construction and leak-proof. The top opening should be large enough so that the used sharps can be dropped into the container without the need to overfill it. These containers should have a top that closes easily and tightly when it is full, and they should be placed at convenient locations throughout the laboratory. When full, a container should be decontaminated by

autoclaving and then it and its contents should be incinerated.

- In modern laboratories instrumentation is a potential source of laboratory accidents. These accidents may involve chemical or electrical hazards or the possibility of infection with a biological agent. Centrifuges – ultra, high speed, or clinical – are always a potential source of aerosols. Care should be taken to load and unload centrifuge tubes containing infectious or harmful material in a biosafety cabinet. It is also prudent to use sealed tubes or safety heads while centrifuging such dangerous material. Automated analyzers are another potential source of danger in the laboratory. Blood or serum samples are often introduced into the instrument under pressure, which can increase the potential for aerosolization. The level of containment of such equipment will depend on the risk assessment and the infectious nature of the material.
- A program for insect and rodent control should be in place.
- If an autoclave is not present in the laboratory, all potentially infectious material for decontamination must be taken out of the laboratory in containers that preclude both aerosolization and leakage of the contents.

BIOSAFETY LABORATORIES

The design or refurbishment of virology laboratories increasingly has to respond to an increasingly national and global regulatory environment, and advances in scientific, technical, and industrial biosafety capabilities (Advisory Committee on Dangerous Pathogens 2001; Health Canada 2004; US Department of Health and Human Services 1999; World Health Organization 2004). Primary and secondary containment practices are increasingly more complex and their introduction varies throughout the world. There is a need to establish a common system for the implementation of common standards for future design and operation of virology laboratories that ensures worker and public confidence in biocontainment and biosafety strategies employed. Laboratory operation should also introduce a detailed record system for the monitoring and revalidation of facilities, equipment, and plant which should become more detailed the higher the biosafety level (BSL) category.

Working with potentially infectious viruses in the microbiological laboratory requires an appreciation both of work practices and of the facilities needed to make such laboratories a safe environment. Guidelines on the safe handling of pathogens have evolved over the past decade and have reached the point where there is general agreement on the basic principles of biosafety in the laboratory (Table 4). Four biosafety levels have been described (BL1–BL4), which comprise combinations of laboratory practices and procedures, safety equipment, and laboratory facilities appropriate for the operations performed and the hazard posed by the infectious agent. Essentially, the numerical designation of a safety level increases with an increase in the risks involved in working with an agent.

The levels of containment are intended to reflect the risks encountered when working with biological agents as categorized in the various hazard groups. All laboratories in which there is likely to be exposure to human

Table 4 *General summary of relation between hazard groups and biosafety level, work practices, and containment level*

Hazard group	Biosafety level (BL)	Working practices and procedures (use)	Primary engineering control requirements
1	BL1	Standard microbiological practices (SMP)	No special engineering requirements; containment achieved by adherence to standard laboratory practice
2	BL2	BL1 work practice, plus:	
		Limit access. Limit aerosols. Biohazard signs. Laboratory code of practice. Protective personal equipment (PPE): gloves, laboratory coats, face protection as needed. Infectious waste decontaminated	Procedures that produce potentially infectious aerosols performed in a biological safety cabinet (BSC). On-site autoclave required
3	BL3	BL2 work practice, plus:	
		All virus material contained. Restricted access. PPE: gloves, protective laboratory clothing, respiratory protection as needed	Inward airflow. Air-lock facility. Exhaust air discharged from laboratory via HEPA filtration (optional). On-site/ integrated autoclave required
4	BL4 (maximum containment)	BL3 work practice, plus	
		Change of clothing before entry. Shower on exit. All waste autoclaved before leaving facility. Regular engineering and biosafety maintenance	HEPA-filtered supply and exhaust air. Work undertaken in BSC class III cabinets or BSC II using an air-supplied positive full-body pressure suit in an air-tight laboratory. Integrated laboratory required. All waste decontaminated

pathogens (whether or not they are to be propagated or concentrated) require a minimum of BL2 containment. When there is a likelihood or strong indication that material (specimens or samples) contains BL3 or BL4 agents, additional controls are necessary.

Many national guidelines list the essential laboratory procedures that are basic to good laboratory practice (Table 5). It must be emphasized that good microbiological practice is fundamental to laboratory safety and cannot be replaced by specialized equipment or safety barriers, which can only supplement it.

It should be noted that although these classifications may be reasonable for clinical and research laboratories, they are not applicable to many industrial, food science, and agricultural laboratories.

Rules associated with animal facilities parallel those for laboratories. Additional considerations should be given to the requirements of individual species that take into account behavior, husbandry requirements, housing standards, zoonoses, parasites, and size (Advisory Committee on Dangerous Pathogens 1997; Richmond and Quimby 1999).

Biosafety level 1

BL1 practices, safety equipment, and laboratory facilities require no special engineering features for work with organisms that present no danger to humans. Examples of laboratories that may be operated at this level include undergraduate training and teaching laboratories. In these laboratories work is undertaken with well-characterized agents that are most unlikely to cause disease in normal healthy adult humans. Many agents not normally able to produce disease in healthy individuals may produce severe illness in elderly people, the immunodeficient, or the immunosuppressed, and can cause allergic or toxogenic responses, so appropriate precautions must be taken. Also, vaccine strains that, because they are attenuated in virulence, do not usually produce disease in healthy individuals may produce severe disease in some individuals. The latter two categories of organisms should be manipulated under BL2 conditions.

Work is generally conducted on the bench, and specialized containment equipment is not normally

Table 5 *Exposure controls: summary of minimum containment requirements for laboratories and animal rooms*

	Containment levels			
Containment requirements	**1**	**2**	**3**	**4**
Laboratory site: separated from other activities in the building	No	No	Yes	Yes
Facility: sealable	No	No	Yes	Yes
Ventilation				
Workplace maintained at air pressure negative to atmosphere	Opt	Opt	Yes	Yes
Through safety cabinet	No	Opt	Opt	No
Mechanical: direct	No	Opt	Opt	No
Mechanical: independent	No	No	Opt	Yes
Supply and extract air HEPA filtered	No	No	Yes, on extract	Yes on input and double on extract
Airlock	No	No	Yes	Yes
Airlock: with shower	No	No	No/Opt	Yes
Effluent treatment	No	No	Yes	Yes
Autoclave site				
On site	No	No	No	No
En suite	No	Yes	Yes	Yes
In laboratory: free-standing	No	No	Opt	No
In laboratory: double-ended	No	No	Rec	Yes
Microbiological safety cabinet/enclosure	No	Opt	Yes	Yes
Biosafety cabinet	NR	I	I/III	III I/II[a]
Facility to contain own equipment	NR	No	Yes as far as reasonably practical	Yes
Safe storage of biological material		Yes	Yes, secure storage	Yes, secure storage
Efficient vector control, e.g. rodents and insects		Yes, for animal containment	Yes, for animal containment	Yes

NR, not required; Opt, optional; Rec, recommended.

a) Class I and II biological safety cabinets permitted with use of positive-pressure suits.

required. Laboratory personnel should have specific training in the procedures undertaken within the laboratory and be supervised by experienced senior staff. The following laboratory facilities and basic work practices apply to viruses assigned to BL1.

LABORATORY FACILITIES

In the interests of safety, floors should be slip resistant, seamless, be impermeable to liquids, and resistant to most if not all chemicals. Laboratories should be designed so that the floors, walls, and ceilings are easy to clean. Benchtops should be impervious to water and resistant to acids, alkalis, organic solvents, and moderate heat. Laboratory furniture should be of similar resistant materials and be arranged so as not to obstruct workers while performing their duties. Equipment should be placed where it is easily accessible for cleaning and, if it is likely to produce an aerosol, in the safest possible location. Attention should be paid to door swings because a door opening in the wrong direction has the potential to knock items from someone's hands. Equipment must not be placed near thermostats, because it may interfere with temperature control. Floors should be nonskid, to reduce the likelihood of slipping. Hand-washing facilities must be provided, preferably near the point of exit.

Biosafety level 2

Conditions described for BL2 are usually applicable to clinical, diagnostic, research, and teaching facilities in which work is done with a wide variety of microorganisms that cause human disease and may be a hazard to laboratory workers but unlikely to spread to the community. Laboratory exposure rarely produces infection, and effective prophylaxis or treatment is usually available. Many of the agents that require BL2 containment are already present in the community, and community vaccination programs for them are routine.

Hepatitis A virus, herpes simplex types 1 and 2, measles virus, Epstein–Barr virus, and certain viral vaccines are among those that can be manipulated at the BL2 level. Generally the agents that are assigned to this level cause bloodborne diseases and do not have a history of infection via the respiratory route. It is not surprising, then, that the usual routes of laboratory-acquired infections with agents in this group are auto-inoculation, ingestion, and mucous membrane exposure to the infectious agent. Procedures with agents assigned to this level that have a high probability of aerosol production should be conducted in primary containment equipment (e.g. Class 2 biosafety cabinet) or similar devices.

The competence expected of laboratory workers is greater than that of a newly qualified graduate. Personnel at this level need to be familiar with the institution's safety policy, to have received training in the handling of the viruses and be supervised by a competent senior member of staff.

LABORATORY DESIGN

The laboratory requiring BL2 containment is generally similar in construction and design to a BL1 facility. It also incorporates criteria for microbiological practices in association with additional primary and secondary containment facilities (Figure 1).

The equipment is selected according to the following principles:

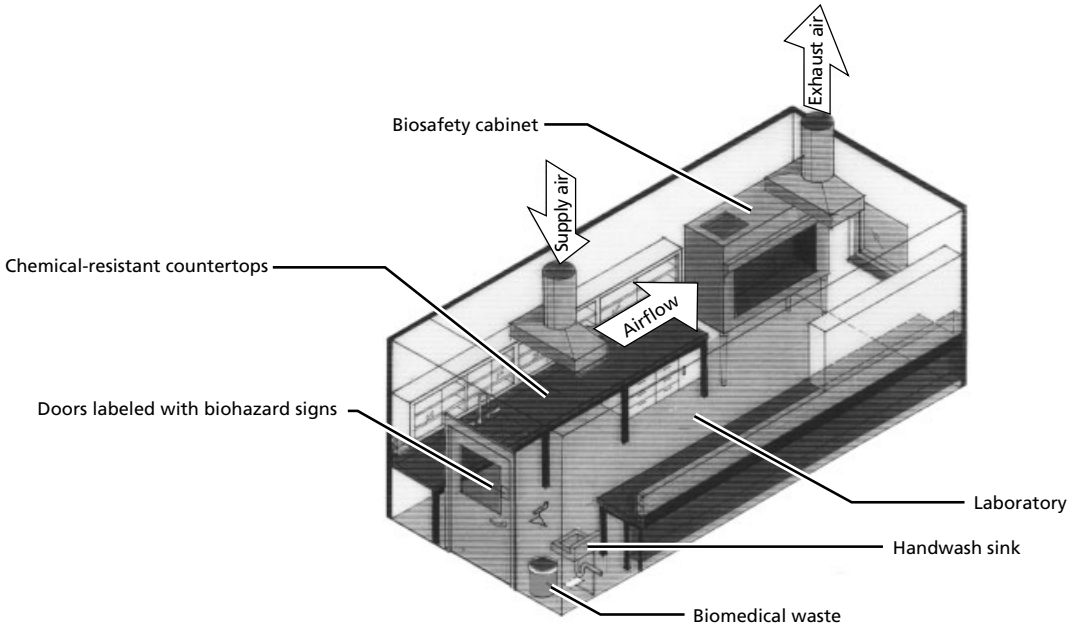

Figure 1 *A schematic of a generic BL2 laboratory design (courtesy of Smith Carter, architects, engineers, planners, interior designers).*

- Designed to prevent or limit exposure of the operator to infectious material.
- Constructed of materials that are resistant to corrosion and meet structural requirements.
- Installed to aid operation, maintenance, cleaning, decontamination, and safety testing.
- Complies with safety specifications.

Laboratories that anticipate working with potentially infectious material should use a biosafety cabinet, isolator, or other suitable containment. Standard laboratory working practice is undertaken at this level, with additional features that reflect the higher containment level (see Tables 3, 4, and 5). Procedures with the potential for creating infectious aerosols should be conducted within a biosafety containment cabinet. These include grinding, blending, vigorous shaking or mixing, sonic disruption, and opening containers of infectious materials. Intranasal inoculation of animals and harvesting infectious tissues from animals or eggs should also be done in a biosafety cabinet or equivalent. Any work with high concentrations of infectious agents should be carried out in a containment cabinet. The reduction of aerosols is also a consideration when working with many of the analytical machines found in any virology laboratory. Special precautions should be taken with machines such as cell sorters and when loading analytical machines where the sample may be under pressure and more likely to produce an aerosol. In many cases a splash-guard may suffice.

There may be occasions when agents routinely manipulated at BL2 may require BL3 containment, or at least BL3 practices. This usually occurs when the procedures produce concentrations significantly exceeding the physiological concentration of the agent in nature. A higher biosafety level should also be considered for studies involving animals.

Biosafety level 3

All the laboratory design features and working practices required for BL2 are applicable to BL3, with special emphasis on some of them. The work practices, safety equipment and facilities for BL3 apply when working with indigenous or exotic agents and when aerosol infection is a significant possibility resulting in disease that may have serious, or even lethal, consequences. Agents for which BL3 safeguards are routinely recommended include *Hantavirus* (Hantaan virus, Seoul virus, Sin Nombre virus) and St. Louis encephalitis virus. Two of the more exotic agents that require BL3 containment are Rift Valley fever virus and yellow fever virus, hemorrhagic fever viruses from Africa that can be worked with at this level provided workers are immunized.

Although auto-inoculation, ingestion, and mucous membrane contamination are hazards with these agents, the major concern is aerosol infection. The requirements for BL3 are more stringent than those for BL2 and are aimed at controlling aerosol production and possible spread into the community.

The laboratory staff must understand the safety procedures, as well as the risks involved in working with the agents used in their laboratory. Training, including the use of specialized equipment, should be done by competent scientists who have experience of working with the viruses contained at this level.

LABORATORY DESIGN

The laboratory has engineering and design features and physical containment equipment additional to those found at BL2 (see Tables 4 and 5). Principal differences from BL2 requirements are that the laboratory must be separated from other laboratory space by an anteroom and that personnel access is strictly controlled. The laboratory must be maintained at an air pressure negative to the atmosphere (maintain a verifiable inward directional air flow) and extracted air must be high efficiency particulate air (HEPA)-filtered (in some countries) and discharged to the outside so that it is dispersed clear of adjacent buildings or air intakes (Figure 2). Additional aerosol protection when working with animals is afforded by a variety of newly designed flexible-film isolators (Figure 3).

LABORATORY PRACTICES

All work involving infectious material is undertaken within biosafety cabinets by staff wearing full frontal gowns, gloves, and eye protection. Alternatively, some laboratories prefer to use class III cabinets. Contaminated solid materials that are to be decontaminated at a site away from the laboratory are sealed in a leak-proof container before being removed to an autoclave and then incineration. Contaminated liquids are autoclaved or disinfected in the laboratory area. An autoclave should be available in the laboratory or laboratory suite.

Biosafety level 4

This containment level is to be used when working with viruses that cause severe human disease (some with a high mortality rate), and present a serious hazard to laboratory workers for which there is no vaccine or generally no reliable treatment. A variety of agents causing hemorrhagic fevers, including Lassa virus, Marburg virus, Ebola virus, Crimean-Congo hemorrhagic fever virus, and related viruses, are those most commonly studied at BL4.

LABORATORY DESIGN

The laboratory is either a separate building or an isolated zone equivalent to a separate building within a building. Mainly because of their high construction and

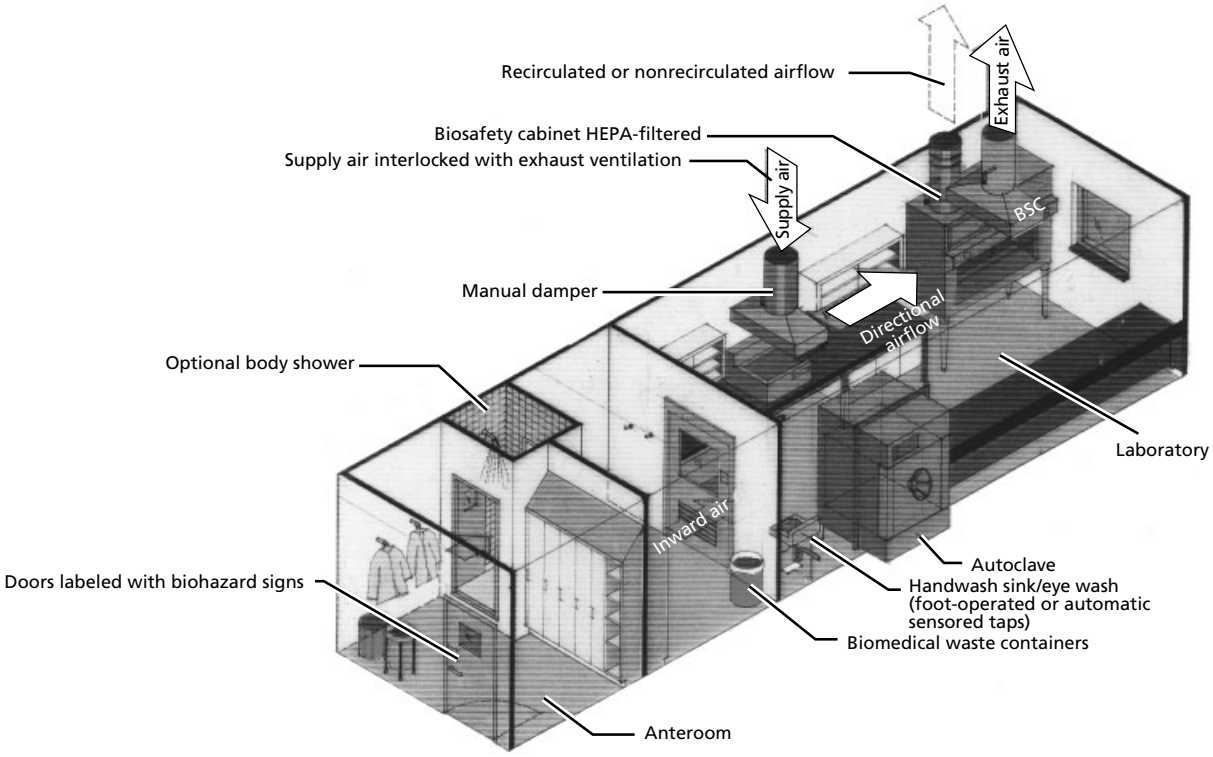

Figure 2 *A schematic of a generic BL3 laboratory design (courtesy of Smith Carter, architects, engineers, planners, interior designers).*

operational costs, there are fewer than ten BL4 laboratories in the world.

There are two operational designs that provide efficient primary containment. The first and oldest system is based on protecting the worker from exposure by containing the agent within a series of interconnecting airtight class III biosafety cabinets (Figure 4).

Each cabinet is equipped with its own HEPA-filtered air supply and extracts exhaust air via HEPA filters in series, and can be independently sealed and fumigated without interference with the rest of the system. All equipment (refrigerators, freezers, microscopes, centrifuges, and incubators) is built as an integral part of the system. All staff has a complete change of clothing and shower after each day's work. All work is conducted through glove ports. The cabinet system is connected to a double-ended high-containment autoclave, through which all liquid and solid waste is decontaminated before being removed for incineration. A chemical 'dunk tank' or formaldeclave is located at the other end of the system, through which suitably packaged material can be taken in or out of the system. The whole system is incorporated within a laboratory providing environmental protection and operating an interlocking HEPA-filtered supply and exhaust air system.

The alternative system, 'the suit laboratory' isolates the workers from the laboratory environment by means of fully encapsulating suits supplied with air from outside the laboratory (Figure 5). By the use of special construction techniques (impermeable surfaces and welded ductwork) the laboratory facility provides the biosafety barrier that ensures the protection of the exterior environment. Work with infectious material is carried out within class II biosafety cabinets. Air from the room and biosafety cabinets is removed via HEPA filtration, the HEPA filters are also an integral component of the supply air ductwork. A special chemical shower must be provided to decontaminate the surface of the suit before the worker leaves the area. A double-doored autoclave is provided for decontaminating waste materials to be removed from the suit area. When necessary, appropriate material may be removed from the laboratory, without heat treatment, by proper packaging and removal through the chemical shower or a dunk tank.

Laboratory practices

Basic work practices are undertaken in the same manner in both systems. Because of the complexity of the work, a detailed code of practice should be developed and form part of an individualized training program. On entering, staff should put on a complete change of clothing; before leaving, they must shower before putting on their own clothing. Entry and exit of personnel and supplies must only be through an airlock or pass-through system. All fluid effluents from the facility, including shower water, must be rendered safe before final release.

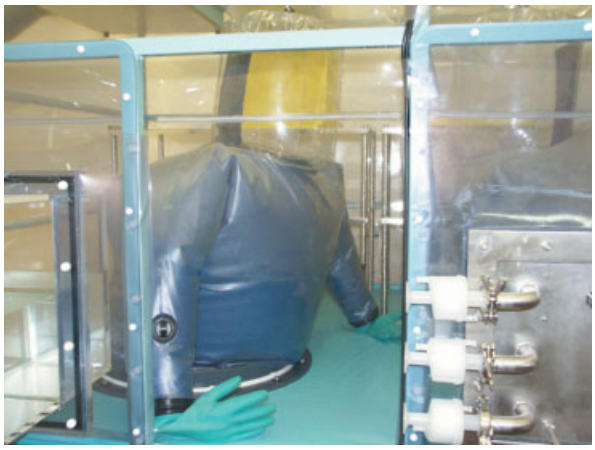

Figure 3 *Flexible-film isolator design for animal containment level 3 and 4 work (courtesy of Health Protection Agency, UK).*

Figure 4 *Cabinet-line BL4 laboratory (courtesy of Health Protection Agency, UK).*

A regular, rigorous, preventative maintenance program for the engineering controls, air flow, autoclave, safety cabinets, etc., should be developed to ensure continued integration of the facilities and suitability of the safety procedures. Within the UK the Health and Safety Commission institute regular safety inspections of the facilities, safety management, and procedures.

LABORATORY WASTE

The general principle involved in the treatment of laboratory waste is that all infectious or potentially infectious laboratory waste must be rendered noninfectious before leaving the laboratory. An alternative is to develop a system whereby infectious material can be safely delivered to an off-site disposal facility. A robust disinfection and waste policy is regarded as an operational necessity at this level.

In general, local regulations cover the disposal of infectious waste. There are different interpretations of what constitutes 'infectious waste,' so this must be considered when developing a waste management program. A program designed to minimize the production of regulated waste will reap cost savings because disposal of regulated waste is far more costly.

PACKING AND SHIPPING OF INFECTIOUS MATERIALS

The safe shipment of infectious substances or diagnostic specimens within or between countries is important for everyone involved with the process, basic guidance being provided by the World Health Organization (1997). Although no reports of illness have been attributed to the transportation of such materials, there are numerous areas of conflicting guidelines throughout the world. Because these packages have the potential for harboring infectious agents and move in public places during their journey, their transportation is strictly regulated. Postal and transport authorities have always been aware of the potential hazards to their employees of infectious material transported and handled by them.

In many countries such material is sent through the mail, and local regulations apply; guidelines are often issued (e.g. the *Post Office Guide* in the UK and the *Postal Service Manual* in the USA). The USPS requirements for the mailing of 'diseased tissue, blood, serum, and cultures of pathogenic microorganisms' are listed in their Postal Service Manuals.

The US Department of Transportation, the UK's Health and Safety Executive, and Canada's Transport Canada have major responsibility for safe transportation and provide the authorization for the movement of hazardous materials within their respective countries and to foreign countries. The importation of infectious agents that are predominately pathogenic to animals also needs to take into account various national regulations and permit requirements (UK: Importation of Animal Pathogens Order 1980, 1998; Canada: Animal Disease Protection Act; USA: USDA, APHIS 9 CFR Parts 94 and 95). Workers sending infectious material to other laboratories should ensure that these laboratories have the facilities to work with the agent. This applies particularly to the transfer of viruses in hazard groups 3 and 4. In response to the anthrax attacks in the USA during 2001, the USA (2002 42 CFR Part 73) and UK (Home Office 2001) introduced antiterrorism legislation which made laboratories and their personnel accountable and responsible for possessing, working with, and transferring high-threat pathogens known as 'selected agents.'

An agreement between the Universal Postal Union (UPU), the International Air Transport Association (IATA), and the International Civil Aviation Organization (ICAO) led to new regulations for overseas mail in the 1990s. These are currently being modified and due for publication in 2004/5. The IATA/ICAO guidelines and procedures also should be considered because they were designed to facilitate the safe shipment of

Figure 5 *BL4 suit laboratory (courtesy of Lyon CL4 facility, France).*

infectious substances while ensuring the safety of the transport personnel and the general public. The regulations define the terms 'diagnostic specimen,' 'biological product' and 'etiological agent,' and give minimum packaging requirements and volume limits for each.

The regulations define a diagnostic specimen as 'any human or animal material including, but not limited to, excreta, secretions, blood and its components, tissue, and tissue fluids, being shipped for the purposes of diagnosis (excluding live infected animals).' These must be transported under ICAO/IATA packing instruction 602. Infectious substances are 'substances containing viable microorganisms or toxins known or suspected to cause diseases in animals or humans (including HIV)' and are transported according to ICAO/IATA packing instruction 650.

With regard to packaging, all guidelines indicate that no one may knowingly transport or cause to be transported, directly or indirectly, any diagnostic specimens or biological product which they reasonably believe may contain an etiological agent unless such material is packaged to withstand leakage of contents, shocks, pressure changes, and other conditions incident to ordinary handling in transportation. The major decision to be made, then, when determining the transport requirements for any sample is whether it contains an etiological agent. It is prudent to be conservative in this matter and assume that each specimen may contain an agent unless it is certain that it does not.

The current packaging requirement is for triple packaging. A securely closed, watertight primary container is enclosed in a second, durable watertight container, with enough material in the space between them to absorb all the contents of the primary container in the event of leakage. Each set of primary and secondary containers is then enclosed in an outer shipping container constructed of fiberboard, cardboard, wood, or other material of equivalent strength. An etiological agent/biomedical material sticker is required for the outer mailing package. Any packaging requiring solid carbon dioxide (dry ice) should ensure that it permits the release of carbon dioxide gas to prevent the build-up of pressure.

Although on 1 January 1995, IATA (a voluntary organization of air carriers) issued requirements for packaging, and has established a certification procedure for packaging companies who wish to provide packages to ship 'infectious material' on aircraft, the issues of updated guidelines is expected in 2004/5. Certification of packaging will continue to be a requirement. With the increased concern surrounding the transport of infectious material internationally and nationally, individuals should recognize that the importation and export of infectious materials requires the approval of a number of government departments and biosafety and biosecurity agencies.

SUMMARY

An increasing variety of publications already covers the many topics involved in general safety, laboratory safety, and biosafety. In this chapter we have tried to make virologists aware of the range of guidelines and regulations that affect work in a virology laboratory. We have also attempted to present the issue of biosafety from the view of the scientist. It is increasingly recognized that virological scientific programs need to be conducted in an efficient, safe, and secure manner. Because it is the scientists who should have the best knowledge of the nature of the agents under investigation, including factors such as pathogenic potential, they should play a pivotal role in the development of continuing biosafety policy.

The biosafety professionals have knowledge of the guidelines and regulations that apply to the operation of a virology laboratory. They also have knowledge of the latest in validated biosafety technology and practices that have been developed around the world. In addition, occupational safety and health professionals generally have information in such areas as transportation of specimens and requirements for importation of agents, which can help the laboratory function more efficiently. Increasingly it is recognized that scientists need to be responsible and accountable for the agents they work with and provide both the public and regulatory agencies evidence-based information that work is conducted within appropriately designed containment systems.

With the current expansion of high containment laboratories throughout the world it is essential that international cooperation and consensus is established in facility design, commissioning, operation, and maintenance in accordance with our understanding of infectious disease processes. Equally the establishment of well-managed biosafety training programs address the 'duty of care' required. The operational integrity of

these facilities will be dependent upon the establishment of good working relationships between scientists, specialist engineers, and biosafety professionals being established. This will ensure that the primary mission of the laboratory, the research, developmental and detection programs, can be conducted efficiently, safely, and securely.

The laboratory diagnosis of viral infections

STEVEN SPECTER AND MAURO BENDINELLI

Principles of diagnosis	1	Analysis of the host's immune response to the infecting virus	13
Detection of virions or their components	2	Quality assurance/quality control	16
Detection of viral infectivity	8	From laboratory findings to diagnosis	17
Characterization of detected viruses	10	References	17

During the past three decades the diagnostic virology laboratory has emerged as an important adjunct to patient care. This is a result of several factors, including enhanced technology that has allowed for more accurate, useful and rapid detection of viruses, improvements in patient management resulting from increased understanding of viral pathophysiology, and the development of a growing arsenal of antiviral chemotherapeutic agents. Molecular biology and antigen detection techniques have emerged as the methods of choice for rapid viral detection in many cases. This often allows detection and quantitation of virus in a matter of a few hours, resulting in direct application of collected results to patient healthcare. The viral diagnostic laboratory now has a vast array of methods to assist in diagnosis, including cytology, cell culture, antigen detection, electron microscopy, nucleic acid detection, measurement of antibodies, and, most recently, antiviral susceptibility testing. These techniques are facilitated by the development of specific reagents, test kits, and automated instruments, many of which are commercially available, as well as published algorithms for how to test for specific viral agents.

In an age when administrators are examining all costs, the performance of viral testing is often driven by outcomes assessment. The laboratory is now able to provide data that lead to cost savings related to:

- number of hospital days saved due to rapid and accurate diagnosis
- decrease in unnecessary antibiotic use
- improved hospital infection control
- application of specific antiviral therapy or other patient management issues.

These all have become valid reasons for performing testing, in addition to the age-old standards of collecting epidemiologic information and screening the blood supply.

Thus, this chapter strives to assess the methods currently in use for their importance in achieving viral diagnoses, with little comment on the actual manner in which these tests are performed. For this reason many of the historically important procedures may only receive passing mention.

PRINCIPLES OF DIAGNOSIS

In the course of virus infection it is possible to detect virus, viral antigens, nucleic acids, or antibodies to the virus as a means of identification of the etiologic agent. A good understanding of viral pathophysiology and host response is needed in order to determine the most appropriate specimen(s) to collect and the best type of testing to perform. During the viral incubation period, which can last from 1 day to months or even years depending on the virus, virus or viral subunits are the best targets for detection methods. This is also a period when virus may be found in blood or other body fluids

in some infections. By the time signs or symptoms of disease become apparent, virus is usually present in the target tissues but may be more readily isolated or otherwise detected from other tissues. For example, enteroviruses are more easily detected in stool than in the cerebrospinal fluid (CSF) in infections of the central nervous system (CNS). Collection of a serum sample early in infection is also important since the rise in antibody titers in later specimen(s) is often a useful way to identify a cause of infection. For serological identification of virus it is necessary to either test for IgM antibodies as an indicator of recent infection or to look for a significant titer rise. This must be at least a two-dilution increase to limit the possibility that technical error is a factor (most commonly a fourfold rise, since use of twofold dilutions is mostly performed). For persistent infections or late infection it may be difficult to isolate virus; thus, detection of viral antigen or nucleic acids may be easier than virus.

Specimens

Collection and submission to the laboratory of an appropriate sample is a vital factor in successful diagnosis. Ideally one should know exactly what is necessary to collect and submit specimens to a particular laboratory to optimize results (Smith 2000) (Table 1). This is best accomplished by contacting the laboratory to which the specimen will be submitted for direction.

Specimens should be collected and submitted to the laboratory as rapidly as possible after the recognition of a clinical problem. Failure to get the laboratory a good specimen is the greatest contributor to improper results. The suspected etiology(ies) should help guide the choice of specimen site(s). Not all specimens are directly related to the clinical presentation and knowledge of the most appropriate specimen(s) for each condition as well as the laboratory that is going to be used are important. It is best to err on the side of too much sample, if the amount of material needed is in question, as most laboratories do not complain about too much material as compared to too little. Of similar importance is the submission of vital supportive data on the label of the container for the specimen including patient name, identification number, specimen source, date and time of collection, and ordering physician. Each specimen should be accompanied by a requisition form with identical information as the specimen label plus other useful information such as clinical diagnosis and suspected virus(es).

Another important factor for successful laboratory diagnosis is transport of the specimen to the laboratory. A number of commercial media are available to preserve specimens during transport including Culturettes, Micro Test Multi-Microbe (M4-3), Virocult, Viral Transport Medium (VTM) and ViraTrans. While these all-purpose transport media are usually sufficient for the transport of most specimens, occasionally a specific specimen type may require special medium (Johnson 1990).

Table 1 *Specimens useful for viral studies*

Specimen type	Disease category (examples)
Nasopharyngeal wash or aspirate	Respiratory tract infection Certain exanthems CNS infections (especially enteroviruses)
Throat wash or swab	Respiratory tract infection
Sputum	Respiratory infection (HSV, CMV)
Bronchoalveolar lavage	Lower respiratory infection (CMV, influenza virus, parainfluenza virus)
Rectal swab or stool (5 mg)	Gastroenteritis and enterovirus infections
Cerebrospinal fluid	Meningitis, encephalitis
Brain biopsy	Meningitis, encephalitis (HSV, *Rabies virus*)
Blood	CMV, HIV, HBV, HCV
Vesicle fluid or lesion scraping	HSV, VZV, HPV
Endocervical swab	Genital infections (HPV, HSV)
Swab (eye)	Ocular infections (adenovirus, HSV)
Urine	CMV, BK virus, mumps virus
Serum	Antibody studies (most viruses)

DETECTION OF VIRIONS OR THEIR COMPONENTS

Cytopathology

One of the oldest and most rapid methods of detecting viruses is to directly examine stained clinical material using light microscopy. Cytological alterations that are pathognomonic for specific viruses can be readily visualized in virus-infected tissues and cells (Table 2). More often, the examination of material by microscopy may only raise a suspicion of viral infection or may limit detection to a viral family, requiring more specific methods for viral identification. Nevertheless, these rapid examinations may quickly rule in or out viral infection. Cytological staining using Giemsa (Tzanck preparation), Papanicalaou (Pap) or Wright stain, while rapid, has relatively low sensitivity when compared with modern methods of antigen or nucleic acid detection. Inability to distinguish herpes simplex virus (HSV) from varicella-zoster virus (VZV) somewhat limits the utility of Tzanck preparations.

The most commonly used viral cytology procedure is the Pap stain of cervical scrapings to detect premalignant lesions. Since its implementation nearly 50 years ago, Pap staining has helped to dramatically decrease the incidence of cervical cancer. The most common

Table 2 *Cytopathology of viral infections*

Virus	Clinical presentation	Inclusion bodies/Cytologic finding
Adenovirus	Hemorrhagic cystitis	Intranuclear, basophilic
	Pneumonia, upper respiratory tract infection	Intranuclear, eosinophilic (early); basophilic (late)
	Acute keratoconjunctivitis	Intranuclear, eosinophilic (early); basophilic (late)
BK polyoma virus	Urinary tract	Intranuclear, mucoid (early); cytoplasmic, dense, full, basophilic (late)
CMV	Urinary tract	Intranuclear, basophilic surrounded by halo (owl eye)
		Intracytoplasmic, eosinophilic
	Pneumonia	Cytomegaly, small intracytoplasmic, eosinophilic
HSV	Tracheobronchitis	Large ground-glass nucleus (early); intranuclear, eosinophilic (late); multinuclear cells
	Local cystitis, generalized infection	Large ground-glass nucleus (early); intranuclear, eosinophilic (late)
	Herpes genitalis	Multinuclear cells
HPV	Cervical dysplasia, condyloma accuminatum	Enlarged nucleus (hyperchromatic), intranuclear, basophilic (rare)
		Koilocytes (perivascular cytoplasmic clearing and vacuolar degeneration)
Measles virus	Nasal secretions in prodrome	Lymphocytic nuclei in mulberry-like clusters
	Pneumonia	Intranuclear and intracytoplasmic, eosinophilic; multinucleated giant cells
	Exanthem	Intracytoplasmic; multinucleated giant cells
Molluscum contagiosum virus	Genital lesions	Intracytoplasmic, large, dense staining, nucleus displaced bean-shaped squamous cells
	Papule on eyelid or conjunctiva	Intracytoplasmic, basophilic, dense; nucleus displaced
Parainfluenza virus	Bronchiolitis, pneumonia	Intracytoplasmic, eosinophilic; cytomegaly; single or multiple nuclei
RSV	Tracheobronchitis, pneumonia	Intracytoplasmic, basophilic, large multinucleated cells
VZV	Chickenpox, shingles	Intranuclear, eosinophilic, multinucleated cells

abnormal findings using the Pap test are atypical squamous cells of undetermined significance (ASCUS) and atypical glandular cells of undetermined significance (AGUS), which are associated with human papillomavirus (HPV) infection. In follow-up, HPV DNA testing can be useful for identifying women who are more likely to have underlying high-grade squamous intraepithelial lesions (Solomon et al. 2001). The management of patients with equivocal Pap tests is a clinically debated topic and has led to the re-evaluation of the need for this test and development of new clinical paradigms, which may soon preclude the common use of this procedure in favor of molecular tests for HPV. Smith and Yassin (2000) have written a chapter elsewhere that details many of the uses for cytology in viral diagnosis.

Electron microscopy

Electron microscopy (EM) can be used to directly examine specimens for the presence of viral particles. Most commonly, negative-staining methods are used to directly visualize viruses. EM is particularly helpful when trying to detect non-cultivatable or fastidious viruses, although high concentrations are required (Chrystie 1996; Petric and Szymanski 2000). It is rapid and relatively inexpensive, provided an electron microscope is available to the laboratory. In recent times, the emergence of new viral agents has emphasized the value of EM, notably for Ebola virus, hantaviruses, and other agents causing viral hemorrhagic fevers. It has also been suggested that EM could play an important part in early identification of an etiologic agent in a biological warfare or bioterrorist attack. The major limitations of EM are the high cost of the microscope, the expertise needed, and the frequent lack of precise identification of the virus detected, as well as low sensitivity and specificity. Successful detection requires the presence of 10^5 or greater particles/ml. EM is effective for identification of virus morphologically by family, which may be sufficient clinically in many cases, and can be enhanced by the use of antibodies (immune EM), which permits identification of specific viruses.

The rapidity of EM and ability to visualize the actual virus particle are the major advantages of this technique.

Negative staining of liquid specimens can be accomplished in under an hour and specimens that need concentrating by ultracentrifugation, agar diffusion, or pseudoreplica methods can be done in about 2 hours. In solid tissues the specimens would require thin sectioning and this would result in a 2-day process to accommodate the steps of fixation, staining, embedding, and then sectioning. EM is particularly useful for gastrointestinal infections, as virions are often in high concentration. Other specimens, such as urine or CSF, usually require concentration.

Detection and quantitation of viral antigens

Immunological methods are highly effective for detection of viral antigens. They offer a high degree of sensitivity and specificity, are rapid, and the costs are reasonable. Availability of commercial reagents facilitates the detection of many agents. Virtually all methods use antibodies that are tagged with a fluorochrome, enzyme, or radiolabel. Radioimmunoassay is used to a much lesser extent today due to issues of exposure to radioisotopes and the high cost of disposal of radioactivity.

IMMUNOFLUORESCENCE

The direct staining of clinical specimens using monoclonal or polyclonal antibodies bound to fluorescent dye is extensively used in many laboratories for the detection of a wide variety of viral antigens. This may be accomplished using either direct or indirect techniques. In direct immunofluorescence (IF), a single fluorochrome-labeled antibody is used. Indirect IF uses two antibodies, one specific for the antigen under scrutiny and a second fluorochrome-labeled antibody to the immunoglobulin (species specific) used as the first antibody. Indirect IF offers a few advantages, including increased sensitivity and one reagent (the second antibody) that can be used for testing for many viruses. There are many uses for IF including direct staining of smears, cells present in body fluids, tissues, and applications of flow cytometry or cell sorting (McSharry 2000; Schutzbank and McGuire 2000; Madeley and Peiris 2002).

IF has several distinct advantages: it is rapid, simple to perform, and does not require live virus. Results in some cases can be obtained in 1–2 hours, thus impacting on patient management, need for hospitalization, length of hospital stay, and mortality. Specimen requirements are simpler than those for viral culture since maintenance of live virus is not needed. In addition, the visualization of results allows for determination of specificity, examination of the appropriateness of the specimen, and specimen quality. The quality of a specimen is a critically important factor in viral diagnosis and has come under greater scrutiny by regulatory agencies in recent years. Determining that specimens contain sufficient numbers of cells, proper cell types, etc., can be very important in reflecting on the predictive value of the test result.

The IF methods also have their limitations: they require special microscopes, which can be expensive, specially trained microscopists who can interpret results accurately, and reagents that are specific for a particular virus. Thus, multiple smears would be needed to test for several viruses and a new virus would not be detected. It is therefore advisable to use IF in combination with culture methods for detection of viruses. Diagnosis is dependent on the quality of specimens as with all tests, so it is important that uniform, well-made smears be submitted for IF testing.

ENZYME IMMUNOASSAYS

Enzyme immunoassays (EIA) can be performed to detect either antigens or antibodies in clinical specimens. This versatility has resulted in widespread use of EIA in diagnostic virology. Most commonly these assays are performed using a solid-phase format, referred to as enzyme-linked immunosorbent assay (ELISA), with the particular target reagent bound to plastics in a microtiter well (Leland 2000). Many reagents are commercially available for detection of viruses and this form of testing is routine in many laboratories. EIAs are generally highly specific, have high sensitivity, and can be performed rapidly, within minutes to hours. Some solid-phase assays have been adapted to a disposable membrane format for use in physicians' offices, notably for influenza and respiratory syncytial virus (RSV). Also, EIA can be used for the detection of antigens in tissues using immunoperoxidase staining (Docherty et al. 2000).

There are some limitations to EIA, including lack of availability of reagents for some viruses, lack of cost-effectiveness for viruses that have a large number of serotypes (e.g. rhinoviruses) that are not cross reactive, and less sensitivity compared to molecular techniques.

RADIOIMMUNOASSAYS

Radioimmunoassays (RIA) have generally fallen out of use for most viral assays due to the expense of disposal and the potential of radiation exposure, and have generally been replaced by EIA. RIA rivals EIA in specificity and sensitivity and could be used for the same antigens as EIA if desired. Details on use of RIA in viral diagnosis can be found elsewhere (Mushahwar and Brawner 2000).

Detection and quantitation of viral nucleic acids

Recent years have witnessed an exponential growth in the use of diagnostic methods based on the search for

viral nucleic acids in clinical samples. The advantages of this approach are, in fact, several-fold (Table 3). In particular, rapid turnaround times for all viruses, including the ones that are fastidious or noncultivable (Table 4) and do not accumulate sufficient amounts of antigenic material in the host's tissues, or express unusual, not readily detected antigens (Ireland et al. 2000) to be detectable with current immunoassays, and relative ease of automation represent important features in the clinical virology setting since they permit significant improvements in the management of viral diseases without weighing unbearably on work loads. The common denominator of all genome-based methods is the use of stretches of nucleic acids (oligonucleotides, cDNA, RNA) that are complementary to, and thus capable of hybridizing with, segments of the viral genome being targeted. It follows that, although the many, variably sophisticated methods that have been designed around this basic principle vary greatly, choosing the correct segment of viral genome to be targeted is always very critical. In fact, because genome detection methods are extremely sensitive to sequence variation, selected sequences should be as conserved as possible in order for the method to detect and quantify all the possible variants of the virus with equal efficiency. This may sometimes be hard to achieve, as exemplified by the difficulties encountered in developing diagnostic methods that reveal with sufficient efficiency all the lentiviruses that may cause AIDS, including all subtypes of group M human immunodeficiency virus type 1 (HIV-1), group O HIV-1, and human immunodeficiency virus type 2 (HIV-2).

For several years, the only practical means for revealing the presence of viral genetic material in clinical samples was by nucleic acid hybridization techniques, which, however, were limited in sensitivity or required radioactive reagents. The hybridization-based assays that were designed for the diagnostic laboratory routine were therefore relatively few and found limited application. The advent of amplification techniques, which increase the copy numbers of selected segments of nucleic acids (nucleic acid amplification) or the signals generated by these when coupled to appropriate detectors or probes (signal amplification) has permitted the development of assays with exquisitely high levels of sensitivity and tremendously expanded the diagnostic potential of viral genome detection. Indeed, currently the detection of viral genomes is considered to be the most accurate indicator of infection for several viruses. Consequently, a large share of the virological tests carried out in an average diagnostic laboratory is presently based on this approach, albeit the high cost of many commercial reagents often remains a critical issue.

HYBRIDIZATION TESTS

In certain viral infections, selected clinical specimens can contain enough viral genetic material to be detectable directly, i.e. without the need for amplification technologies. In these cases, genome detection may be successfully carried out by reacting the specimens with nucleic acid probes of appropriate specificity and checking whether these have bound to target viral DNA or RNA. Technical variations are numerous. Examining thin-tissue sections or smears (in situ hybridization) may provide clinically useful histological information in addition to virus detection, but requires too much expertise and is too cumbersome for routine use. Thus, hybridization tests are usually performed on extracted nucleic acids in solution or, more frequently, immobilized on a solid support (e.g. dot-(spot)-blot hybridization). In the latter instance, extracted nucleic acid can be digested with restriction enzymes and electrophoresed (e.g. Southern-blot hybridization), thus allowing for much more specificity. The probes can be either DNA or RNA, may vary extensively in length, covering the entire viral genome or segments of it, and can be labeled with a variety of signal-generating systems (biotin, digoxigenin, etc.), although only ^{32}P and other radioactive tracers guarantee maximum sensitivity. Some hybridization tests also provide a semi-quantitative estimate of sample content in viral nucleic acids.

In past years, hybridization tests have found large practical application for detection of certain viruses,

Table 3 *Advantages and limits of genome detection methods in the laboratory diagnosis of viral infection*

Advantages	Limits
High sensitivity and specificity	Risk of cross-contamination
Detection of fastidious or noncultivable viruses	Risk of cross-reactions with nonrelevant nucleic acids
Virus detection also in clinical samples from which virus isolation can be difficult (patients treated with antivirals, CSF, etc.)	Risk of false negatives and false positives due to inhibitors or degradation of primes, probes, and templates
Quantitation of viral load	Viral phenotype not analyzable
Ease of automation	Comparatively high cost of commercial methods
High throughput	Detection of clinically irrelevant viruses
Rapid turnaround time	
Specimen deterioration less critical than for virus isolation	

Table 4 *Slow, difficult or impossible to isolate in tissue culture from clinical specimens*

Human virus
Coronaviruses
Enteric adenoviruses (serotypes 40 and 41)
Epstein–Barr virus (EBV)
GB virus-C (GBV-C)
Hepatitis A virus (HAV)
Hepatitis B virus (HBV)
Hepatitis C virus (HCV)
Hepatitis delta virus (HDV)
Hepatitis E virus (HEV)
Human herpesvirus 8 (HHV-8)
Human immunodeficiency virus (HIV)
Human metapneumovirus
Human papillomavirus (HPV)
Human parvovirus
Human polyomaviruses BK virus and JC virus
Human T-lymphotropic virus (HTLV)
Norwalk virus and other caliciviruses
Rotaviruses
Selected enteroviruses (most coxsackie A viruses)
Torque-teno-virus (TTV)

such as HPV in anogenital specimens and hepatitis B virus (HBV), hepatitis delta virus (HDV), and parvovirus B19 in plasma, but have now been almost completely replaced by more sensitive amplification-based techniques. As examples, the lower limit of sensitivity of commercial hybridization assays for HBV and parvovirus B19 detection in plasma ranged around 10^5–10^7 genome copies/ml whereas current amplification methods consistently yield a positive result with only a few hundred copies (Bendinelli et al. 2000; Heegaard and Brown 2002).

AMPLIFICATION METHODS

In the large majority of viral infections, no matter whether acute or chronic, the amount of genetic material of viral origin present in patient tissues is below the detection threshold of even the most sensitive among the direct hybridization tests discussed above. This explains the great success of many amplification methods that have been introduced in diagnostic virology in the last decade. In fact, these are capable of specifically and reproducibly detecting 10–100 viral genomes, thus performing at levels that were previously achievable only by the isolation of viruses capable of growing with great efficiency in tissue culture. Another important reason is that several amplification-based methods have permitted the development of quantitative assays, which precisely determine the number of viral genomes (viral load) in plasma and other specimens. This, in conjunction with the recent recognition that viral load determinations reflect and reliably measure active infection, has led to widespread use of quantitative assays for monitoring the levels of virus in the plasma of patients infected with chronic viremia inducing viruses, such as HIV, HBV, hepatitis C virus (HCV), and human cytomegalovirus (CMV). Viral loads are in fact now considered important parameters for treatment decision-making. Thanks to expanded availability of suitable reagents coupled with improved understanding of other technical issues, viral load assays have rapidly become increasingly reliable and user friendly and have acquired an important role in the clinical management of the above infections, contributing significantly to improved patient care.

Signal amplification methods

In essence, these methods are evolved formats of the hybridization tests discussed above, which have been designed to increase manifold – and make easily measurable – the strength of the signals generated by DNA or RNA probes that have formed hybrids with template viral nucleic acids. Several stratagems have been conceived for this purpose and exploit different technologies representing the basis for a number of widely used commercial kits. These include EIA technologies using monoclonal antibodies to specific nucleic acid hybrids, chemiluminescent technologies using triggerable substrates, and the recently developed branched-chain DNA (bDNA) technology. The latter consists of an intricate network of simultaneous hybridization events between multiple sets of oligonucleotide probes (capture probes, extender and amplifier secondary probes, labeled tertiary probes), some of which contain unnatural bases to optimize their complementarity performance characteristics. Since the intensity of amplified signals is proportional to the number of template sequences present in the specimens being tested, these assays are valuable not only for detecting but also for quantitating viral nucleic acids over a wide range of concentrations. For example, the HIV bDNA assays currently on the market can detect as few as 50 viral genomes per ml plasma. However, in general signal amplification assays tend to be somewhat less sensitive than methods based on nucleic acid amplification. On the other hand, they are less prone to technical problems generated by carryover contamination (see below).

Nucleic acid amplification methods

These methods are based on the use of enzymatic machineries that replicate nucleic acids under controlled conditions in vitro, increasing their copy number to a point where detection is possible by conventional or nonconventional techniques. The template amplified can be either viral DNA or RNA (target amplification) or, less frequently, the detectors that have interacted with viral nucleic acids (probe amplification). The polymerase

chain reaction (PCR) developed by Mullis and colleagues at the Cetus Corporation in the late 1980s (Mullis et al. 1986) is the conceptual progenitor of all methods in this category and still represents a widely exploited technology in a variety of nested, non-nested, monoplex, multiplex, and quantitative configurations, that in many instances have become standard laboratory practice. For amplification of RNA viruses, PCR-based methods require that target RNA is first converted into cDNA by a reverse transcriptase (RT) or by a bifunctional enzyme having both RT and polymerase activities [reverse transcriptase polymerase chain reaction (RT-PCR)]. However, several other methods have been developed that achieve viral nucleic acid amplification by using different principles and enzymatic systems. These include nucleic acid sequence-based amplification (NASBA), transcription-mediated amplification (TMA), and strand displacement amplification (SDA), which use a variety of enzyme combinations and amplification schemes. An example of probe amplification methods are the ligase chain reaction (LCR), the cycling probe technology (CPT), and the cleavase invader assay. Some such techniques require that the reaction mixtures undergo cycles of defined temperature changes, thus needing specific instrumentation, while others are isothermal and need no special instruments (Table 5).

Nucleic acid amplification methods are at high risk of carryover contamination, the source being mainly the sequences amplified (amplicons) in previous runs, which readily become dispersed in the environment and generate false-positive results, but also other specimens. Control of cross-contamination requires the implementation of rigorous physical precautions, the description of which is beyond the scope of this chapter, as well as the need to include in each assay appropriate numbers of negative control samples interspersed with test samples. It is also important to note that the enzymatic reactions at the basis of nucleic acid amplification assays are variably prone to inhibition by a multiplicity of substances, including heme, heparin, urine, calcium alginate, polysaccharides, and polyamines. The latter problem is usually overcome by the use of extensive nucleic acid purification procedures or of systems that specifically capture the target template.

Table 5 *Nucleic acid amplification methods used in the laboratory diagnosis of viral infections*

Method	Template amplified	Thermal cycling required
PCR	Target DNA	Yes
RT-PCR	Target RNA	Yes
NASBA	Target RNA	No
TMA	Target RNA	No
SDA	Target DNA	No
LCR	Detector DNA	Yes
CPT	Detector chimeric DNA-RNA	No
Cleavase invader	Detector DNA	No

Microarrays

Microarrays are amplification/hybridization methods miniaturized in such a way as to make it possible to assay, in a single run, specimens against a large number (thousands) of probes and consist of slides or microchips that carry microspots of cDNA or oligonucleotides bound to their surface. In perspective, this technology is expected to allow not only the search of many different viruses in a single test but also the simultaneous recognition of clinically and epidemiologically useful characteristics of detected virus (genotype, susceptibility to drugs, etc.) that at present need to be investigated separately (see below) as well as cellular gene alterations characteristic of a specific type of pathology. Although offering much promise, microarrays have yet to find wide application in the diagnosis of viral infections.

Real-time methods

The term real-time refers to methods in which the two major phases of amplification technologies, i.e. amplification and amplified product detection, occur simultaneously in a single, closed tube or well. These methods require intercalating dyes, probes, or molecular beacons labeled in such a way that the signal emitted changes concomitant with amplicon formation and dedicated instruments with precision optics that reveal such change as soon as it has occurred. They considerably shorten assay times, have an extremely high throughput and minimize cross-contamination problems (Mackay et al. 2002).

Commercial kits and automation

Virus detection and quantitation using commercial assays in kit format and with an increasing level of standardization and automation have gradually invaded most diagnostic laboratories. In fact, the performance characteristics of well standardized commercial assays having built-in carryover protection systems are generally superior to those of the in-house-developed PCR and NASBA assays (many of the other methods are too complex to be developed independently in the user laboratory), that are, however, still in use for testing clinical samples for the presence of uncommon viruses and for cost containment. Commercial kits often come with automated or semiautomated platforms. Automated steps may include sample preparation, nucleic acid extraction, amplification reaction, reading both sample and appropriate control values, data processing, and report generation. Automation can dramatically decrease laboratory-to-laboratory differences as well as labor requirements. The automation level of real-time techniques is often quite high. Rapid point-of-care viral

genome detection methods may also become available in the future, possibly as a spinoff of the portable amplification systems that are being developed for screening the environment for pathogens considered potential biological weapons. A note of caution regarding these advances is that a loss of the technical skills needed for handling and characterizing viruses is also anticipated.

DETECTION OF VIRAL INFECTIVITY

Animal inoculation

The use of animals to grow viruses for laboratory identification has virtually disappeared from the diagnostic laboratory. This has resulted more from the development of sensitive techniques to detect viruses, as well as the health risks and the costs involved in handling the animals. It is likely that animal inoculation will be limited to specialized laboratories who might investigate suspected new pathogens for which other techniques have not yet been developed. A detailed description of animal inoculation is provided in Landry and Hsiung (2000).

Virus isolation in embryonated eggs

Similar to the use of animal inoculation, use of embryonated eggs has yielded to cell culture and direct detection methods for viral diagnosis. The embryonated hen's egg, however, was a very useful vessel for growing viruses, which could be cultivated on the chorioallantoic membrane or in the allantoic or amniotic sacs. Eggs are still used for the large-scale production of some viruses in vaccine production processes (e.g. influenza viruses).

Eggs used for virus isolation must be obtained from a facility that raises them in specific pathogen-free conditions and dedicated equipment is required. Eggs are incubated at 37°C in a humidified atmosphere (40–70 percent) and rotated several times every day to ensure the health of the developing embryo. Eggs are examined by candling, a visual inspection process using a light box with a hole at the top, to make certain that the embryos are developing properly. A detailed description of inoculation and evaluation procedures is described by Landry and Hsiung (2000).

Virus isolation in cell culture

Work in the 1930s pioneered the use of cell culture for the propagation of viruses. Since that time the numbers and types of cultured cells have expanded tremendously and variations of standard uses of cell culture have enhanced the ability to detect and identify viruses (Landry and Hsiung 2000). As a result of these changes, viruses can be isolated more rapidly and in many cases viral identification also results.

STANDARD CELL CULTURE

Three types of culture are routinely used to isolate viruses: primary cells, diploid cell lines, and heteroploid cell lines. Cells may be used as monolayers or cell suspensions to isolate viruses. Lymphocytes for cultivation of HIV and certain herpesviruses, such as Epstein–Barr virus (EBV), human herpesvirus 6 (HHV-6), and human herpesvirus 7 (HHV-7), have been especially useful in suspension culture. Each cell type has distinct characteristics that make it susceptible to a limited number of viruses (Table 6). Thus, it is often important to use in parallel several cell types in order to cover the array of viruses that might be associated with pathology in a particular illness or organ system. For example, respiratory tract infection during the traditional season for such infections might include human diploid fibroblasts as well as HEp-2 cells, primary monkey kidney cells, and A549 cells, which can support growth of almost all of the common causes of respiratory tract infections and can help differentiate among them (Landry and Hsiung 2000). In addition to susceptibility, sensitivity and the speed with which cells begin to show infection are factors to be considered in selecting cell lines. Other important factors to consider in setting up a cell culture laboratory are:

- whether or not to prepare and maintain cell lines in-house or purchase them commercially, which must be based on cost and availability
- what are the common specimens encountered so that appropriate numbers of the most needed cells are readily available (this may be seasonally adjusted)
- what is the availability of experienced skilled technologists.

Cell cultures must be carefully maintained and replaced regularly to ensure that cells will be capable of replicating virus when needed, as older cultures often have reduced susceptibility and contaminated cultures cannot yield useful results. This includes visual inspection prior to inoculation and addition of antibiotics and antifungal agents to specimens in the initial processing steps. Typically, tubes for standard cell culture are 16×125 mm screw-cap tubes and they are held at 35°C. When inoculated, cultures may be maintained in stationary position or in roller tubes and incubated at the same temperature except for certain viruses (e.g. rhinoviruses that are incubated at slightly lower temperatures). Tubes are usually kept at a slight angle (5–7°C). Cells are observed daily for evidence of infection.

DETECTION OF VIRAL PRESENCE

Classically, detection of viral infection is dependent upon light microscopy of unstained cells for visualization of evidence of cytopathology. Cytopathic effect (CPE) is the term used for morphological changes noted as a result of viral replication in the cell culture. The CPE of

Table 6 *Cell lines sensitive to common viral agents*

Cell line	Viruses
A549 cells	Adenovirus, HSV
HeLa cells	HSV
HEp-2 cells	Adenovirus, HSV, RSV
Human embryonic kidney	Adenovirus, BK virus, HSV
Human diploid fibroblasts	CMV, HSV, VZV, enteroviruses, rhinoviruses
Madin–Darby canine kidney (MDCK)	Influenza viruses
NCI-H929	Adenovirus, enteroviruses, MuV, measles virus, parainfluenza viruses, RSV
Primary monkey kidney cells	Enteroviruses, influenza viruses
Primary rabbit kidney cells	HSV
Engineered cell lines	
BHK-21 (baby hamster kidney-inducible β-galactosidase gene with HSV-inducible promotor)	HSV
Super E-mix (CaCo-2 and BGMK-high expression of decay accelerating factor)	Enteroviruses
Mixed cell cultures	
E-mix A (RD and NCI H292)	Enteroviruses
E-mix B (BGMK and A549)	Enteroviruses
Super E-mix (CaCo-2 and BGMK) high expression of decay accelerating factor)	Enteroviruses
H and V mix (CV-1 and MRC5)	CMV, HSV, VZV
R-mix (A549 and ML)	Adenoviruses, influenza A and B viruses, parainfluenza viruses, RSV

cells may be described as clumping, destruction, granulation, rounding or vacuolation, giant cell or syncytia formation, or refractile cells. A presumptive identification of the etiologic agent may often be made, with a high degree of accuracy, based on the type of CPE in the cell line(s) used, specimen source, and information on the clinical presentation. It is important to examine cells at least once every 2 days and to maintain sham-inoculated controls for each cell line inoculated. The presence of adventitious agents in cells, especially simian viruses in primary monkey cells, is not uncommon.

In some circumstances, viruses will not cause a visible CPE and it is necessary to resort to other methods to detect their presence. Mumps virus (MuV) will not normally cause CPE but addition of guinea pig red blood cells (RBC) to infected primary monkey kidney cells will result in adherence of the RBC to the cells (hemadsorption), thus demonstrating the presence of infection. This results from a viral glycoprotein (hemagglutinin) being inserted into the cell membrane as part of the viral replicative cycle. Alternatively, viruses that do not cause CPE following infection may be detected using an interference assay. In this regard, rubella virus (RUBV) isolation may be detected by interference with echovirus 11 to replicate and cause cell destruction of African green monkey kidney cells.

Whilst all the assays described will isolate virus and may provide presumptive evidence, they do not provide definitive evidence of the identification of the etiologic agent. Identification can be achieved by using specific antiviral antibodies, most effectively monoclonal antibodies, in conjunction with cell culture. This can be achieved by using antibodies labeled with a fluorochrome (IF) or an enzyme (EIA) as described above.

Enhanced cell culture

Over the past few decades several advances have been introduced that have allowed for more rapid, sensitive and cost-effective use of cell culture. The first of these involved low-speed centrifugation of cell cultures to enhance the infectivity of viruses. Subsequently, the use of labeled antibodies for early detection of viral antigen allowed for greatly decreased time to detection as compared to awaiting development of CPE. Thereafter, cell culture has been enhanced by the identification of genetic regulatory elements that are specific to particular viruses, allowing for cell lines to be engineered to yield highly specific detection of a virus. More recently, the admixture of different cell types into a single culture vessel has allowed for a broader array of viruses to be identified in a single tube.

CYTOSPINNING (SHELL VIALS)

The use of the shell vial assay was adapted for detection of CMV as reported by Gleaves et al. (1984). The assay used MRC-5 cells (human diploid fibroblasts) grown on a coverslip in a vial, infected with a specimen, and submitted to low-speed centrifugation followed by overnight incubation. Labeled antibody to an early antigen of CMV is used to stain cells after 24 or 48 hours and

often yields a positive result a week or more sooner than waiting for the development of CPE. When used in combination with standard cell culture, the shell vial assay can result in more rapid detection and increases the overall rate of detection for CMV. The success of this assay for CMV has stimulated development of shell vial assays for other viruses and testing can now be done for adenovirus, enteroviruses, respiratory viruses, HSV and VZV. Depending on the virus suspected, an increased number of shell vials was inoculated, the time of incubation was extended and the variety of cell lines used was increased (Olsen et al. 1993). In the case of detection for a variety of viruses, such as respiratory viruses, a cocktail of antibodies can be used to determine if infection is present. The antibodies are used in such a way that the staining pattern is suggestive of a particular virus. Subsequent testing of a second shell vial containing the positive specimen using a monospecific antibody can then identify the etiologic agent.

ENGINEERED CELL LINES

Principles of histochemistry, genetic engineering, and cell culture were combined to enhance the development of a rapid, specific method for detection of HSV by Stabell and Olivo (Olivo 1996). They used BHK-21 (baby hamster kidney) cells that had been stably transformed with a β-galactosidase from *Escherichia coli* attached to an HSV-inducible promoter. When these cells are infected with either herpes simplex virus 1 (HSV-1) or herpes simplex virus 2 (HSV-2), the β-galactosidase is induced and then an X-gal colorimetric substrate is added, infected cells turn blue, while other viruses do not induce the enzyme and cells remain colorless. This method has been incorporated into a commercial kit that has been marketed as the enzyme-linked virus-inducible system (ELVIS) (Olivo 1996). When compared to standard isolation in cell culture that takes considerably longer at times, this test was highly sensitive and specific for both herpes simplex viruses. There are advantages to this method including its rapidity, use of relatively inexpensive substrate as compared to antibodies, and the ability to use cells to look for both the color change and CPE. The method is adaptable for other viruses, both DNA and RNA viruses, and a format for antiviral susceptibility testing for HSV (Olivo 1996) may further broaden the usefulness of this approach.

MIXED CELL CULTURES

The most recent significant development in virus isolation methodology is the use of a mixture of cells in a shell vial format. The choice of cells has been focused on the ability to isolate and identify viruses that have a common pathological presentation, such as enteroviruses or respiratory viruses. The cell mixture allows for a broader range of viruses to be isolated in a single culture. The mixtures have been designated by the cell types included in the culture and the specimen type submitted. R-mix uses a combination of A549 cells and mink lung cells and is useful for the detection of adenoviruses, influenza viruses, parainfluenza viruses, and RSV (Huang et al. 2000; St George et al. 2002). There are three combinations used for enteroviruses, designated E-mix A (RD and NCI-H292) and E-mix B (BGMK and A549) and Super E-mix (CaCo-2 and BGMK cells that have been genetically engineered to express a receptor for enteroviruses), which will also detect some additional viruses (Buck et al. 2002; Huang et al. 2002). The choice would depend on specimen type and clinical diagnosis since enteroviruses are seen in a variety of disease entities. In addition, there are H and V mix cells for the detection of herpesviruses (CMV, HSV, and VZV) that use CV-1 and MRC-5 cells (Huang et al. 2000). Preliminary results using these cell mixtures indicate that they perform similarly to or better than conventional cell culture or single-cell shell vial cultures and are more cost effective. By contrast, these cell mixtures do not appear to be as sensitive as PCR in comparison testing.

CHARACTERIZATION OF DETECTED VIRUSES

Viruses detected in clinical specimens by one or more of the methods discussed above generally need to be further investigated in order to achieve their precise identification (typing). In addition, they may need to undergo supplemental analyses that can provide clinically useful information, including antiviral drug susceptibility testing.

Typing

A precise identification of detected viruses is often necessary because viral agents belonging to different species or types within a same family or genus may vary greatly in pathogenic potential, and most virus detection methods do not allow such differentiation. Typing is also essential for epidemiologic surveillance purposes. Criteria that may be of guidance in typing a virus detected in a clinical specimen are numerous, including nature of the specimen, epidemiologic data, virion morphology and physical–chemical properties, electrophoretic pattern of segmented viral genomes, presence or absence of a lipid envelope, range of infectable cell types or animals, type of CPE or pathological manifestations produced, ability to agglutinate the RBC of different animal species, etc. However, generally such elements only provide presumptive evidence that permits one to narrow, sometimes substantially, the number of type-specific tests the laboratory will eventually need to perform. For example, assessing the

hemagglutination properties of an adenovirus isolated in tissue culture may assign it to one of the subgenera A–F but does not obviate the need for further typing. In fact, ultimate identification is based on an accurate definition of their antigenic makeup (serotyping) and/or nucleotide sequence analysis (genotyping) of detected viruses, the choice between the two being mainly dictated by how detection has occurred.

SEROTYPING

Viruses demonstrated by isolation in tissue culture, embryonated eggs, or experimental animals, or revealed by antigen detection methods are generally typed serologically. This is achieved by investigating how selected biological properties of the isolate behave when this is probed with type-specific immune sera. Although neutralization remains the most reliable means of serotype classification due to its exquisite specificity, it is technically demanding and labor-intensive. Also, it may be complicated by the poor neutralizability of certain fresh isolates by antisera raised against prototype viral strains or by the concomitant presence of more than one virus in the sample. In the case of viruses for which a profusion of different serotypes exist, performing the neutralization tests with pooled antisera represents a considerable help since it reduces the number of immune sera that need to be individually used in final identification. For example, serotyping of enteroviruses can be facilitated by the use of standardized antiserum pools provided by international agencies.

Additional frequently used methods for serotyping are inhibition of hemagglutination or hemadsorption and examination of virus-infected cells by IF or other immunostaining techniques. Finally, especially when the virus is difficult to cultivate, dissection of intertypic antigenic differences can be carried out with enzyme immunoassays, immune EM (which relies on the antibody-mediated agglutination of viral particles), immunochromatography, and other serological tests.

GENOTYPING

Although applicable to any virus, genotyping is most frequently used for the ones that have been demonstrated by nucleic acid detection and consists in analyzing segments of the viral genome that present unequivocally distinct type-specific nucleotide sequences. Genome regions suitable for typing can be the same used for virus detection as in the case of HCV genotyping (Zein 2000; Nolte 2001). However, because detection methods often target highly conserved genomic segments, genotyping frequently requires the prior amplification of additional carefully selected segments of the viral genome. For example, while human T-lymphotropic virus (HTLV) detection by PCR in Ficoll-purified peripheral blood mononuclear cells (PBMC) is usually carried out with primer sets targeted to the *tax* gene, differentiation of human T-lymphotropic virus type 1 (HTLV-1) and human T-lymphotropic virus type 2 (HTLV-2) is achieved by amplifying positive samples in a region of the *pol* gene (Schüpbach and Gallo 2000). Amplified segments are then sequenced, and obtained sequences compared to those existing in data banks with the help of special computer algorithms. Alternatively, the viral genotype can be deduced from the patterns generated by the amplicons when sized or examined for restriction fragment length polymorphism (RFLP), electrophoretic mobility following duplex formation with reference amplicons (heteroduplex mobility assay), denaturation at different temperatures (melting curve analysis; Whiley et al. 2001), or binding to carefully chosen genotype-specific oligonucleotide detectors immobilized on solid supports, such as membrane strips (line probe assay). The latter method has been exploited in several commercial kits since it is technically the least demanding. However, sequencing is regarded as the 'gold standard' since it permits pairwise comparisons, calculation of genetic identities on the basis of percent homology, and performance of phylogenetic investigations that may be useful for documenting epidemiologic links and other purposes. In addition, if the tracts of viral genome analyzed are sufficiently long, sequencing has the potential of revealing viral hybrids that may form as a result of recombinational events between viruses belonging to different genotypes. For some viruses, recombinants are a common occurrence. For example, recombinants of HIV-1 not only are frequently found in multiply exposed patients but also have the ability to be transmitted from patient to patient (circulating recombinant forms; Thomson et al. 2002).

As an alternative molecular strategy to classification, proposed, for example, for differentiating among orthopoxviruses (Ropp et al. 1999) and HCV genotype identification (Schröter et al. 2002), group- or type-specific PCR assays can be constructed which provide a positive result only when a specific viral group or type is present in the clinical specimen. Of note, this strategy has the potential to give a definitive diagnosis based on a single assay without the need for additional testing but is practicable only when the number of possible genotypes is minimal. Examples are the detection of the polyomaviruses BK virus and JC virus in urine (Biel et al. 2000) and of coxsackie virus A16, a frequent cause of hand-foot-and-mouth disease (Bendig et al. 2001).

Differentiating between wild-type and attenuated vaccine virus strains

This differentiation is necessary whenever a virus suspected to be responsible for a clinical form is detected in a patient who has recently been immunized against the same virus by means of an attenuated

vaccine or has been in contact with vaccinees. The assays involved are generally conducted in reference laboratories and may be phenotypic and/or genotypic. For example, discrimination between vaccine and wild-type strains of poliovirus can be based on in vitro growth behavior at different temperatures, intratypic serodifferentiation using strain-specific antibodies, RFLP patterns, or sequencing of PCR products. Molecular methods have found application also for discriminating the vaccine strains of the measles virus (Bellini and Rota 1998) and varicella virus (Loparev et al. 2000) from their wild-type counterparts.

ANTIVIRAL DRUG-SUSCEPTIBILITY TESTING

Patient treatment with antiviral agents frequently – if not invariably, especially if therapy is sufficiently prolonged – determines the emergence of virus mutants that show a decreased susceptibility to the drug(s) used and often also to other drugs having mechanisms of action similar to the ones in use. Because this usually leads to reduced patient response to therapy, revealed by rising viral loads and/or clinical deterioration, monitoring patients for the appearance of drug-resistant mutants is gradually becoming routine in clinical practice for evaluating whether and how antiviral regimens have to be modified. This is in turn impacting on diagnostic virology laboratories to an increasing extent. Currently, viruses obtained from antiviral naive patients are generally drug sensitive. However, as with antibacterial drugs, increased availability and use of powerful antiviral agents is likely in the future to lead to the circulation in the community of viruses that present baseline drug susceptibility characteristics that diverge to a variable extent from naive viruses. This development, which already has been observed with HIV-1 (Boden et al. 1999), is bound to extend the need for drug-susceptibility testing of viruses prior to initiation of treatment.

Phenotypic drug-resistance assays

Ideally, for better reflecting what is happening in patients, drug-resistance profiles should be based on the phenotype characteristics of detected viruses. This implies that the virus is isolated in tissue culture, grown at sufficiently high titers, titrated, and finally tested for the ability to replicate in the presence of graded concentrations of each of the drugs of interest. Thus, conventional phenotypic assays are laborious and, with the almost sole exception of HSV-susceptibility testing, take weeks to be completed. In addition, concerns exist that in vitro passage may result in the selection of an altered virus population having drug-susceptibility characteristics different from the one in the patient. In the case of HIV-1, an effort to circumvent these shortcomings has been the development of recombinant virus-based phenotypic assays, in which the relevant genes are directly PCR amplified from the patient and inserted into engineered HIV-1 clones from which such genes have been deleted, and the resulting chimeras subjected to phenotype analysis. It should be noted, however, that even the latter assays do not resolve the other major pitfall of phenotypic resistance tests, namely that attempts to standardize protocols and interpretation guidelines have met with limited success, due to the many technical and interpretational variables that may influence assay results. These include assay format (plaque reduction, dye uptake, yield reduction, flow cytometry, etc.), virus dose, type of cell substrate, viral strains adopted as drug-susceptible and resistant controls, duration of incubation, readout (CPE, accumulation of viral components, infectivity, etc.), and endpoint (50 versus 90 or 99 percent inhibition).

Genotypic drug-resistance assays

Due to the problems inherent to phenotypic assays, for certain viruses (HIV-1, HBV, CMV, influenza), these have been largely replaced by tests that analyze the genome of detected viruses. The procedure most often used consists in amplifying and sequencing the entire genetic region(s) known to control drug susceptibility. Alternatively, if the mutations involved are limited in number or only the most common need to be detected, PCR amplification can be confined to short genome segments, and the resulting amplicons examined by restriction enzyme digestion, melting curve analysis, or line probe assays, as well as by automatic or hybridization sequencing. Genotypic assays are much faster and less labor intensive than phenotypic assays but may miss resistant mutants that are still in the minority in the patient's total viral population. A further limitation stems from the fact that the multiple effects of individual mutations can make it extremely difficult to infer how different combinations of mutations, generated, for example, as a result of multidrug therapies, can impact on actual viral phenotype (level of resistance, cross-resistance, multidrug resistance, etc.). Of note, for HIV-1, an interesting solution has been to scrutinize the nucleotide sequences against constantly updated databases that embrace large numbers of data correlating HIV-1 genotype to phenotype (virtual phenotype). For a recent review of genotypic testing for HIV-1 drug resistance see Shafer (2002).

Viral parameters of poorly defined clinical utility

As discussed in the above sections, viral load and drug-susceptibility determinations have become an integral part in the management of several viral diseases. In recent years, however, there have been numerous efforts to identify further virological parameters that may help at formulating precise prognoses and effective antiviral treatments. One avenue has consisted in attempts to

correlate disease severity with variably subtle differences that may exist among different strains of a given virus or may evolve as a result of virus–host or virus–drug(s) interplay. For example, in HIV-1 the features considered have included genetic complexity, tropism for lymphocytes or macrophages, co-receptor usage, cytopathicity, syncytium-inducing ability, sensitivity to antibody-mediated neutralization, and replicative capacity. In particular, the latter parameter has received attention especially following the introduction of highly active antiretroviral therapy (HAART) due to the observation that certain drug-resistant HIV-1 isolates with mutated enzymes exhibit impaired replication rates (Brenner et al. 2002), leading to controversy regarding whether failing drugs should be stopped or rather continued in order not to remove the force that provides selective advantage to such unfit mutants (Deeks et al. 2001).

Similar studies have also involved several hepatitis viruses, although the range of parameters considered has been more restricted due to failure of these viruses to grow in vitro. HCV quasi-species composition has received particular attention in the hope that the swarm of viral variants found in patients may provide a recapitulation of the selective forces that have impacted and are impacting on the virus and of virus ability to evolve and resist host's defense mechanisms (Maggi et al. 1997). Although the findings in chronically infected patients have been inconclusive (Farci et al. 2002), recent evidence suggests that, when studied in the viral hypervariable region 1 at the time of seroconversion, quasispecies composition can predict the outcome of acute HCV infection (Farci et al. 2000).

A second approach has been trying to find correlations between disease progression and status of the infecting viruses in patients tissues. An early example was the correlation that was established between HBV replication activity and HBeAg detection in plasma (Bendinelli et al. 2000). More recently, suggestions have been put forward that detection of CMV DNA in plasma and not only in the peripheral blood leukocytes of bone marrow transplant recipients correlates with increased likelihood of progression to clinical disease (Boeckh et al. 1997) and that detecting viral mRNA, particularly late rather than early transcripts, in the tissues of transplanted patients is an indication of persistent infections reactivation (Lam et al. 1998; Gerna et al. 1999; Blok et al. 2000; Van den Bosch et al. 2001). Also, determining the physical state (integrated versus episomal) of HPV DNA in genital samples has been proposed as a measure of the risk of oncogenic progression (Kalantari et al. 2001).

To date, however, the overall practical product of these studies has been disappointing, since few, if any, of the parameters proposed have reached general acceptance and none has found extensive application in everyday clinical and laboratory practice. It should also be noted that, at least as currently performed, many of the parameters considered are too laborious for most clinical virology laboratories and are susceptible to artifacts. As an example, viral quasispecies analysis implies the amplification of selected regions of the viral genome followed by cloning or separation by gel mobility of the resulting amplicons and sequencing of the different variants (Gomez et al. 1999) or, as suggested in a recent report, mass spectroscopy of the peptides encoded by such amplicons (Ayers et al. 2002). Similarly, discriminating between viral genomic DNA and the cDNA formed as a result of mRNA reverse transcription and amplification can be extremely arduous. It is therefore to be expected that, even if eventually validated, many of the proposed parameters will remain in the realm of clinical research for a long time.

ANALYSIS OF THE HOST'S IMMUNE RESPONSE TO THE INFECTING VIRUS

Cell-mediated immune responses

Early attempts to exploit cell-mediated immune (CMI) responses, in particular delayed hypersensitivity skin tests, for the diagnosis of viral infections led to the conclusion that they could at most have some utility in epidemiologic surveys. The measurement of CMI responses has had a resurgence in the past two decades as a tool for monitoring patients who are virus infected or at risk of becoming infected. This is related to our recognition of the pathogenetic significance of cellular immune function and cytokines in viral infections. HIV infection and AIDS are perhaps the circumstances where this is most thoroughly used but other states of immunocompromise, notably bone marrow transplantation, have seen benefits from such testing. Testing of CMI function has included measurement of a variety of functional and nonfunctional parameters (Table 7), including circulating lymphocyte subset counts, cytotoxic T lymphocytes (CTL) and natural killer cell activities, response to specific antigens and to polyclonal lymphocyte phytomitogens, and cytokine production and profiles. Mawle (1996) has written a useful review that details many of the assays used to measure cellular immunity.

The determination of total T lymphocytes as well as the number of helper ($CD4^+$) and cytotoxic ($CD8^+$) T cells has achieved its greatest importance in HIV-infected individuals as this is used for staging of disease, evidence of progression to AIDS, and as an indication of

Table 7 *Cell-mediated immunity used for clinical virology*

Cell numbers	Cell functions	Cytokines
CD4, CD8, CD4:CD8 ratios	Cytotoxic T cells	T helper cell populations
NK cells	NK cells	Th1 – IL-2, IFN-γ Th2 – IL-4, IL-1

efficacy of antiviral therapy. Absolute cell numbers as well as CD4:CD8 cell ratios are used for these purposes. The availability of monoclonal antibodies to measure these cell numbers has made this testing easy to perform in virtually any laboratory; however, it is more precisely accomplished using flow cytometry.

Testing of cellular cytotoxicity is usually performed using a radioactivity label release (^{51}Cr) assay. This testing requires a step to separate and collect PBMCs and then test them under conditions that are optimal for measuring virus-specific CTL. This testing has been used in evaluating AIDS patients and individuals with herpesvirus infections but is still not routinely used in the clinical laboratory.

Nonspecific or antigen-specific blastogenic responses as a measure of immune competence provide insight into CMI function, either generally or regarding a specific disease. More recently there has been an association of subsets of helper T cells with immune status, such that production of specific cytokines is associated with a predominance of CMI [Th1 cells, which produce interferon-gamma (IFN-γ) and interleukin (IL)-2] or antibody responses (Th2 cells, which produce IL-4, IL-5 and IL-10). Th1 responses are considered to favor a better prognosis in HIV infection and many virus infections, whereas Th2 responses would be considered to be important in other types of infections.

Antibody responses

Although at present somewhat overshadowed by the recent success story of molecular methods, serological tests for antiviral antibodies (serodiagnosis) have had and still have an important position in the diagnosis of viral infections. The reasons are several-fold. First, certain serological tests (in particular, detection of antiviral IgM) represent a rapid means for identifying several acute viral infections. Second, the technologies most frequently used are within reach of most laboratories since they do not demand the expertise and the equipment that are instead essential for most other virological procedures. Third, serology is theoretically valuable for establishing an etiologic diagnosis in all viral diseases, regardless of whether the etiologic virus is easily demonstrable by direct means or not. Fourth, serological tests are generally inexpensive in labor and reagents. Fifth, the market offers a vast selection of high-quality serological reagents, many of which are available in kit format and are suitable for automation. Finally and possibly most importantly, if the implicated virus is one of the many that tend to persist for prolonged periods of time or indefinitely in their hosts, serodiagnosis represents the only means, together with viral load determination when available, by which it can be demonstrated that a primary infection or a reactivation of a chronic infection is ongoing at the time of disease. When clinical, anamnestic, and epidemiologic data are compatible, this represents strong evidence that the disease under scrutiny is indeed caused by that virus.

Classically, the procedures exploitable for serodiagnosis include virus neutralization (which for decades has been the standard against which the other test systems were evaluated), complement fixation (CF), hemagglutination inhibition (HI), passive agglutination of latex particles or RBC, immunoblotting, indirect IF, and RIA. These methods are still in use for some viruses (e.g. neutralization for poliovirus and CF for uncommon agents for which no other assay is available), or for selected purposes (e.g. immunoblots for confirmation of HIV or HCV seropositivity assessed with other methods). However, currently, the scene is dominated by solid-phase EIAs, that have become enormously popular in diagnostic virology as well as in other fields due to their sensitivity (comparable to RIA), speed, ability to measure antibodies of different isotypes, use of nonhazardous reagents, and aptitude to be automated. The antigens used are purified viral preparations and, increasingly, recombinant or synthetic peptides. It is, however, possible that in the future, other practical methods will be adapted for viral serology. For example, flow-cytometry-based serological methods are being advocated for their ability to detect antibodies to more that one virus in a single assay (Álvarez-Barrientos et al. 2000).

For viruses that constantly cause chronic infections (HIV-1 and HIV-2, HTLV-1 and HTLV-2) or are very uncommon (rabies in unvaccinated individuals), the interpretation of serological data is unique since the detection of antibodies of any isotype virtually always denotes infection. For all other viruses, demonstration of ongoing infection by serology requires that the antiviral antibody response is shown to have been elicited (boosted in the case of virus reactivations) recently. This is a consequence of the long duration of most antiviral antibodies, often with little or no reduction in total titer for many years or lifelong, particularly if they have been generated by systemic infections. Thus, mere seropositivity reveals that the individual has been exposed to the tested virus but is not informative of whether this has occurred recently or more or less remotely or even as the result of artificial immunization. In a sense, seronegativity may be more informative because it excludes the infection or indicates that antibody production has not yet started.

Demonstration that an antiviral antibody response has been triggered recently can be achieved with one or more of the approaches below.

TITRATION OF PAIRED SERUM SAMPLES

Two serum samples, one collected as early after disease onset as possible (acute-phase serum) and the second at least 1 week later (convalescent-phase serum), are titrated for antiviral antibodies simultaneously and in the same run. Although seroconversion is rarely

observed especially in systemic diseases with an incubation period of weeks, this approach often permits the observation of a significant rise (fourfold or greater) in total or IgG antibody titer between the first and the second serum. Major pitfalls of this procedure are:

- if the acute-phase serum is drawn too late, antibodies may be already reaching peak levels and a significant rise in titer can be missed
- the result of testing is very often retrospective and, therefore, of little use for patient care.

DETERMINATION OF ANTIVIRAL IGM IN SERUM

This approach is currently the most widely used. Typically, during acute primary virus infections virus-specific IgM antibodies appear in serum between 5 and 10 days after initiation of infection, reach peak concentrations at 2–4 weeks, and then usually decline to undetectable levels at 2–4 months, although they may last considerably longer in some infections. In the course of persistent infections, IgM antibodies are usually negative, although they can briefly reappear during episodes of intense reactivations of virus replication. Thus, detecting IgM to a given virus, with or without the corresponding IgG, even in a single serum sample obtained during the acute phase of illness, denotes current or very recent primary infection or reactivation of a persistent infection by that virus. By contrast, the presence of virus-specific IgG but not IgM signifies past infection. Examples of acute viral infections in which specific IgM tests are particularly useful for diagnosis include hepatitis A, rubella, measles, CMV and EBV infections. Also, because IgM as well as IgA do not cross the placental barrier, detecting antibodies of these classes in a newborn is strongly diagnostic for a congenital infection.

The development of sensitive, specific, and reproducible tests for antiviral IgM that can be used on a routine basis has taken considerable effort, mainly due to the possible presence of IgM rheumatoid factors (RF) which, by binding to the Fc portion of IgG, can generate false positives and/or abundant IgG which can compete for antigen binding and produce false negatives. Methods used in the past have relied on IgM physicochemical separation or inactivation by reducing agents and on IgG removal with certain bacterial cell wall proteins (*Staphylococcus aureus* protein A, streptococcal protein G) or other means. However, the ones presently employed are almost exclusively variations around the use of highly selective class-specific anti-IgM antibodies to detect and/or to capture the IgM. The commercial kits that utilize the latter technology are numerous, varied for the use of different solid-phase supports, have different indicator labels to signal IgM–anti-IgM complex formation, and different inbuilt systems for RF and IgG removal (not needed for capture assays), and are generally dependable.

MEASUREMENT OF ANTIBODIES AGAINST DIFFERENT VIRAL EPITOPES

The various subsets of antibodies generated in response to an infecting virus and directed to diverse epitopes of the structural and nonstructural viral proteins may present consistent and marked differences in the kinetics of appearance, decline, and disappearance that are utilizable for staging the infection. This approach has wide application in HBV and EBV serology, where measuring separately the antibodies directed to different antigens has considerable clinical utility. As an example, Table 8 provides a key to the interpretation of the serological profiles to EBV that are most frequently encountered.

DETERMINATION OF ANTIVIRAL IGA IN SERUM

Appearance, level, and duration of serum IgA are less predictable than either IgG or IgM. In general, however, IgA antibodies are made acutely, like IgM antibodies although they tend to last longer. Albeit no IgA assay is widely used in routine diagnostic testing, detection of virus-specific serum IgA has been suggested to have practical utility in several situations. These include identification of HIV-1 infections in newborns (Moodley et al. 1997), rapid diagnosis of influenza (Voeten et al.

Table 8 *Interpretation of serological test results for EBV infection*

Anti-VCA[a] IgM	Total anti-VCA	Total anti-EBNA[b]	Total anti-EA[c]	Interpretation
–	–	–	–	No infection
+	±	–	±	Acute primary infection
+	+	+	–	Recent infection
–	+	–	+	Recent infection in immunocompromised
+	+	+	+	Resolution of acute primary infection or reactivation
–	+	+	+	Past infection or reactivation
–	+	+	–	Past infection

a) VCA, viral capsid antigen.
b) EBNA, EBV nuclear antigen.
c) EA, early antigen.

1998) and dengue fever (Talarmin et al. 1998), and diagnosis of EBV-associated nasopharyngeal carcinoma (Hsu et al. 2001).

DETERMINATION OF ANTIVIRAL ANTIBODY AVIDITY

This approach exploits the fact that the strength of antibody binding to antigens increases with time after initiation of immune responses. The parameter used (avidity index) is the ratio of the antibody titers obtained in a standard serological assay (generally EIA) with and without treating the formed antigen–antibody complexes with an appropriate concentration of a protein denaturant, such as urea or guanidine, before addition of the secondary antibody. The test has been successfully used in the diagnosis of a number of viruses, including several herpesviruses, hantaviruses, encephalitis viruses, HCV, and measles virus. In pregnant women, it has been found valuable, together with other assays, for measuring the risk of transmitting CMV infection to the fetus (Lazzarotto et al. 2001).

ANTIBODY IN ALTERNATIVE SPECIMENS

Due to the blood–brain barrier, normally the CSF is devoid of IgM and has an IgG content 250–500-fold lower than serum. Thus, in the absence of concomitant signs of barrier damage, finding specific IgM or increased CSF/serum ratios of specific IgG is indicative of intrathecal antibody synthesis resulting from CNS infection. For alphaviruses, bunyaviruses, and flaviviruses, the presence of specific IgG in the CSF is highly suspicious, although only the presence of specific IgM is truly diagnostic. For more common viruses, CSF antibody analysis provides diagnostic hints only if evidence of intrathecal synthesis is obtained. Currently, it is almost always preferred to examine the CSF for viral nucleic acids.

Studies have also advocated the testing of urine and oral, ocular, or genital fluids for antiviral antibodies as easily obtainable, noninvasive alternatives to serum or plasma or as a means for obtaining additional information in selected clinical conditions. In general, these specimens have proven valuable for epidemiologic purposes but are not commonly used for diagnosis. Methods need to be developed specifically or validated for use with each type of specimen and some are commercially available. For maximum sensitivity, assays may be designed to recognize IgA as well as IgG and IgM antibodies (Zmuda et al. 2001).

CAUTIONARY NOTE

Serodiagnosis of viral infections can be complicated by a number of factors (Table 9), thus calling for considerable judgment in the interpretation of results. Whenever possible, serological diagnoses should be confirmed with virus detection methods.

QUALITY ASSURANCE/QUALITY CONTROL

Quality assurance affects all aspects of the diagnostic laboratory through a comprehensive program that strives toward constant improvement (Warford 2000). Oversight of services related to the virology laboratory includes specimen handling (collection, transport, storage, and testing), monitoring of procedures, reporting of results and their interpretation. The importance of laboratory participation in this process is well documented (Nutting et al. 1996). Laboratories in the USA are currently highly regulated under the Clinical Laboratory Improvement Act, instituted in 1992, which provides strict standards for quality improvement. These regulations address personnel qualifications, assessment of competence and defined responsibilities, written and approved procedures, quality control for test reagents and equipment (includes maintenance), test method verification and validation, proficiency testing of all analytes and staff members, analysis and improvement of all laboratory services, and a well-documented reference section for accreditation requirements, methods,

Table 9 *Considerations for interpreting serological data for diagnosis of viral infections*

Considerations
Superficial infections may elicit no or very weak systemic antibody responses
Antibody production may be delayed or absent in newborns, elderly, and immunocompromised individuals
IgM antibodies may persist for protracted periods after primary infections or may be stimulated in reactivation of latent viruses
False-positive IgM tests are a common occurrence in certain lymphoproliferative disorders
Reinfections and reactivations may not produce significant rises in total and IgG antibodies
Antibodies may cross-react within certain virus groups (e.g. alphaviruses, herpesviruses, parainfluenza viruses)
Passively acquired IgG antibodies are common finding in newborns and in individuals recently treated with blood transfusions or immunoglobulins
Antibody appearance in the CSF may be delayed by 2–4 weeks
Defects in the blood–brain barrier produced by any nonviral neurological disease can cause leakage of serum antibodies into the CSF

and quality assurance literature. Five major areas have been identified where quality assurance is mandated:

1. documentation of competency testing, staff duties and training
2. a well-maintained procedures manual that conforms to National Committee for Clinical Laboratory Standards (NCCLS) formatting
3. proficiency testing
4. quality control
5. a specimen log complete that includes test requisitions (Warford 2000).

The goal of these quality assurance efforts should be the constant improvement of laboratory services to the benefit of patient care. In other countries, regulations are more or less detailed and enforced but there is no doubt that a stringent quality control surveillance is of great help in keeping good patient care standards.

A comprehensive program for quality control that is well documented and regularly reviewed must include all procedures performed in the diagnostic virology laboratory. When appropriate, corrective actions must be taken in a timely manner and must be documented in writing. Quality control is documented by daily checking of all materials and equipment with weekly review by a supervisor. Excellent quality control practices are essential to establish the reliability of clinical laboratories and for the provision of good patient care; this is dependent on attention to all details for all aspects of the laboratory. A particularly important issue for the clinical virology laboratory is prevention of contamination, which is critical to successful performance of both molecular diagnostic techniques and cell culture. Nearly all issues related to quality control measures and scheduling are covered in documents prepared by the NCCLS and can be found at their website (www.nccls.org).

FROM LABORATORY FINDINGS TO DIAGNOSIS

Demonstration of a virus by cell cultures or EM is virtually always a definitive indication that virus is present in a disease state. Whilst this usually is suggestive of an etiologic role for the particular virus, this is not always the case. Results may be complicated by mixed infections with more than one organism or an organism might be isolated that does not have a pathogenic role. Recently, it has been discovered that many respiratory tract infections result from infection with human metapneumovirus. In several cases this virus and other human respiratory pathogens have been detected concurrently and it is not yet clear whether one or both viruses contribute to disease pathology. Alternatively, certain small round viruses can be routinely visualized in the gastrointestinal tract but association with any pathology has been far more difficult to establish. The same can presently be said of TT virus and related anelloviruses, which are found, often at high titers, in the circulation of many diseased and healthy individuals, with no apparent relation to disease.

Presence of virus as determined by detection of viral nucleic acid is indicative of current or recent viral infection but does not necessarily reflect that live virus is present nor that the virus is responsible for the ongoing clinical manifestations. There has been extensive evaluation of the detection of quantities of nucleic acid to determine viral load and its relationship to disease state, progression, and the efficacy of antiviral therapy (Johanson et al. 2001). It is clear that viral load determination in plasma is very important in infections by CMV, HCV, HBV, and HIV.

Serological tests are more complex to interpret but have the potential of demonstrating that the virus is sustaining a primary or reactivated infection at the time clinical symptoms are present (see above).

In all cases, detection of virus, viral antigens, or viral nucleic acid is preferable to antibody detection as an indicator of current or recent viral infection. In many cases, direct testing for virus rather than antiviral antibody can provide rapid diagnosis that can be vital in affecting the management of the patient or patient contacts. Improved technology, automation, and reagents have allowed rapid, cost-effective viral detection, which has contributed significantly to better patient care.

Thus, the viral diagnostic laboratory has become a most important adjunct to patient care. The physician can be provided data on rapid, sensitive, and accurate testing that can identify a virus, indicate its genotype, phenotype, and/or serotype as is appropriate. In this regard, in an increasing number of cases the physician can select an antiviral agent and can even tailor drug combinations to avoid specific patterns of antiviral resistance. It is exciting to recognize the advances we have witnessed over these past 30 years in viral diagnosis and therapy, and to project to the future when even more effective tools can be expected to impact on the ability of physicians to help their patients.

INTRODUCTION

Vaccines are among the most effective and cost-effective means for the prevention of disease. The development of viral vaccines predates the recognition of viral agents as causes of disease by over a century; their use has resulted in marked decreases in the incidence or eradication of diseases that were important causes of human mortality. Vaccines are now available to prevent 13 viral diseases, and new generations of vaccines being developed through molecular techniques hold the promise of providing protection against others.

The modern era of vaccine development began with the demonstration by Jenner that inoculation with cowpox virus provided protection against smallpox and the subsequent wide use of variolation to protect against this disease. The effective use of variola vaccine worldwide culminated, in 1980, in the certification of eradication of smallpox after a decade-long campaign coordinated by the World Health Organization (Fenner et al. 1988). By 1977, viral vaccines to prevent rabies, influenza, yellow fever, poliomyelitis, measles, rubella, and mumps had also been developed and used with striking success to reduce the disease burden due to these viruses. Following the eradication of smallpox, global immunization programs to prevent six childhood diseases, including poliomyelitis and measles, were implemented (Galazka 1994). These programs have achieved 70–75 percent global coverage with these vaccines, and are now being expanded to include hepatitis B vaccine (all countries) and yellow fever vaccine where this disease is endemic (World Health Organization and UNICEF, 2002; Vaccines and Biologicals 2002a). A goal for global eradication of poliomyelitis was established for the year 2000; to date, disease incidence has been reduced by 99 percent, with disease endemic in only six countries and eradication certified in the Americas (1994), the Western Pacific (2001), and Europe (2002) (Vaccines and Biologicals 2004). The global strategy, which includes achieving high routine infant vaccination coverage for oral polio vaccine, mass vaccination campaigns with house-to-house vaccination to interrupt remaining chains of transmission, and intensive surveillance for acute flaccid paralysis in children, is being implemented in the remaining countries where polio is endemic (Hull et al. 1994). A regional campaign to eliminate measles has interrupted disease transmission in the Americas; the key elements of this strategy are now being implemented in Africa and elsewhere through a global partnership whose goal is to reduce global measles mortality by 50 percent by 2005 (de Quadros et al. 2003; Strebel et al. 2003).

Viral vaccination has also seen new challenges, including a return to the use of smallpox vaccine in response to the threat of bioterrorism, withdrawal of the use of effective rotavirus vaccines in the USA due to rare adverse events (intussusception), and public concern over safety of viral vaccines including measles, mumps, rubella (MMR), and hepatitis B (Centers for Disease Control and Prevention 2003c; Murphy et al. 2001; Institute of Medicine 2001a, 2002a).

IMMUNOPROPHYLAXIS OF VIRAL INFECTIONS

The primary objectives of viral immunoprophylaxis are to prevent viral infection or to modify viral disease. Active immunoprophylaxis with viral vaccines stimulates the immune system to develop antibodies, cell-mediated immunity, or both, to prevent infection (e.g. measles, polio), and is usually given before exposure to disease. Vaccines (e.g. rabies, hepatitis B, and hepatitis A) may be effective in preventing disease after exposure, because the immune system is stimulated during the long incubation periods of these infections. Vaccines intended to modify the course of previously established infection (e.g. human immunodeficiency virus (HIV) infection, varicella vaccine to prevent or modify herpes zoster) are currently undergoing clinical trials.

Passive immunoprophylaxis, using pooled immunoglobulins prepared from human or animal serum or monoclonal antibodies from cell culture, can provide temporary protection against infection (pre-exposure prophylaxis for hepatitis A, respiratory syncytial virus) or can prevent or modify infection after exposure (disease-specific immunoglobulins to prevent rabies, hepatitis B, varicella).

TYPES OF VIRAL VACCINES

The two classic approaches to active viral immunization include inactivated viruses or their purified components, and live-attenuated vaccines. For some viral diseases, both approaches have been used (poliomyelitis, measles, influenza).

Inactivated viral vaccines

Inactivated vaccines may consist of whole virus particles, purified antigenic surface proteins or smaller peptide epitopes (Table 1). Inactivated whole virus vaccines are produced by the multiplication of virus in other animal species (e.g. rabies in mouse brain); in eggs, chick embryos or allantoic fluid (influenza, measles, mumps); or in cell culture (rabies in human diploid cells, polio, rubella), followed by purification and inactivation. Whole virus vaccines have the advantage of producing immune responses not only to surface proteins but also internal components, which may help eliminate viral infection. In the past, purified antigenic protein vaccines have been produced either by disruption of whole virus and purification of component proteins (split virus influenza) or by purification from the blood of virus carriers (plasma-derived hepatitis B vaccine). Newer generations of inactivated vaccines have been developed by genetic engineering, inserting DNA that encodes antigenic viral proteins into other micro-organisms (*Escherichia coli*, yeast, CHO cells, other viruses), which produce recombinant proteins that are subsequently purified (hepatitis B surface antigen, human papilloma virus (HPV) capsid polypeptides, and herpes simplex virus (HSV) glycoproteins in yeast). Most inactivated vaccines are combined with an adjuvant such as aluminum hydroxide (alum) to increase the immunogenicity of the vaccine. However, vaccines

Table 1 *Currently available inactivated viral vaccines*

Vaccine	Vaccine type	Uses
Inactivated polio	Killed whole virus	Universal childhood immunization (some developed countries); immunization of immunocompromised people
Hepatitis B	Purified HBsAg produced by recombinant yeast, mammalian cells or from plasma	Routine childhood or adolescent immunization; immunization of high risk adults; postexposure immunization with HBIG
Influenza	Killed whole virus, subvirion or purified surface antigen preparations	Vaccination of high risk individuals, elderly, children 6–23 months
Rabies	Killed whole virus	Postexposure vaccination of individuals, with HRIG; pre-exposure: veterinarians/travelers
Hepatitis A	Killed whole virus	Pre-exposure vaccination: high risk people and travelers
Japanese B encephalitis	Killed whole virus	Pre-exposure vaccination of travelers to endemic areas; routine or mass vaccination in endemic areas
Tick-borne encephalitis	Killed whole virus	Pre-exposure vaccination of travelers to endemic areas; (?) routine or mass vaccination in endemic areas
Under development (late stage)		
Human papillomavirus (prophylactic)	Virus-like particles prepared from surface capsid proteins (L1) produced in yeast	Pre-exposure vaccination of at-risk persons
Herpes simplex	Subunit glycoproteins D and B producd in yeast	Pre-exposure vaccination of at-risk persons

adjuvanted with alum lose potency when the vaccine is frozen.

New approaches to development

Other methods for producing inactivated vaccines include the use of synthetic peptides and idiotypic antibodies. Synthetic peptides, initially produced in 1963, were thought to have great promise as vaccines, especially as DNA sequencing technologies permitted identification of the precise sequences of antigenic sites of viral proteins (Brown 1988). The antigenic sites of viruses may be identified by determining the three-dimensional structure of the virus, comparing sequences of mutant and wild-type viruses or identifying hydrophilic regions of surface proteins and constructing peptides duplicating these sequences. Production of highly purified peptides is feasible, potentially inexpensive and results in a well-defined product without risk of containing adventitious agents. The feasibility of inducing protection in an immunized animal model has been demonstrated by use of an icosapeptide of the surface protein of the foot-and-mouth disease virus (Murphy and Channock 1990). However, other efforts with human disease viruses have met with less success. Peptides are often poorly immunogenic, may stimulate development of binding but not neutralizing antibodies, do not generally induce T-cell responses unless coupled to larger proteins, and cannot mimic conformational epitopes. Efforts to overcome these limitations include coupling the peptide genetically to a fusion protein (e.g. HBsAg), coupling to peptide carriers containing T-cell helper epitopes, and incorporating antigens into aggregates or self-assembling particles (Ellis 2004). Although experimental vaccines have been produced (influenza, foot-and-mouth disease) and found to be protective in animals (canine parvovirus and mink enteritis virus), at present it is uncertain whether viral vaccines for use in humans will follow (Meloen et al. 1995; Ellis 2004).

Anti-idiotype vaccines are based on the principle that neutralizing antibodies to viral antigens contain the mirror image of these epitopes, known as idiotypes. Anti-idiotype antibodies can be generated that mimic the conformation of the original viral epitope, and can then be used to induce neutralizing antibodies in the host. Immunization with anti-idiotype antibody results in the development of neutralizing antibodies to several viruses (poliovirus, hepatitis B surface antigen (HBsAg), rabies) and protection against disease in animal models (Dalgleish and Kennedy 1988). However, the levels of antibodies induced have been less than those induced by the original antigen, and the practicality of this approach for viral vaccines, for which many alternative production methods are available, remains to be demonstrated (Ellis 2004).

Transgenic plants have been engineered to produce viral antigens (e.g. HBsAg), with the potential advantages of producing low cost vaccines which can be administered orally (fed to recipients). Studies to date have demonstrated production of specific mucosal and serum antibodies against antigens in mouse models and reduction in disease in a pig gastroenteritis model, but studies in humans are still at an early stage (Kapusta et al. 2001).

Inactivation of viral vaccines

Inactivated whole virus vaccines produced in culture, animal tissues, or human serum must be subjected to steps that can inactivate the original virus as well as any adventitious agents that may be present in the initial substrate. Formalin has been most commonly used to ensure inactivation of residual viral activity in such vaccines. A balance between the concentration of formalin and the duration of treatment is needed to eliminate residual infectivity of the virus without destroying immunogenicity. Inadequate inactivation of poliovirus by formalin resulted in an outbreak of paralytic poliomyelitis due to inactivated polio vaccine soon after its introduction in the USA (Nathanson and Langmuir 1963). Review of this incident subsequently led to improvement in methods of viral purification and quality control of formalin inactivation procedures. Other inactivating agents that may be used include heat, acetylethyleneimine, and β-propiolactone. These inactivating agents may also provide protection against adventitious agents which can replicate in the cell or animal substrates used to produce vaccines. However, this protection depends on the sensitivity of the agent to the inactivation process. The failure of formalin to inactivate SV40 virus contamination in inactivated polio vaccine originating from monkey kidney cell substrate between 1955 and 1963 raised concern about the safety of this vaccine (Melnick and Stinebaugh 1962). Although some genomic studies suggest SV40 infection may be associated with rare carcinomas, such as mesothelioma and ependymoma, multiple epidemiological studies have not documented increased risk of any cancers in recipients of inactivated poliovirus vaccine (IPV) produced during this period (Institute of Medicine 2002b).

DNA vaccines (plasmid vaccines)

DNA vaccines represent a highly promising strategy for vaccine development. DNA-encoding antigenic portions of viruses – envelope, core, or nucleoprotein – are inserted into a plasmid, which can be injected directly into the host as ‘naked’ DNA, free of protein or nucleoprotein complexes. Host cells take up the DNA and may express the encoded proteins. Because the proteins are produced intracellularly, they enter the major histocompatibility complex (MHC) class I pathway and stimulate a strong cell-mediated immune (CMI) response, in contrast to inactivated vaccines, which enter

the MHC class II pathway and produce, primarily, an antibody response (Fynan et al. 1995; McDonnell and Askari 1996). This predominantly cell-mediated immune response may assist in immune control of both acute and chronic viral infections. The method of vaccine delivery may determine the nature of the T-helper response; saline injections induce primarily Th1 response (CMI), whilst delivery by microprojectiles ('gene-guns') induces Th2 response (antibody). Multivalent vaccines can be constructed that include multiple antigens from a single organism or antigens from several different organisms, or include chimeric proteins (e.g. interleukin-2 immunoglobulin) constructs that enhance immune response. Although prototype naked DNA vaccines have generally elicited weak immune response, facilitation of immune response has been accomplished by incorporation into gene-guns and by coating with cationic lipids, lipospermines, and other molecules that facilitate transfer across membranes (Ellis 2004).

A prototype naked-DNA vaccine using the core nucleoprotein of influenza virus has been developed that protects mice from lethal doses of both homologous and heterologous strains of influenza virus. This vaccine induces both humoral antibody and CMI. Although antibodies to surface glycoproteins protect against infection from the homologous strain, it is likely that CMI provides protection against heterologous strains. DNA vaccines have been demonstrated to stimulate CMI to surface and internal proteins to HIV, hepatitis B virus, influenza virus, and other viruses in animal and primate models and in human trials (Srivastava and Liu 2003). DNA vaccines have also been shown to elicit antibodies against various viral proteins, including influenza, HIV, HBV, rabies virus glycoprotein, herpes simplex glycoproteins, papillomavirus, and hepatitis C virus. Secretory antibodies can be induced through formulation with cationic lipids, encapsulation in microparticles, and other approaches. Candidate vaccines to prevent hepatitis B virus, HIV, and influenza have reached phase 1 or 2 clinical trials in humans. Candidate HIV vaccines induced weak lymphoproliferative responses and interferon chemochines in naive subjects, but these did not persist. Similar trials in HIV-infected persons increased CMI response to rev, nef, and tat, but produced no changes in lymphocyte subsets. However, an HBV DNA vaccine delivered by gene gun has induced protective levels of antibody in naive subjects. Some candidate vaccines induce strong and long-lasting responses in infant experimental animals, indicating their potential use in routine childhood immunizations (Butts et al. 1998).

A promising new approach is to use DNA vaccines in a sequential vaccination strategy, in which the first dose is a DNA vaccine followed by a dose of a live recombinant vectored vaccine (e.g. vaccinia virus, canarypox virus, or adenovirus) carrying similar genes. This strategy is being pursued most actively for HIV vaccines. The combination of DNA vaccine containing multiple proteins of simian immunodeficiency virus (SIV) and HIV, boosted with modified Ankara vaccinia strain containing similar antigens, has induced strong cellular and weak antibody immune responses and protected against virulent SIV infection (Amara et al. 2001). Key concerns about DNA vaccines include possible mutagenesis if the DNA plasmid becomes inserted into the host genome; the potential for developing tolerance to the antigen because of ongoing production in host cells; and the potential for immune attack on the cells producing the encoded antigen.

Live-attenuated viral vaccines

Currently available live-attenuated virus vaccines have been prepared by two approaches: (1) from related species of virus (Jennerian approach: vaccinia to prevent smallpox; rhesus rotavirus), and (2) by serial passage of virus through live organisms or through one or more cell culture lines (Table 2). Examples of the latter include yellow fever vaccine, developed via passage of wild virus in mice and subsequently in chick embryos; and polio (types 1 and 3) and measles vaccines, initially passaged in monkey kidney cells and chick embryo fibroblasts, respectively. Concern about the presence of adventitious viruses in animal-derived cell lines (SV40 virus in monkey kidney cell lines) has led to increased use of human diploid cell lines for producing live virus vaccines (rubella, varicella, polio). Several cell lines (WI-38 and MRC-5) are now commonly used. The World Health Organization has established guidelines for assessing the safety of vaccines produced in human cell lines (World Health Organization 1987).

Live-attenuated vaccines may also be produced via genetic reassortment. Among viruses with multiple-strand genomes, reassortants that combine the genomes encoding antigenic surface proteins from wild virus strains with genomes from attenuated or related strains of virus (cold-adapted influenza; rhesus- or bovine-based rotavirus vaccines) have been developed and shown to be effective (Murphy 1993; Kapikian 1994).

New approaches to development

Other approaches to the development of live virus vaccines include directed mutagenesis, use of strains of viruses from related species, and use of viral vectors such as vaccinia, and canarypox. Methods for direct mutagenesis include growth in low temperatures (25 or 32–34°C) to select temperature-sensitive or cold-adapted strains which do not grow well at human body temperature (Murphy and Channock 1990). Molecular biological techniques, combined with better understanding of molecular aspects of viral replication, can be used to develop specific mutations, such as deletion mutants,

Table 2 *Currently available live-attenuated viral vaccines*

Vaccine	Vaccine type	Uses
Oral polio	Attenuated trivalent	Routine childhood immunization; mass campaigns
Measles	Attenuated (Schwarz, Moraten, others)	Routine childhood immunization; mass campaigns
Rubella	Attenuated (RA 27/3)	Routine childhood immunization; adolescent girls; susceptible women of childbearing age
Mumps	Attenuated (Urabe or Jeryl Lynn)	Routine childhood immunization
Measles, mumps, rubella (MMR)	Attenuated	Routine childhood immunization (one or two doses)
Varicella	Attenuated (Oka strain)	Routine childhood immunization; susceptible adolescents and adults
Influenza	Cold adapted/reassortants	Immunization of high risk children/adolescents/adults
Yellow fever	Attenuated (17D)	Routine immunization or mass vaccination in endemic areas; vaccination of travelers to endemic areas
Smallpox (limited availability)	Vaccinia virus	Vaccination of research workers, military, BT response teams
Under development		
Rotavirus	Rhesus reassortants (four serotypes). Bovine reassortants, human neonatal rotavirus strain	Routine childhood immunization
Herpes zoster	Attenuated (Oka strain)	Adults

which are unlikely to revert to wild strains. Vaccines developed from related animal viruses include rhesus and bovine rotavirus as candidate strains to prevent human rotavirus infection, including reassortants that incorporate the surface protein genes for human rotavirus types 1, 2, 3, and 4 (Kapikian 1994; World Health Organization 2003b). Bovine parainfluenza virus 3 induces neutralizing antibodies to human parainfluenza virus type 3, and is a candidate vaccine to prevent this disease.

Large viruses such as vaccinia, other orthopoxviruses, and adenovirus can incorporate DNA that encodes essential proteins from other viruses (e.g. hepatitis B, rabies, measles hemagglutinin, or fusion proteins), attached to viral promoters that ensure adequate production of these antigens (Perkus et al. 1985; Moss et al. 1988). Vaccination results in replication of the parent virus, production of the encoded viral proteins and stimulation of both humoral and cell-mediated immunity. Although there has been some success in inducing immune response to the encoded proteins (HBsAg, influenza A, herpes simplex glycoprotein, rabies) and protection has been induced in experimental animals, concern about the potential for serious adverse events following vaccinia vaccination and limited success in inducing a strong antibody response have hampered development of vaccinia recombinants for humans. The use of canarypox virus, which undergoes only abortive infection in humans, may overcome concerns about the safety of such vaccines, and candidate vaccines have induced high levels of antibody against rabies glycoprotein and the measles hemagglutinin gene in humans. Yellow fever vaccine virus is being used as a foundation for development of Japanese encephalitis virus (JEV) and West Nile virus vaccines, through substituting JEV and West Nile surface antigens for those of yellow fever virus (Langevin et al. 2003; Monath et al. 2003).

Sequential vaccination, either live vectored vaccines followed by protein or glycoprotein antigens, or with DNA vaccines followed by genetically engineered live vaccines, has produced stronger antibody and cell-mediated immunity than either antigen alone (Ellis 2004). Vaccination with a DNA-based HIV vaccine followed by canarypox HIV vaccine has produced promising results for preventing HIV infection (Amara et al. 2001), while vaccination with a DNA-based vaccine followed by adenovirus vaccine has provided protection against Ebola virus infection in animals (Sullivan et al. 2003).

RISK OF ADVENTITIOUS AGENTS

Possible contamination with adventitious agents is also a concern with live virus vaccines (Waters et al. 1972). A series of tests for potential contaminating agents is undertaken during vaccine development, safety testing, and postlicensing monitoring of vaccines (World Health Organization 1987). However, concerns regarding agents not detectable by current methods continue to arise despite the apparent safety of these vaccines.

Immunological basis of response to active immunization

Development of an immune response generally requires the interaction of T lymphocytes with antigen processing and presenting cells (dendritic or macrophages) (McDevitt 1980; Lanzavecchia 1985; Claman 1992). T-cell response is induced following the uptake of antigen by mononuclear phagocytes or dendritic cells, and can be enhanced by use of an adjuvant; the antigen is processed

and presented, in association with MHC antigens, to T-helper cells. T cells recognize polypeptide antigens of 8–20 amino acids in size, presented in association with specific MHC molecules; the type of MHC molecule with which the antigen is presented by antigen-processing cells depends on the source and processing of the polypeptide. These in turn determine the primary type of T-cell response, either cytotoxic or helper. Presentation to T-helper cells results in secretion of immune mediators (cytokines) that can stimulate the maturation of naive T cells and communicate between leukocytes (via interleukins) to regulate the immune response (Baker 1975; Reinherz and Schlossman 1980; Arai et al. 1990).

Antigens from inactivated vaccines are absorbed into vacuoles, and processed and presented with MHC class II antigens; antigens from live-attenuated vaccines or vectored vaccines, produced within the cell, are processed in microtubules and presented with MHC class I antigens. Depending on the antigen and its MHC presentation, T lymphocytes differentiate into either T-helper type 1 cells (Th1, stimulated by MHC I-associated antigen), which mediate CMI, or T-helper 2 (Th2, with MHC II), which assist B cells in developing antibody production. Each of these subsets produces different interleukins and other immune mediators responsible for modulating the immune response.

An antibody response to an initial dose develops 2–6 weeks after immunization with inactivated antigens but may be incomplete even after two doses; after effective priming, booster responses occur within 4–14 days. The initial response is usually IgM antibodies, followed within weeks by IgG antibodies. Response to live vaccines follows a cycle of replication of the vaccine virus, and a period of several weeks or months for full development of the immune response. Response to measles vaccination is usually maximal by 6 weeks, but in younger children antibody titers may continue to rise for several months after vaccination.

Immune response to inactivated and live-attenuated vaccines

INACTIVATED VACCINES

Inactivated or purified viral vaccines induce responses only to the components present in the vaccine. Multiple doses, usually three or more, are necessary to induce a satisfactory response that will persist for long periods; booster doses may be necessary to ensure lasting protection. Most inactivated vaccines are given parenterally, and induce either no mucosal antibody or lower levels than live-attenuated vaccines administered by the oral or nasal routes. Inactivated vaccines may have limited ability to induce T-cell-mediated immunity, which is induced more strongly by antigens produced intracellularly as occurs with replication of live viral vaccines. Microencapsulation of inactivated viral vaccine antigens in microparticles prepared from polylactide-coglycocide and polylactide polymers can allow delayed release of these antigens over many months, and shows promise for reducing the number of injections required to successfully immunize with inactivated antigens (e.g. hepatitis B) (Singh et al. 1997).

The advantages of inactivated vaccines are the absence of risk of disease due to the vaccine virus, given adequate inactivation; greater thermal stability and ease of handling in routine vaccination programs; and a lower risk of contamination with active adventitious agents than in live-attenuated vaccines. Nevertheless, examples of both inadequate inactivation and presence of active adventitious agents were documented in the past in inactivated polio vaccine (Nathanson and Langmuir 1963; Mortimer et al. 1982), although these problems have not been observed with hepatitis B, hepatitis A, or any other recently developed inactivated vaccines. Inactivated vaccines can be given safely to people with immunosuppressive conditions.

A disadvantage of inactivated vaccines is the possible potentiation of the disease that the vaccine is intended to prevent. The original killed measles vaccines induced a detectable immune response, but recipients exposed to wild measles virus developed atypical measles with systemic symptoms and giant cell pneumonia (Annunziato et al. 1982). Subsequent analyses indicated that the formalin treatment destroyed the antigenicity of the measles fusion protein, resulting in an unbalanced response (to hemagglutinin only). Similar accentuation of respiratory syncytial virus disease in recipients of a formalin-inactivated vaccine was observed in early trials, and later shown in experimental animals to result from stimulation of formation of binding, but not neutralizing, antibodies to the surface F and G glycoproteins (Murphy and Channock 1990).

LIVE-ATTENUATED VACCINES

Live-attenuated vaccines have the advantage of inducing a complex immunological response simulating natural infection. Replication of the vaccine organism and processing of antigens mimic those of the natural organism, and both humoral and cell-mediated responses are generated to a variety of antigens. Because these antigens are similar or identical to those of the wild organism, responses are usually more effective and cross-reactive than those induced by inactivated vaccines. In addition, mucosal antibody may be stimulated directly by such vaccines when administered through oral or nasal routes (McGhee et al. 1992). Administration of oral or nasal live vaccines is more convenient than injection of inactivated vaccines. Immunity induced by one dose of a live-attenuated vaccine is long lasting, possibly life-long. However, the strength of humoral response is usually less than that

of natural infection, and detectable antibodies may wane with time and result in some loss of protection. Induction of immunity by live vaccines can be inhibited by passively acquired antibody, whether from transplacental acquisition from the mother or from receipt of immunoglobulin-containing blood products; thus, achieving optimal response relies on ensuring that passive antibody (e.g. of maternal origin or acquired through administration of blood products) has declined to noninterfering levels. In addition, because the response may be incomplete (90–95 percent) after a single dose, two or more doses may be necessary to induce sufficient immunity to protect both the individual and the community.

The potential disadvantages of live vaccines include residual virulence of the vaccine in both healthy and immunocompromised hosts; possible contamination with adventitious agents; possible interference of response by other viral infections; and greater lability of the vaccine. Potential reversion to virulence has been well demonstrated with oral polio vaccine, paralytic poliomyelitis occurring in either vaccinees or their contacts at a rate of approximately 1 per 2.5 million vaccine doses distributed, with greatest risk after the first vaccine dose (Strebel et al. 1992). Persistent viral infection may occur in immunocompromised people after inadvertent use of measles and oral polio vaccines, and may rarely occur in healthy adults given rubella vaccine (Institute of Medicine 1991, 1993). However, measles vaccine has not been linked to the development of subacute sclerosing panencephalitis. Early lots of oral polio vaccine and yellow fever vaccine were contaminated with SV40 virus and avian leucosis virus, respectively. Although these were not linked with any long-term consequences (Waters et al. 1972), cell substrates used for vaccine production are now tested to ensure that these and other known pathogenic viruses are not present. Nevertheless, it may not be possible to ensure the absence of any adventitious agents in live virus vaccines. The stability of live virus vaccines depends on appropriate handling. Such vaccines require a sound cold chain, with storage at either 0–4°C (measles; measles, mumps, rubella (MMR)) or −15°C (polio, varicella), which can increase the cost of vaccination and impede their use in developing countries.

Determinants of response to viral vaccines

Vaccine and host characteristics are the primary determinants of vaccine response. Response may be affected by vaccine dosage, adjuvant, route and site of administration, number and timing of doses, and vaccine handling. Vaccine doses are determined before licensing to ensure a high level of response; adjuvants such as aluminum salts (hydroxide or phosphate), used only with inactivated antigens, stimulate a better response with a lower dose of antigen. New adjuvants based on improved understanding of immunology of vaccine response are now in clinical trials, and promise further to enhance the immune response in future inactivated viral vaccines (Jennings et al. 1998). An oil–water emulsion MF59 is now used in a split virion influenza vaccine that increases immunogenicity compared with that achieved with alum adjuvant (Ellis 2004). The route of administration – intradermal, subcutaneous, intramuscular, or mucosal – can determine both the strength and the nature of the immune response. Mucosal administration (intranasal or oral) stimulates higher levels of mucosal immunity (IgA antibodies), which may inhibit disease transmission with greater effectiveness than parenteral administration, which induces limited or no mucosal response (McGhee et al. 1992). Intradermal vaccination with low doses may induce antibody responses similar to those induced by intramuscular or subcutaneous administration of recommended doses, but is more difficult to deliver precisely and achieves less predictable responses. Intramuscular injections should be given in the anterior thigh (infants) or deltoid (older children and adults); injection into the buttocks produces a lower response in adults, probably owing to delivery of the vaccine into adipose tissue (Centers for Disease Control and Prevention 1991). The timing of vaccine doses is important: a minimum interval of 1 month between primary doses is usual for inactivated vaccines; delay of a third or reinforcing dose for 6 or more months after the first enhances the response and duration of antibody persistence, and is preferred unless high risk of disease necessitates shorter intervals. Intervals of 4–6 weeks are considered necessary to ensure optimal response to successive doses of live virus vaccines. The recommended routes and sites of administration and the timing of doses are devised to ensure optimal effectiveness in disease prevention and should therefore be used.

Host factors

Host factors that affect immune response include genetic factors (MHC polymorphism), age, nutritional and immune status, gender, pregnancy, and smoking. Although genetic factors, such as MHC polymorphism, are known to affect response at a molecular level, they have a limited effect on population response to available vaccines. Age is an important factor in response to immunization. Newborn infants generally do not develop as strong a response to inactivated vaccines as older infants or children (hepatitis B), and with certain vaccines maternal antibody may inhibit response (IPV, hepatitis A). For live vaccines such as measles, inhibition of the response by maternal antibodies determines the optimal timing for vaccination in early childhood.

The response to vaccines is excellent in young and adolescent children and in young adults, but decreases with increasing age. Male gender in adults and pregnancy have minor negative effects on antibody response of limited clinical significance; smoking decreases response to many antigens, and may increase the risk of nonresponse when other negative factors are present (Hadler and Margolis 1992). Extreme debilitation, acquired or congenital immunodeficiency disorders, diseases or treatments that cause immunosuppression, and some chronic diseases (renal disease, diabetes) can decrease immune response. For people with such conditions, inactivated vaccines are recommended despite lower effectiveness but may require higher or more frequent doses to achieve optimal response; live vaccines are often contraindicated owing to the risk of disseminated disease and possible death due to the vaccine organism (Centers for Disease Control and Prevention 2002a).

Measurement of response

Ideally, reliable laboratory tests should be available to measure the presence and strength of each of the major effectors of protection against the disease. In practice, tests for the presence of antibody are usually available (e.g. radioimmunoassay (RIA), enzyme immunoassay (EIA), complement fixation, immunofluorescent techniques), but these often do not measure the presence of functional (neutralizing or opsonizing) antibody. Tests for CMI are generally available only in research facilities. For some diseases, such as hepatitis B, polio, and measles, there are reliable tests for neutralizing antibodies and the levels needed to confer protection are known; however, only for hepatitis B are inexpensive tests widely available. For other diseases such as rubella and measles, commercial tests are available, often using EIA methods, but specificity is often less well defined, and sensitivity may be lower than that of neutralization assays. Development of better laboratory methods to measure protection and to permit rapid diagnosis of acute disease will remain a priority of disease control programs.

PRELICENSURE VACCINE EVALUATION

Licenses are granted only after extensive review of safety and efficacy data. Before licensing, vaccines are studied first in animals and then in small numbers of humans to determine safety, immunogenicity, and optimal dosages and schedules (phase I and II trials). Phase III trials examine safety and efficacy in larger numbers (1 000–10 000) of subjects. Nevertheless, prelicensing trials are limited in their ability to detect rare adverse reactions (frequency less than one per 1 000–10 000 doses) to vaccination, or adverse events in specific risk groups. Phase IV trials postlicensing may include larger numbers of vaccinees and can better define the frequency of uncommon adverse events. Linking the records of vaccination and of medical outcome in large numbers of children in health maintenance organizations (HMO) or other providers of comprehensive medical care can provide a way to assess causality of temporally related adverse events. In addition, postmarketing surveillance permits detection of new or unanticipated adverse events; reporting of such events observed after vaccination is required in many countries.

PRINCIPLES OF IMMUNIZATION PROGRAMS

The development of successful disease control programs requires safe and effective vaccines and effective public health strategies to prevent disease. Strategies for vaccine use are based on knowledge of epidemiology, consideration of whether eradication or reduction of disease is the primary goal, and the potential for implementing effective programs to deliver vaccines either to the entire population or to target groups (Table 3).
Among the critical aspects of disease epidemiology are: (1) whether the disease causes infection universally in humans (e.g. poliomyelitis, measles, rubella, varicella, and hepatitis B in some populations) or only in certain geographic areas or in specific groups (hepatitis B in developed countries, rabies, yellow fever); (2) the primary age groups affected; (3) the primary reservoir for infection, including whether an animal reservoir exists (rabies, yellow fever) or infection occurs naturally only in humans (hepatitis B, hepatitis A, measles, mumps, rubella, varicella, poliomyelitis); and (4) whether the virus causes only acute infection or results in chronic or latent infection. Strategies targeted at eradication may be considered for diseases without substantial animal reservoirs or chronic or latent infection in humans, whereas reduction must be the initial goal when animal (rabies) or human reservoirs (hepatitis B, varicella) exist (Centers for Disease Control and Prevention 1993c). Mathematical modeling of the possible impact of vaccines on disease incidence may be helpful for selecting immunization strategies (Fox et al. 1972; Anderson and May 1990; Halloran et al. 1994).

Considerations of cost-effectiveness of vaccination programs have also become increasingly important when developing vaccination strategies. Universal use of vaccines to prevent polio, measles, mumps, and rubella saves money when direct costs of health care are considered (Hatziandreu et al. 1994). Studies showing that universal use of varicella and hepatitis B vaccines resulted in savings in combined direct (health care) and indirect costs influenced the development of policy for universal use of these vaccines in the USA (Lieu et al.

Table 3 *Approaches to the control of viral diseases with vaccines*

Disease	Proportion of population infected	Primary age of infection[a]	Chronic carrier	Animal reservoir	Eradicable with vaccine	Type of vaccination program
Polio	High	Child	No[b]	No	Yes	Child; mass campaigns
Smallpox[c]	High	Child	No	No	Yes	Child; containment
Measles	Universal	Child	No	No	Yes	Child; mass campaigns
Rubella	Universal	Child/adult	No	No	Yes	Child; adolescent girls/women
Varicella	Universal	Child	Yes[d]	No	Possible[e]	Child; adolescent; adult (susceptible)
Hepatitis B	Variable	Child/adult	Yes	No	Possible[e]	Infant; adolescent; high risk adult
Influenza	High	All	No	H + A[f]	No	High risk persons (e.g. elderly, chronic medical conditions, infants 6–23 months)
Yellow fever	None to high	All	No	Yes	No	High risk; universal
Rabies	Very low	All	No	Yes	No	High risk; post-exposure

a) Prior to wide use of vaccine.
b) On rare occasions immunodefficient individuals have excreted poliovirus for several years (Kew et al. 1998).
c) Smallpox was certified as eradicated in 1980.
d) Latent infection.
e) Potentially eradicable after several generations of vaccination or if human carriage of virus can be eliminated, or latency-defective vaccine can be developed.
f) Human and animal.

1994; Margolis et al. 1995). More recently, cost-effectiveness studies of varicella vaccine considering both the effect of a vaccination program on varicella and estimated effects on herpes zoster morbidity from modeled data have suggested that a childhood vaccination program may not be cost saving if varicella vaccination leads to an increase in herpes zoster (Brisson and Edmunds 2002).

Programs based on universal vaccination of infants or young children have been implemented successfully (poliomyelitis, measles) in both developed and developing countries (Hinman et al. 1999). Alternative approaches include universal vaccination of adolescents (rubella, hepatitis B), universal vaccination of all or some adults (influenza), and vaccination only of certain target groups or exposed people (rabies, hepatitis B, influenza). Mass immunization campaigns targeted at specific age groups are important in efforts to reduce the incidence of disease rapidly and in eradication and elimination programs for poliomyelitis and measles (Hull et al. 1994; de Quadros et al., 2003).

Vaccine schedules

Childhood immunization programs are now recommended in all countries and have resulted in substantial declines in the occurrence of vaccine-preventable diseases in both developed and developing countries (Galazka 1994; Centers for Disease Control and Prevention 1999b,c; Vaccines and Biologicals 2002a). Childhood immunization schedules are usually established by national governments or advisory bodies. In the USA, policy is established by the Advisory Committee on Immunization Practices (ACIP) of the US Public Health Service and the Committee on Infectious Diseases of the American Academy of Pediatrics (AAP), in consultation with the American Academy of Family Physicians (Centers for Disease Control and Prevention 2002a; Committee on Infectious Diseases 2003; Zimmerman et al 2003; Centers for Disease Control and Prevention 2005a). With effect from July 2004, the unified childhood and adolescent immunization schedule recommends use of vaccines to prevent six viral diseases in all children and adolescents: measles, mumps, rubella, polio, hepatitis B, and varicella (Figure 1). In addition, influenza vaccine is recommended for all children 6–23 months of age and their contacts, as well as contacts of infants <6 months of age, because children in this age group are at substantially increased risk for influenza-related hospitalization. Two viral vaccines are also recommended for select groups: hepatitis A vaccine for children and adolescents in areas of the country with high disease incidence and influenza vaccine for children $\geqslant$6 months with certain risk factors (including asthma, cardiac disease, sickle-cell disease, diabetes). With recommended universal hepatitis B vaccination of children, immunization can start at birth or any time up to 2 months of age, although the schedule indicates a preference for administering the first HepB dose to all newborns soon after birth and before hospital discharge. Routine doses are scheduled at 2, 4, and 6 months of age (diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP); *Haemophilus influenzae* type b (Hib); polio vaccine (IPV only); and hepatitis B). MMR is recommended at 12–15 months of age and varicella vaccine at 12 to

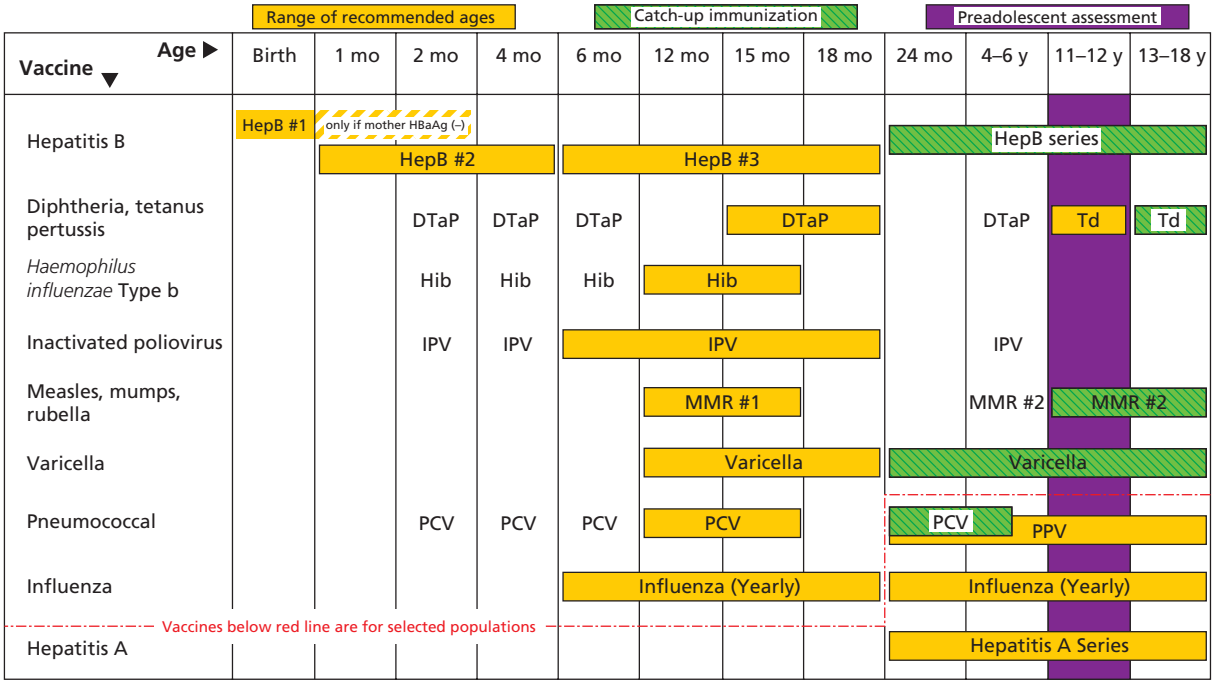

Figure 1 *Recommended immunization schedule, USA, 2005 (approved by the Advisory Committee on Immunization Practices, the American Academy of Pediatrics, and the American Academy of Family Physicians). This schedule indicates the recommended ages for routine administration of currently licensed childhood vaccines for children through age 18 years. Any dose not administered at the recommended age should be administered at any subsequent visit when indicated and feasible. Green bar with diagonal lines indicates age groups that warrant special effort to administer those vaccines not previously administered. Licensed combination vaccines may be used whenever any components of the combination are indicated and other components of the vaccine are not contraindicated. Providers should consult the manufacturers' package inserts for detailed recommendations. Readers should consult www.cdc.gov/nip/acip/recs/child-schedule.htm for footnotes and additional information.*

18 months. Booster doses of DTaP and polio vaccine are recommended at school entry, with the second MMR dose given at primary school entry (Centers for Disease Control and Prevention 1998).

During the early adolescent years (age 11–16 years), immunization status should be assessed to provide a Td booster to ensure that the second dose of MMR has been given, to provide the primary series of hepatitis B vaccine to children who have not already received it and to ensure immunity to varicella. More detail is provided in footnotes to the schedule available at: www.cdc.gov/nip/recs/child-schedule.htm#julydec. Another version of the schedule is provided for children and adolescents who start immunization late or who are at least 1 month behind.

In the UK, recommendations for immunization are issued and periodically updated by the Departments of Health (Joint Committee on Vaccination and Immunization 1996, update available at www.immunisation.nhs.uk. Differences between the USA and UK schedules include, in the USA, a Hib booster between 12–18 months, a dose of DTaP at 15–18 months, and routine use of hepatitis B, varicella, pneumococcal conjugate, and influenza (for children 6–23 months) vaccines, use of hepatitis A vaccine in high incidence areas and use of influenza vaccine in children >6 months with high risk conditions, and in the UK use of meningococcal C conjugate vaccine for all children, and bacillus Calmette–Guerin (BCG) vaccine, and an IPV booster dose at age 13–18 years (as Td/IPV).

Routine childhood vaccinations and schedules vary in other countries (Hinman et al. 1999; Salisbury and Olive 2004). Polio and measles vaccination are universal, and rubella, mumps, and hepatitis B vaccination are offered by most developed and some developing countries. The World Health Organization recommends that all countries provide immunization to prevent seven diseases, including polio and measles, vaccinations being given at birth, at 6, 10, and 14 weeks of age, and at 9 months of age, respectively (Table 4) (Vaccines and Biologicals 2003). Hepatitis B vaccination, beginning at birth or 6 weeks of age, is now recommended in all countries, with primary goal to prevent perinatal and infant HBV transmission in countries with high or intermediate HBV endemicity. Yellow fever vaccination is recommended at 9 months of age in areas where this disease occurs. The World Health Organization (WHO) recommends that a second opportunity for measles vaccination should be offered either through routine immunization or in a vaccination campaign. The Global Alliance for Vaccines and Immunization (GAVI) provides support for the poorest countries to introduce previously under-utilized

Table 4 *Vaccine schedule for Expanded Program on Immunization, World Health Organization*

Age	Vaccine(s)
Birth	TOPV, BCG, Hep B
6 weeks	TOPV, DTP, Hep B, Hib
10 weeks	TOPV, DTP, Hep B, Hib
14 weeks	TOPV, DTP, Hep B, Hib
9 months	Measles, yellow fever (in endemic areas)
After 9 months	Measles second opportunity

BCG, bacillus Calmette–Guérin; DTP, diphtheria and tetanus toxoids and pertussis vaccine; Hep B, hepatitis B; three-dose series beginning at birth; Hib, *Haemophilus influenzae* type b, recommended in high incidence countries; TOPV, trivalent oral polio vaccine dose at birth (optional). Measles second opportunity may be done either as part of the routine schedule or in a campaign.

hepatitis B, yellow fever, and *H. influenzae* type b vaccines.

Vaccination of adults is also recommended in many countries. In the USA, although the childhood immunization program has greatly reduced the burden of vaccine-preventable disease among children, substantial vaccine-preventable morbidity and mortality from diseases such as hepatitis A, hepatitis B, influenza, and pneumococcal infections continue to occur among adults. Each year the ACIP approves the schedule for the routine vaccination of persons aged >19 years (Figure 2). The Adult Immunization Schedule is a harmonized schedule accepted by the American Academy of Family Physicians (AAFP) and the American College of Obstetricians and Gynecologists (ACOG) (Centers for Disease Control and Prevention 2003a).

Influenza vaccination is recommended for high-risk groups and in some countries for all older people (>50 years in the USA) (Figure 2) (Centers for Disease Control and Prevention 2004; Hinman et al. 1999), and >65 years in many developed countries including UK, France, Canada (National Advisory Committee on Immunization, Canada (NACI) 2002 www.hc-sc.gc/pphb-dgspsp/naci-ccni) and Australia (www1.health.gov.au/immhandbook). In addition, vaccination of adults at risk for hepatitis B, hepatitis A, pneumococcal disease, meningococcal disease, measles, mumps, rubella, and varicella may be recommended on the basis of licensing of vaccines and the burden of disease in a risk group, as well as a lack of history of previous disease or immunization. A Td booster is recommended every 10 years.

Simultaneous administration of vaccines

All childhood vaccines may be given simultaneously if necessary, on the basis of data from many studies showing that most vaccines can be given at the same time without compromising safety or immunogenicity. Simultaneous administration of all vaccines for which a person is eligible increases the probability that a child will be fully immunized at the appropriate age. Use of combination vaccines can reduce the number of injections required at a single visit and is preferred over separate injection of their equivalent components (Centers for Disease Control and Prevention 1999d, 2002a). Thus, DTP, Hib, IPV, hepatitis B, MMR, and varicella vaccines may be given simultaneously (King and Hadler 1994). Interference between live virus vaccines other than OPV (e.g. MMR, varicella) can, theoretically, occur if they are given not simultaneously but within close intervals; therefore, live virus vaccines should either be given simultaneously or at least 28 days apart (Centers for Disease Control and Prevention 2002a). Data are limited concerning interference between live vaccines. Interference has been found between certain vaccines for travelers (cholera and yellow fever) (Centers for Disease Control and Prevention 2002a) and in a study conducted in two US health maintenance organizations, children who received varicella vaccine <28 days after MMR vaccination had a greater risk (2.5-fold higher) of varicella vaccine failure compared with those who received varicella and MMR vaccines simultaneously or ⩾28 days apart (Verstraeten et al. 2003). In contrast, one study did not show interference with seroresponse to yellow fever vaccine among persons who received monovalent measles vaccine 1–27 days earlier (Stefano et al. 1999). Immunoglobulins or blood products containing immunoglobulins inhibit the response to certain live virus vaccines (MMR, varicella). The duration of inhibition of response is related to the dose of immunoglobulins, and algorithms have been devised for calculating appropriate delays of MMR, measles, or varicella vaccination after administration of such products (Centers for Disease Control and Prevention 2002a; Siber et al. 1993). In general, MMR and varicella vaccines should be delayed at least 3 months after giving the usual doses of immunoglobulin (to prevent hepatitis A) or blood products, for 5 months after administration of measles immune globulin (IG) or varicella-zoster immune globulin (VZIG) and for longer after higher doses (e.g. ⩾11 months after 2 g/kg IGIV for treatment of Kawasaki disease) (Centers for Disease Control and Prevention 2002a).

Vaccination in specific situations

VACCINATION OF PREMATURE INFANTS

Infants born prematurely, regardless of birth weight, should be vaccinated at the same chronological age and with the same schedule as full-term infants. Some studies suggest that response to hepatitis B vaccine may be diminished in infants with birth weights below

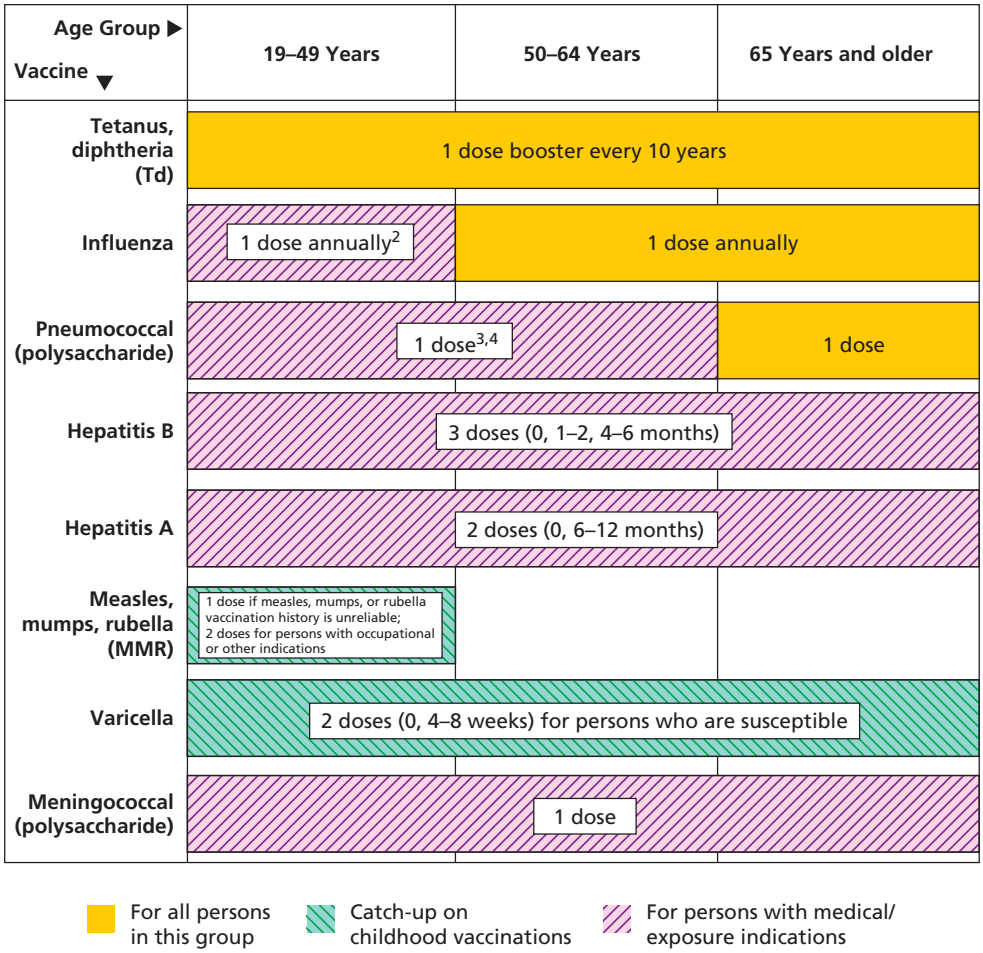

Figure 2 *Recommended Adult Immunization Schedule, 2003–2004 (approved by the Advisory Committee on Immunization Practices, and accepted by the American College of Obstetricians and Gynecologists, and the American Academy of Family Physicians) (Centers for Disease Control and Prevention, 2003a). Readers should consult www.cdc.gov/nip/acip/recs/child-schedule.htm for footnotes and additional information.*

2 000 g; in an infant born to a HBsAg-positive mother and mothers with unknown serostatus, the premature infant should receive hepatitis B vaccine and hepatitis B immune globulin (HBIG) $\leqslant$12 h after birth. If these infants weigh <2 000 g at birth, the initial vaccine dose should not count towards the completion of the hepatitis B vaccine series and three additional doses should be administered, beginning at 1 month of age. In an infant born to an HBsAg-negative mother, vaccination can be initiated either when the infant reaches 2 000 g or at 2 months of age with administration of other childhood vaccines (Centers for Disease Control and Prevention 2002a; Committee on Infectious Diseases 2003).

VACCINATION OF PREGNANT WOMEN

The risk from vaccination during pregnancy is largely theoretical and no evidence exists of risk from vaccinating pregnant women with inactivated virus or bacterial vaccines or toxoids. Hepatitis B and influenza vaccines may be given to those at high risk of these diseases. Because women in the second and third trimester of pregnancy have an increased risk for hospitalization due to influenza (Neuzil et al. 1998), influenza vaccine is recommended for all women who will be pregnant during the influenza season (Centers for Disease Control and Prevention 2004). Live viral vaccines, in general, should not be administered during pregnancy or to women who may become pregnant in the next 4 weeks. However in some circumstances, the benefit of vaccinating a pregnant woman with a live viral vaccine may outweigh the risk when the probability of exposure is high and when infection might cause harm to the mother or the infant, but the vaccine is unlikely to do so (Centers for Disease Control and Prevention 2002a). Live virus vaccines, such as MMR and varicella, are contraindicated in pregnant women on theoretical grounds; however, as no cases of congenital rubella syndrome or congenital varicella syndrome have been reported after MMR or varicella vaccination among over 200 susceptible women exposed during the first

trimester of pregnancy (for rubella vaccine) and >100 susceptible women (for varicella vaccine), inadvertent vaccination is not a reason to interrupt pregnancy (Centers for Disease Control 1989; Shields et al. 2001). Pregnant women may receive OPV (or IPV) and yellow fever vaccines if there is a risk of exposure. Vaccination of family members with MMR live virus vaccine does not pose a risk to pregnant women and because the risk of transmission of varicella vaccine virus is very low, MMR and varicella vaccine should be administered, as indicated, to the children and other household contacts of pregnant women (Centers for Disease Control and Prevention 1996, 1998). Breast-feeding does not adversely affect the responses to live or killed vaccines.

VACCINATION OF PEOPLE WITH ALTERED IMMUNOCOMPETENCE

People with altered immunocompetence require special consideration for vaccination (Centers for Disease Control and Prevention 1993b). Such individuals are often at increased risk of serious adverse consequences of disease; they may also be at increased risk of serious consequences of vaccination or of a poor response. Important groups of immunocompromised people include those with congenital immunodeficiency diseases; acquired immune deficiency syndrome (AIDS); hematopoietic or disseminated malignancy; immunosuppression because of administration of chemotherapy, systemic corticosteroids, radiation or other toxic drugs; and other chronic conditions, including splenectomy and diabetes. All such people can be vaccinated safely with killed, recombinant, subunit, and conjugate vaccines, which are usually recommended in the same doses and schedules as for immunocompetent individuals. Certain vaccines (e.g. influenza) may be specifically indicated for such people. The response to both killed and live vaccines, however, may be suboptimal, and higher doses or an increased number of doses may be needed to ensure protection. Live viral vaccines are generally not recommended for any of these groups, except for people with chronic medical conditions (e.g. diabetes), because of a known or theoretical risk of disseminated infection due to the vaccine. An exception is the recommendation of MMR vaccine for persons with HIV infection without severe immunocompromise, because of the high risk of serious consequences of wild measles infection (Onorato et al. 1988; Centers for Disease Control and Prevention 1998). Similarly, because of the high risk of serious consequences of wild varicella disease, varicella vaccine is licensed for use in immunocompromised people in Europe and in the USA is available under a research protocol for children with acute lymphoblastic leukemia in remission, can be used in persons with impaired humoral immunity, and should be considered for asymptomatic or mildly symptomatic HIV-infected children who should receive two doses of varicella vaccine, 3 months apart (Centers for Disease Control and Prevention, 1999e).

INTERNATIONAL TRAVELERS

International travelers may be at increased risk of exposure to vaccine-preventable diseases, even in developed countries. All children, adolescents, and adults planning international travel should be up to date for all routine childhood immunizations. For certain vaccines, children who travel overseas or live abroad should be vaccinated at an earlier age than recommended for children remaining in the USA. Before their departure, children aged $\geqslant$12 months should have received two doses of MMR vaccine separated by at least 28 days. Children aged 6–11 months should receive a dose of monovalent measles vaccine before departure or MMR if monovalent vaccine is not available (Centers for Disease Control and Prevention 1998). Other viral vaccines that should be considered before travel include hepatitis A and B vaccines, yellow fever, Japanese encephalitis, and rabies (if exposure to rabid animals is anticipated). The need for these vaccines should be determined by consulting specific guidelines for travelers (Centers for Disease Control and Prevention 2003b).

Vaccine safety and vaccine injury compensation

Viral vaccines, like other vaccines, usually cause only minor local and systemic adverse reactions, such as induration and pain at the injection site, fever, and malaise. Serious or life-threatening reactions can occur after some viral vaccines, such as paralytic poliomyelitis following oral polio vaccine, disseminated measles vaccine virus infection in immunocompromised children, or encephalitis or viscerotropic disease following yellow fever vaccine. The Institute of Medicine (IOM) in the USA has reviewed available information regarding the possible causality of serious adverse events following each of the licensed childhood vaccines (Institute of Medicine 1991, 1993, 2001a, 2002a), and continues to regularly review evidence regarding potential adverse events caused by vaccination. For many events, information is considered insufficient to determine causality. However, the panels have been able to classify some events definitively, as summarized in Table 5. These comprise the most comprehensive compilation of data on vaccine safety, although controversy still persists about some events. The panel has also examined broader issues of vaccine safety, concluding that evidence favors rejection of the hypothesis that multiple immunizations cause immune dysfunction or type 1 diabetes. Most recently, the panel rejected the hypothesis of a causal relationship between MMR vaccine or thimerosal-containing vaccines and autism (Institute of Medicine 2004). Based on a previous IOM report that

Table 5 *Summary of Institute of Medicine findings on the relationship of adverse events to individual vaccines*

Vaccine	Establishes causation	Favoring causation	Favoring rejection of causation
Measles (see also MMR)	Death from measles vaccine strain in immunocompromised people	Anaphylaxis	None
MMR (see also measles, mumps, and rubella)	Anaphylaxis/thrombocytopenia	None	Autism spectrum disorders
Mumps (see MMR)	None	None	None
OPV	Poliomyelitis in recipient or contact Death from polio vaccine strain in immunocompromised people	Guillain–Barré syndrome[a]	None
IPV	None	None	None
Hepatitis B	Anaphylaxis	None	Multiple sclerosis
Rubella[b] (see also MMR)	Acute arthritis	Chronic arthritis	None

a) A review of all additional information by the USPHS, which included a re-analysis of the Finnish data, concluded that the available data do not support a causal association.
b) Reviewed by an earlier committee. Initial report categories corresponding to those table headings were 'Evidence indicates a causal relationship,' 'Evidence is consistent with a causal relationship,' and 'Evidence does not indicate a causal relationship.'

found evidence inadequate to reject or accept a relationship between thimerosal preservative in some killed vaccines and neurodevelopmental disorders in children (attention deficit disorder and speech or language delays) (Institute of Medicine 2001b), the USA has removed thimerosal from childhood vaccines, although other countries and WHO have concluded there is insufficient evidence of risk to necessitate its removal from vaccines (see www.who.int/vaccine_safety/topics/thimerosal/statement200308).

Contraindications and precautions for each viral vaccine are usually described in the recommendations for use and in vaccine package inserts. For inactivated vaccines, anaphylactic reaction to a constituent or to a previous dose is usually the only contraindication, whereas, for live virus vaccines, any condition that results in immunocompromise (blood dyscrasias, HIV infection, steroid or chemotherapy, etc.) contraindicates use of the vaccine. Pregnancy is usually a contraindication for live vaccines that might be teratogenic (rubella, varicella), but not for inactivated vaccines. Potential recipients should be questioned regarding the presence of such conditions before any vaccine is administered.

Because viral vaccines may, rarely, cause serious adverse events, some countries have established programs to compensate people who develop permanent injury following vaccination (Centers for Disease Control 1988). A specific table of injuries may describe conditions for which compensation is routinely provided; in addition, anyone who can provide medical evidence of causality may be compensated. In the USA, this program is funded by a special excise tax on each dose of vaccine to which the program applies (DTP, OPV, MMR, Hib, hepatitis B, pneumococcal conjugate, and varicella vaccines). Assuring safe injection is also an essential part of immunization programs. Either single-use disposable or autodisable (AD) syringes should be used for each injection. However, improper reuse of disposable syringes, faulty sterilization of reusable syringes, and needlestick injuries pose a substantial risk of transmission of bloodborne infections (HIV, HBV, hepatitis C virus), and potentially add to the burden of these diseases in many developing countries (Hauri et al. 2004). United Nations International Children's Emergency Fund (UNICEF) and WHO now recommend use of AD syringes in all developing countries, to reduce the risk of transmission of bloodborne pathogens (Vaccines and Biologicals 2002b). GAVI is providing funds for purchase of AD syringes to assist the poorest countries to change from sterilized reusable or single-use syringes. WHO and UNICEF also recommend developing systems for the safe use and destruction of all injection equipment. Jet injectors eliminate the risk of needlestick injuries, but also may pose small risk of transmission of bloodborne diseases (Global Programme for Vaccines and Immunization, 1998).

Surveillance for vaccine-preventable diseases and vaccine supply, coverage, effectiveness, and adverse events

Monitoring the impact of vaccination programs and of the safety of vaccines is critical for refining immunization strategies and for assuring the public and medical community that vaccines are safe. Surveillance has shown the high effectiveness of universal childhood vaccines; compared with the prevaccine era, reductions of over 95 percent in the incidence of disease have been observed in the USA for polio, measles, mumps, and rubella (Centers for Disease Control and Prevention 1999b) and a reduction in varicella cases, hospitalizations and deaths of 70 to 80 percent by 2000 (Seward et al. 2002; Davis et al. 2004; Nguyen et al. 2005).

Surveillance for communicable diseases is maintained in each country, and may include any or all vaccine-preventable diseases (Wharton and Strebel 1995). These data should be monitored to assess the effectiveness of the vaccines and of the vaccination program. Surveillance needs vary according to the stage of the vaccination program. Early in implementation of a new vaccination program or before disease control has been achieved, aggregate reporting of total cases may be adequate. As the program progresses to the disease control stage, surveillance should become case-based; for each reported case of disease, confirmation by laboratory testing (virus isolation or serologic testing) and determination of vaccination status are essential to monitor whether continuing infections are due to failure to deliver vaccine or to low vaccine effectiveness. Information on age of cases is used to describe current epidemiology and to refine vaccine strategies. As the elimination of particular indigenous diseases approaches (achieved in the 1990s for measles in Finland, the UK and the USA), determination of chains of transmission, whether the case is indigenous or imported, and rapid implementation of control measures also become crucial (Peltola et al. 1994; Ramsay et al. 2003; Papania et al. 2004). At the elimination stage of a vaccination program, all healthcare providers are urged to report every suspected case of vaccine-preventable disease promptly to the local or national authorities. Monitoring the effectiveness of vaccines after licensing is essential, particularly during outbreaks in highly vaccinated populations, to reassess effectiveness in wide use and to maintain public confidence in vaccination (Orenstein et al. 1988). Monitoring vaccine coverage is also essential to track national and state vaccine coverage levels to identify pockets of unvaccinated people to target vaccination efforts and to maintain high levels of awareness for disease outbreaks (Vaccines and Biologicals 2002a). Documenting high vaccine coverage is also important; measles cases imported into the USA now have very limited spread due to the high levels of population immunity (Centers for Disease Control and Prevention 2002b).

Monitoring of adverse events after vaccination is also usually required in each country; in the USA it is the joint responsibility of the Food and Drug Administration (FDA) and the Centers for Disease Control and Prevention (CDC). Physicians are required by law to report certain events that occur after vaccination, and should report all suspected adverse reactions after vaccination to the vaccine adverse events reporting system (VAERS) (Centers for Disease Control 1988; Chen et al. 1994). Within a year of licensure of live rotavirus vaccine in the USA in 1999, the VAERS received an unexpectedly high number of reported cases of intussusception clustered 3–7 days after rotavirus vaccine. These reports were the signal that led to the decision to conduct scientific studies to determine whether Rhesus–human reassortant rotavirus (RVV) was associated with intussusception. Based on the results from three studies (case–control, case series, and retrospective cohort) which demonstrated a $\geqslant$20-fold increase in risk of intussusception with use of RVV, the ACIP voted to withdraw their recommendation of use of this vaccine in the childhood vaccination program in the USA (Centers for Disease Control and Prevention 1999f).

Vaccine handling and storage

Vaccines are perishable products that require specific care in handling and storage. Ensuring that a vaccine maintains potency and safety is a responsibility shared by the manufacturer and everyone handling the vaccine. Live-attenuated vaccines, especially MMR, yellow fever, and varicella vaccines, are more susceptible to rises in temperature than are inactivated vaccines or toxoids. Vaccinia (smallpox) vaccine, the freeze-dried preparation available for the smallpox eradication program, is an exception and is extremely stable at high temperatures. All adjuvanted inactivated vaccines are sensitive to freezing and must be protected from freezing to ensure potency. Vaccines that are exposed to damaging environmental conditions may suffer loss of potency without a change in appearance. Live-attenuated virus vaccines should be administered promptly after reconstitution, $\leqslant$30 min for varicella vaccine, $\leqslant$1 h for yellow fever vaccine and $\leqslant$8 h after reconstitution for measles and MMR vaccine (Centers for Disease Control and Prevention 2002a). A vaccine quality control program should be established in each clinical practice, focusing on education of personnel, maintenance of equipment, and adherence to routine daily monitoring of vaccines (Committee on Infectious Diseases 2003).

PASSIVE IMMUNOPROPHYLAXIS

Passive immunoprophylaxis consists of the use of purified antibodies prepared from human or animal serum to prevent infection or to modify the course of infection, when given either before or after exposure. The use of such antibodies was developed in the late nineteenth century, when sera from hyperimmunized horses and rabbits were used to treat diphtheria and tetanus. Although the use of antibiotics has largely reduced the use of passive immunoprophylaxis for bacterial infections (except tetanus, diphtheria, and replacement prophylaxis for those who are agamma- or hypogammaglobulinemic or immunocompromised), passive prophylaxis has maintained a role in preventing the serious consequences of several viral infections.

Immunoglobulin preparations currently used for viral immunoprophylaxis or treatment are prepared from human serum by cold ethanol precipitation (Cohn et al.

1946; Oncley et al. 1949). This yields three fractions, enriched in cryoprecipitates, globulins, and albumin, respectively, determined by the specific ethanol concentration, temperature, pH, and ion and protein concentrations. Immunoglobulin prepared by Cohn fractionation consists of mainly IgG types 1, 2, and 3, but is relatively depleted in IgG4. Immunoglobulin preparations maintain the properties of complement activation and opsonization associated with Fc receptors, and may also have immunomodulatory functions. In 1998, a new type of immunoglobulin product – humanized monoclonal antibodies against respiratory syncytial virus – became available in the USA. This immunoglobulin is produced in the NSO cell line and purified by ion exchange and other chromatography. This product has no known adverse reactions and is free from potential contamination from bloodborne agents.

Types of immunoglobulin

Four types of immunoglobulin products are used for viral immunoprophylaxis: pooled human immunoglobulin (prophylaxis for hepatitis A, measles) for intramuscular use; specific immunoglobulins (hepatitis B immunoglobulin (HBIG), rabies immunoglobulin (HRIG), varicella-zoster immunoglobulin (VZIG), vaccinia immunoglobulin (VIG) used to prevent the respective diseases); intravenous immunoglobulin, used for immunoprophylaxis for persons with primary or acquired immunodeficiencies; and specific intravenous immunoglobulin (IVIG) (RSV-IVIG, CMV-IVIG) used to prevent specific diseases in persons at risk (Table 6) (Finlayson 2003). Pooled human immunoglobulin for both intramuscular and intravenous use is generally prepared from large pools of donors (>1 000) who are not screened for specific antibodies; however, the final immunoglobulin preparation is required to have minimal levels of antibodies to measles and polio (neutralizing), diphtheria (antitoxin), and to hepatitis B surface antigen (anti-HBs). Antibodies to other viral pathogens, including enteroviruses, hepatitis A (HAV) and respiratory syncytial virus (RSV), are also present, although titers may vary widely in different lots. Owing to the relatively high frequency of hepatitis A infection in the general population, anti-HAV titers in immunoglobulin lots produced in the USA have remained relatively constant, although they have decreased in recent years in the UK.

Specific immunoglobulins are produced from a smaller donor pool that has either been screened for high titers of the specific antibody (RSV, cytomegalovirus (CMV)) or been boosted by vaccination of donors (hepatitis B, rabies, varicella-zoster) to ensure high levels of antibody. RSV monoclonal antibody is produced in cell culture, in which the human IgG1 gene has had grafted variable regions of murine monoclonal antibody directed against the F glycoprotein of RSV.

Intravenous immunoglobulin preparations are suitable for administering the larger doses needed by certain groups of immunodeficient patients. To prevent the occurrence of immunoglobulin aggregates, which could activate complement and cause serious reactions if given intravenously, techniques to break them down have been developed, including pepsin or plasmin digestion, reduction and alkylation, β-propiolactone treatment, or ultrafiltration and diafiltration (Waldvogel 1981). These are intended to ensure that >80 percent of IgG is present in monomeric form and that minimal aggregates of dimeric or larger forms exist. Since the mid-1990s, IVIG preparations also undergo steps to inactivate any residual viruses, either the solvent-detergent or heat inactivation or nanofiltration (Finlayson 2003). Manufacturing techniques vary among manufacturers and are continually evolving; package inserts should be consulted for each preparation.

Uses of passive immunoprophylaxis

Immunoglobulin preparations may be used as pre-exposure prophylaxis, given before anticipated exposure to a specific viral agent or as postexposure prophylaxis, either to prevent clinical disease (measles, hepatitis B, rabies) or to modify the course of infection (varicella) (Table 6).

PRE-EXPOSURE PROPHYLAXIS

Pre-exposure prophylaxis with immunoglobulin (NHIG) is now limited to hepatitis A prevention. Immunoglobulin is about 80 percent effective when given in a dose of 0.02 ml/kg for short-term protection to travelers to countries where HAV is endemic, or 0.06 ml/kg for protection for up to 6 months. In developed countries, hepatitis A vaccine is now preferred for pre-exposure prevention of hepatitis A.

IVIG is the treatment of choice for preventing bacterial and viral infections in people with primary immunodeficiency disorders associated with low serum IgG levels (Committee on Infectious Diseases 2003). Doses are usually given every 3–4 weeks, but the frequency of treatment may be tailored to the patient's clinical course and trough levels of IgG. Although IVIG treatment is most valuable in preventing bacterial infections, IVIG also reduces the risk of viral infections, including measles, enteroviruses, and RSV. IVIG is recommended to prevent infection in children with HIV infection with hypogammaglobulinemia (AIDS), people with chronic lymphocytic leukemia, and bone marrow transplantation, and is being studied for use in multiple myeloma.

Specific CMV IVIG is indicated for preventing serious outcomes of CMV infection in recipients of solid organ or bone marrow transplants. A 6-week course of therapy beginning within 72 h of transplantation may be used for

Table 6 *Immunoglobulins currently available for use in viral diseases*

Preparation	Route of injection	Uses
Human immunoglobulin (NHIG)	Intramuscular	Pre- and postexposure prophylaxis for hepatitis A; postexposure prophylaxis for measles; treatment of hypogammaglobulinemia
Hepatitis B immunoglobulin (HBIG)	Intramuscular	Postexposure prophylaxis for hepatitis B (with hepatitis B vaccine): perinatal, sexual, blood/body fluid exposure
Human rabies immunoglobulin (HRIG)	Intramuscular + intralesion	Postexposure prophylaxis for rabies (with rabies vaccine)
Varicella-zoster immunoglobulin (VZIG)	Intramuscular	Postexposure prophylaxis for susceptible infants, immunocompromised people, adults
Vaccinia immunoglobulin (VIG)	Intramuscular	Treatment of complications of vaccinia (disseminated vaccinia)
Immunoglobulin (IVIG)	Intravenous	Treatment of agamma- and hypogammaglobulinemia; prevention of viral infections in immunocompromised
Respiratory syncytial immunoglobulin (RSV IVIG)	Intravenous	Prevention of respiratory syncytial virus infection in premature infants and children with pulmonary dysplasia
RSV monoclonal antibody	Intramuscular	Uses same as RSV-IG
Cytomegalovirus immunoglobulin (CMV IVIG)	Intravenous	Prevention of serious CMV infection in transplant patients (experimental)

kidney, liver, lung, pancreas, or heart transplants. CMV IVIG may be used in conjunction with drugs (gancyclovir) to reduce risk of illness when an organ from a CMV-positive donor is transplanted into a CMV-negative recipient.

Two products, high titer RSV IVIG and RSV monoclonal antibodies, are now available in the USA to prevent RSV infection in children with bronchopulmonary dysplasia and in premature infants (<32 weeks of gestation) (Committee on Infectious Diseases 1998, 2003). These products are 40–55 percent effective in preventing the most serious complications of RSV disease in these children. RSV monoclonal antibody is given intramuscularly monthly in doses of 15 mg/kg during the RSV season (November–April in USA) to children up to 24 months of age, and is generally preferred because of ease of administration and because it does not interfere with live virus vaccines. RSV IVIG is given intravenously monthly in doses of 750 mg/kg, and may be preferred in infants with severe pulmonary disease in whom respiratory infections other than those caused by RSV may be important.

POSTEXPOSURE PROPHYLAXIS

Immunoglobulin (0.02 ml/kg) is recommended for postexposure prophylaxis to prevent hepatitis A in susceptible people with household or other close exposure if it can be given within 2 weeks of exposure. Immunoglobulin prophylaxis may modify hepatitis A disease without preventing virus excretion, and therefore should only be given to food handlers with the caution that strict hygienic precautions should be followed for 6 weeks. Some experts prefer not to give immunoglobulin to food handlers. Immunoglobulin may also be given to prevent measles (0.5 ml/kg) in susceptible people at high risk of severe measles (<12 months of age, immunocompromised) if it is given within 1 week of exposure. Postexposure prophylaxis with specific immunoglobulins is recommended to prevent hepatitis B, rabies, and varicella infection. Hepatitis B immunoglobulin (HBIG) is usually given with hepatitis B vaccine to provide passive–active prophylaxis, which may enhance short-term protection and ensure long-lasting immunity: indications for HBIG include perinatal exposure to an HBsAg-positive mother (given as soon as possible after birth); sexual exposure to an HBsAg-positive person; and needlestick, blood, or other percutaneous exposure to HBsAg-positive blood or body secretions (Centers for Disease Control and Prevention 1991). Rabies immunoglobulin is also given as passive–active immunization with rabies vaccine after exposure to a rabies-infected animal; part of the HRIG dose is administered at the wound site and part at a separate site (Centers for Disease Control and Prevention, 1999i). VZIG is indicated for susceptible people at high risk of severe varicella who have household or other sustained contact (at least 1 h direct contact) with an infected individual. Those with highest priority include neonates exposed to maternal varicella (manifest between 2 days before and 5 days after birth), susceptible immunocompromised people, and premature infants born to

varicella-susceptible mothers (Centers for Disease Control and Prevention 1996). It may also be used for exposed adults, although pre-exposure use of varicella vaccine should greatly reduce the use of VZIG over all and particularly in this population.

THERAPEUTIC USES

Immunoglobulin products may, rarely, be used to treat diseases. Vaccinia immunoglobulin (VIG) is the recommended treatment for people with serious complications of vaccinia immunization (disseminated disease, vaccinia necrosum). IVIG has also been used to successfully treat parvovirus B19 aplastic crises and RSV infection (Finlayson 2003).

Immune plasma is still used very rarely to treat established infections with highly lethal infections such as those due to hemorrhagic fever viruses (Maiztegui et al. 1979; Peters et al. 1991). Such experimental treatment employs convalescent serum from a previously infected patient, but poses the risk of serious adverse events, including immune complex deposition and serum sickness.

Adverse reactions

Immunoglobulin products for intramuscular use are very safe, with few adverse events and no risk of transmission of bloodborne diseases. Adverse reactions to intramuscular immunoglobulin are uncommon and usually mild, consisting of local pain or low-grade fever (Barundun and Morell 1981; Finlayson 2003). Allergic reactions may, rarely, occur; the risk is greater in people with isolated IgA deficiency. The risk of systemic reactions is greater (5–20 percent) with IVIG, and is highest in those with agamma- or hypogammaglobulinemia who are beginning therapy. The risk of reaction may be reduced by decreasing the rate of administration or by premedication with antihistamines, analgesics (aspirin or paracetamol/acetaminophen), or steroids. Infrequent serious reactions may include aseptic meningitis, acute renal failure, and anaphylaxis.

Immune globulins may interfere with response to live virus vaccines, particularly measles vaccine. Measles, MMR, and varicella vaccination should be delayed for 3 or more months after HNIG or IVIG, depending on dose.

Intramuscular IgG produced in developed countries has never been implicated in the transmission of bloodborne diseases, such as hepatitis B, HIV infection, or hepatitis C, even before the screening of donor blood for these agents. This elimination of infectious agents is probably due to a combination of exposure to high concentrations of ethanol (20–25 percent) and the presence of antiviral antibodies that neutralize activity or enhance the removal of virus during precipitation and centrifugation (Wells et al. 1986; Cuthbertson et al. 1987). All plasma donors in developed countries are now screened for these agents. Several incidents of transmission of hepatitis C virus (HCV) infection by intravenous immunoglobulin preparations have been reported, including from one US manufacturer after screening of plasma donors for HCV antibodies was initiated (Rousell, 1988; Williams et al. 1988b; Centers for Disease Control and Prevention 1994). Although this step was intended to eliminate most HCV-positive plasma donors, the removal of HCV antibodies may have permitted HCV not complexed with antibodies to remain in the final product. To eliminate this potential hazard, methods of manufacture have been modified using solvent-detergent, heat treatment, or nanofiltration to eliminate the risk. Rarely, immunoglobulin produced in less developed countries has transmitted bloodborne disease, possibly owing to inadequate quality control (Finlayson 2003).

VACCINES RECOMMENDED FOR ROUTINE USE IN CHILDREN

Measles, mumps, and rubella

Live-attenuated measles vaccine is a universally recommended childhood vaccine and is administered most commonly as a single vaccine according to the WHO/EPI schedule at 9 months of age to children in countries following the basic expanded program on immunization (EPI) schedule and as a combined MMR vaccine to children 12–15 months in countries with expanded immunization programs, which include rubella and mumps. The immune response to each component vaccine is similar whether a combined or single product vaccine is administered. Simultaneous administration of MMR vaccine (or individual component vaccines) and other childhood vaccines does not alter the immune responses to any of them. Vaccination with MMR and its component vaccines is contraindicated for pregnant women and for people with moderate or severe febrile illnesses, with a previous anaphylactic reaction to any of the components of the vaccine, or with immunocompromising conditions (Centers for Disease Control and Prevention, 1998). Recent studies suggest that anaphylactic reactions to eggs are not contraindications to vaccination with measles, mumps, or MMR vaccines (James et al. 1995).

In addition to universal immunization of children with a first dose, the World Health Organization recommends that all children should be given a second opportunity for measles vaccination, either through routine vaccination or in a vaccination campaign (Vaccines and Biologicals 2003). Most developed countries have also implemented a schedule calling for a second dose of MMR vaccine The first dose is most commonly administered between 12 and 18 months with some countries administering the second dose before school entry (4–6 years) and others in early adolescence (11–13 years) (Hinman et al. 1999; Salisbury and Olive 2004). The primary aims are to assure that all

children receive at least one dose of measles vaccine and to induce protective immunity in children who have not responded to the first dose of the measles component, but there is the added benefit of increasing the proportion of people immune to mumps and rubella (Centers for Disease Control and Prevention 1998).

MEASLES

Within a few years of the initial isolation of the measles virus by Enders and Peebles (1954), an attenuated vaccine was developed by serial passage of the virus in chick embryo fibroblasts. The first measles vaccine was approved for use in 1963. The most common strains of measles vaccine in current use include the Moraten, Schwarz, and Edmonstron–Zagreb strains (Strebel et al. 2004). An inactivated measles vaccine was withdrawn from production following reports of an atypical measles syndrome characterized by high fever, pneumonia, and an unusual rash that occurred after exposure to wild-type measles virus (Annunziato et al. 1982).

In different countries, measles vaccine routinely administered at 8 months (China), 9 months (EPI schedule), 12–15 months of age (USA, Australia, New Zealand, and many countries in Europe), although some countries administer the vaccine at 18 months (Sweden) or even 2 years (Slovenia, Croatia) (Salisbury and Olive 2004). The maternal antibodies to measles transferred to the fetus across the placenta are sufficient to prevent or reduce the immune response to vaccination in young children (Albrecht et al. 1977). Selecting the most appropriate age for vaccination against measles requires balancing the likelihood of a child retaining maternal antibodies against the possibility of being without antibody protection and being exposed to measles. The rates of seroconversion range from 80–85 percent in 9-month-old children to 95 percent and higher in 15-month-old children (Halsey 1983). However, as mothers acquire immunity from vaccination rather than from natural disease, the levels of maternally acquired antibodies in their infants are lower and they decline earlier (Strebel et al. 2004). Measles vaccine is extremely safe, although 5 percent of children who receive it have a raised temperature of $\geqslant$103°F ($\geqslant$39.4°C) 7–12 days after immunization (Peltola and Heinonen 1986; Centers for Disease Control and Prevention 1998). A smaller proportion of children develop a rash, usually about 10 days after immunization. Rarely, the raised temperature provokes a febrile convulsion. Serious adverse events that are even less common include thrombocytopenia (one per 25 000–40 000 doses) and anaphylaxis (Institute of Medicine 1993).

The worldwide administration of measles vaccine has sharply reduced both the number of cases and the number of deaths attributed to measles. However, in 2001, the use of measles vaccine among children aged 12–23 months had remained between 70 and 75 percent for the last decade. It is estimated that in 2000, there were 40 million cases of measles and 777 000 deaths from measles (Stein et al. 2003) and that measles remained the fifth leading cause of child mortality, accounting for 5 percent of deaths among children <5 years). In the prevaccine era, as many as 130 million cases and 5.8 million deaths may have occurred globally (World Health Organization 1998b). In 2002, the United Nations Special Session for Children endorsed a measles mortality reduction goal of reducing measles deaths by 50 percent by 2005, compared with 1999 estimates. The main strategies for achieving this goal are to achieve high coverage with both the first dose of vaccine and with the second opportunity for measles vaccination. In developing countries, the best strategy for the second opportunity is through supplementary immunization campaigns targeting children 9 months to 14 years, with follow-up campaigns in those aged 9–59 months every 3–5 years. In addition, increased routine coverage to 90 percent or higher will be needed to reduce and maintain absence of measles deaths in these countries (Otten et al. 2003). These strategies were developed in the Americas and are now being implemented in sub-Saharan Africa and many countries in other regions. In the period 2001–2002, 60 million African children in 13 countries received measles vaccine through supplementary immunization activities, and the measles partnership is on target to achieve the 50 percent mortality reduction goal by 2005.

Because measles infection results in lifelong protective immunity, there is no carrier state and humans are the only host, measles is theoretically eradicable (Centers for Disease Control and Prevention 1993c). The availability of an effective vaccine and the successful control of measles in the Americas and some countries in Europe and Asia make measles a potential candidate for eradication after polio (Centers for Disease Control and Prevention 1999g). In 1967, elimination of measles was achieved in the Gambia, and sustained for a 4-year period (Foege 1971). Since that time, strategies for its elimination have evolved that deliver two doses of vaccine using either routine two-dose vaccination, routine vaccination with supplemental mass vaccination campaigns or routine vaccination with a single mass catch-up campaign followed by a routine two-dose schedule. Finland and the USA have achieved elimination based on a routine two-dose program (Peltola et al. 1994; Papania et al. 2004). Most countries in the Americas have used supplemental mass vaccination against measles and by 2003, measles cases had declined 99 percent compared with 1990 and indigenous transmission had been interrupted (de Quadros et al. 2003). The UK, Australia, and some other countries have achieved or are close to achieving elimination using a combination of single mass catch-up campaigns and a routine two-dose schedule (Ramsay et al. 2003; McFarland et al. 2003). Further progress in reducing

mortality and morbidity from measles depends on other countries implementing accelerated activities to achieve its elimination. Molecular epidemiological techniques will take on increasing importance in tracking the transmission of the measles virus and identifying importations (Rota et al. 1996). The World Health Organization has developed a standardized nomenclature to characterize the genetic variability in wildtype measles viruses (World Health Organization 1998a).

MUMPS

The mumps virus was first cultured in 1945 in chick embryos, leading to the development of vaccines that were first licensed in the Soviet Union and the USA in the 1960s (Plotkin 2004a). Several strains of mumps virus have been used to produce vaccine; until recently, the most widely used have been the Jeryl Lynn, Rubini, Urabe, Leningrad-3, L-Zagreb, and Hoshino. All produce seroconversion rates of 90–95 percent. Protective efficacy in clinical trials ranged from 92 to 96 percent. Post-licensure, vaccine effectiveness studied in outbreak investigations have been lower, from approximately 65 to 90 percent (Cheek et al. 1995; Wharton et al. 1988; Plotkin 2004a).

Mumps vaccine is well tolerated and, except for aseptic meningitis, few adverse events have been directly associated with vaccination. Aseptic meningitis has been associated mainly with vaccination with the Urabe and Leningrad strains of mumps vaccine (Plotkin 2004a; Ki et al. 2003; Dourado et al. 2000). When MMR vaccine has been used in mass campaigns, clusters of meningitis cases have been reported, highlighting that a specific vaccine strategy may influence the visibility of relatively rare adverse events and undermine public confidence in the vaccine (Dourado et al. 2000). Many developed countries, including Japan, UK, and other European countries, have removed the Urabe mumps vaccine from the market. These adverse events have had a detrimental effect on vaccination programs, in particular reducing acceptance of the combined MMR vaccine in routine vaccination programs, as well as in mass campaigns. The Jeryl Lynn strain has not been associated with aseptic meningitis and remains the mumps vaccine of choice throughout the world.

Widespread vaccination has greatly reduced the reported incidence of mumps in every country that has introduced mumps vaccine. As a disease without a carrier state and without a nonhuman host, the highly efficacious vaccine makes mumps, like measles, potentially eradicable (Centers for Disease Control and Prevention 1993c). It is not yet known whether a single dose can provide adequate population immunity to eradicate mumps, but it is unlikely given experience with single dose vaccine effectiveness under field conditions. Countries that use MMR in their childhood immunization schedule commonly have a two-dose policy for measles vaccine that also results in two doses of mumps being administered. Russia recommends two doses of mumps-containing vaccine at 12–15 months and 6 years. Using a two-dose schedule of MMR at 14–18 months and 6 years since 1983, Finland has eliminated mumps (Peltola et al. 1994, 2000).

RUBELLA

The mild febrile rash illness due to rubella is important because of the congenital rubella syndrome (CRS). Women infected with rubella during the first trimester of pregnancy frequently give birth to babies with characteristic birth defects. The association between rubella and this congenital syndrome was first recognized as a triad of ocular abnormalities, cardiac defects, and deafness in newborns in Australia in 1941 (Gregg 1941). Subsequent studies have expanded the list of abnormalities in the CRS to include mental retardation, hepato- and splenomegaly, as well as thrombocytopenia, hypothyroidism, and diabetes mellitus. Infection in the first trimester of pregnancy results in the highest frequency of, and most devastating, abnormalities, although infection in the third trimester may cause cataracts (Centers for Disease Control and Prevention 1998).

In the years following the isolation of the virus in 1962, several vaccines were developed. The RA27/3 vaccine strain is now the most commonly used throughout the world (replacing the Cendehill and HPV 77 vaccines in the USA), although the T0-336 and BRD-2 strains are used in Asia and have potency similar to the RA27/3 strain (Plotkin and Reef 2004). Rubella vaccine induces an effective immune response in >95 percent of recipients, which seems to be less affected by maternal antibody than is the response to measles vaccine. Vaccine effectiveness with a single dose, studied during outbreak settings for the RA27/3, as well as some Japanese vaccine strains, has most commonly been >94 percent (Plotkin and Reef 2004).

Rubella vaccination is usually well tolerated, although arthritis or arthropathy may occur. This side-effect is more common in susceptible adult women than in children or adult men (Institute of Medicine 1991; Centers for Disease Control and Prevention 1998). Joint symptoms are usually self-limited, although chronic arthritis associated with rubella vaccine has been reported (Tingle et al. 1986). Symptoms may be less common following vaccination with RA27/3 than after vaccination with other strains. Some workers have found no association with rubella vaccination and the subsequent development of persistent joint symptoms. Inadvertent rubella vaccination during pregnancy has not been associated with congenital defects, but vaccination is contraindicated in pregnancy (Centers for Disease Control, 1989, 1998) and women who receive rubella vaccine should be counseled to avoid pregnancy for 28 days after vaccination (Centers for Disease Control and Prevention, 2001b).

Several strategies have been implemented to control rubella and CRS. Some countries have opted to immunize only women of childbearing age, in practice girls 12–13 years of age, just before their reproductive years. With complete implementation of the program, virus continues to circulate among unvaccinated children and men, providing periodic boosting of immunity in vaccinated women. In theory, the control of CRS is achieved by protecting all women who might become pregnant. In the UK, an immunity level of 97 percent was found to be inadequate to prevent all cases of CRS (Miller 1991). The second strategy is universal vaccination of children. The ultimate aim here is the elimination of rubella transmission and the reduction of CRS by vaccination-induced immunity and herd immunity (Centers for Disease Control and Prevention 1998). Currently, most developed countries combine the two strategies, through universal immunization of children at 12–15 months of age with MMR vaccine or measles, rubella vaccine and immunization of susceptible women with rubella vaccine, and 119 countries have included rubella in routine immunization programs (Salisbury and Olive 2004; Vaccines and Biologicals 2002a). Some countries have conducted mass vaccination campaigns of adults of reproductive age in conjunction with initiating universal child vaccination against rubella (Hinman et al. 1998). Experience with various vaccination strategies in the Pan American Health Organization (PAHO) region in the late 1990s has lead to adoption of one-time mass vaccination of males and females (sometimes ranging from 5–39 years and administered as a combined MR campaign), in addition to introducing MMR in the childhood vaccination program as the most effective way to rapidly reduce virus transmission and more rapidly prevent congenital rubella syndrome. (Castillo-Solórzano et al. 2003). Cuba was the first country to eliminate rubella and CRS through two mass campaigns during 1985 and 1986 that initially targeted women aged 18–30 years followed by children 1–14 years (World Health Organization 2000).

Rubella, like measles, has only a human host and no chronic carrier state, so can theoretically be eradicated. Mathematical modeling suggests that a single dose of vaccine, given universally, should be sufficient to eliminate or even eradicate rubella. To date, Finland and Cuba have declared success in this effort, although the elimination of transmission in the USA is suggested by prolonged periods of no reported disease since the late 1990s, as well as by the epidemiology of CRS between 1997 and 1999, where 41 percent of mothers with CRS births were infected outside the country (Peltola et al. 2000; Reef et al. 2002). Molecular epidemiological methods, similar to those used in measles elimination efforts, in which the genetic information of wildtype viruses is characterized, will aid efforts to track and eliminate rubella virus transmission (Frey et al. 1998; Reef et al. 2002). The major constraints to eradication are a perceived lack of importance because of the mild clinical syndrome and the difficulty in maintaining surveillance for a disease in which half the cases may lack any clinical symptoms. These constraints are changing, however, as experience has been gained with combining rubella with measles surveillance mainly in the Americas (Irons et al. 2003). In developing countries, inadequate surveillance for CRS has meant that its importance is not known. Although rubella is not included in the World Health Organization's Expanded Program on Immunization (Robertson et al. 1997), there has been considerable progress in rubella control and CRS prevention especially in the region of the Americas where almost all countries are now using MMR vaccine in their routine childhood vaccination programs, are integrating measles and rubella surveillance including laboratory testing, and some of which have also initiated mass vaccination campaigns to accelerate rubella control/CRS prevention (Castillo-Solórzano et al. 2003; Irons et al. 2003). The European region has established a target for reducing incidence of CRS to <1 per 100 000 births by 2010. Strategies to achieve the goal of measles elimination by 2007 in this region have included mass campaigns using measles vaccine which have also provided opportunities for countries to launch or accelerate rubella and CRS prevention programs (Spika et al. 2003; Dayan et al. 2003).

Poliomyelitis

Poliomyelitis was a widespread cause of childhood morbidity and mortality in the prevaccine era (Strebel et al. 1992). In 1949, the discovery that poliovirus could be propagated in nonnervous human tissue permitted the large-scale production necessary for vaccine manufacture (Enders et al. 1949). Two standard approaches were pursued: inactivation and attenuation of poliovirus.

Following large-scale field trials of inactivated poliovirus vaccine (IPV) developed by Jonas Salk, IPV became, in 1955, the first poliovirus vaccine to be licensed in the USA (Francis et al. 1957; Salk et al. 1994). IPV contains formalin-inactivated poliovirus types 1, 2, and 3. In 1961, monovalent oral poliovirus vaccines (OPV) developed by Albert Sabin were licensed. Two years later, a balanced formulation of the three monovalent vaccines (trivalent OPV) became available and rapidly replaced IPV as the vaccine of choice for preventing poliomyelitis in the USA and in most other countries. OPV contains live-attenuated polioviruses of the three poliovirus serotypes formulated ratio 10:1:6, with 10^6 median tissue culture infective dose ($TCID_{50}$) of poliovirus type 1, 10^5 $TCID_{50}$ of poliovirus type 2, and $10^{5.8}$ $TCID_{50}$ of poliovirus type 3 (Centers for Disease Control 1982). In the 1980s, enhanced-potency IPVs (eIPV) were developed; eIPV containing 40:8:32

D-antigen units of poliovirus types 1, 2, and 3, respectively, was licensed in the USA in 1987 (Centers for Disease Control 1987).

In most industrialized countries, including the USA before 1997, and virtually all developed countries, the vaccine of choice for the prevention of poliomyelitis is OPV (Centers for Disease Control 1982; Hinman et al. 1999). The primary series of OPV usually consists of three doses in the first 6 months of life, followed by one or more additional doses between 1–2 years of age or at school entry. In the United States prior to 1997, doses were given at 2, 4, and 6–18 months of age, followed by a supplemental dose of OPV at school entry (i.e. 4–6 years). The primary series of IPV consists of between four and seven doses, with two to three doses given in the first year of life and at least one booster dose 6–12 months after the primary series. In the USA, doses are given at 2, 4, and 6–18 months of age, followed by a fourth dose of IPV at school entry. Until 1997, IPV in the USA was indicated primarily for immunologically abnormal infants and their family contacts, and for unvaccinated adults (Centers for Disease Control 1987). Following primary reliance on OPV between 1961 and 1996, the USA revised its poliomyelitis prevention policy with effect from early 1997. Recognizing the absence of indigenous wild poliovirus circulation since 1979, the occurrence of eight to nine cases of vaccine-associated paralytic poliomyelitis (VAPP) annually in the USA and the rapid progress in global polio eradication, the USA revised its policy first to increase the use of IPV, the first two doses of poliovirus vaccine as IPV given at 2 and 4 months of age followed by two doses of OPV at 12–18 months and 4–6 years of age (Centers for Disease Control and Prevention 1997). In 2000, the policy was revised to an IPV-only schedule (Centers for Disease Control and Prevention 2000). OPV is no longer recommended, except in special circumstances such as a child who will be traveling to a polio-endemic area. This schedule ensures development of good humoral immunity, while eliminating the risk of VAPP (McBean and Modlin 1987; Centers for Disease Control and Prevention 2000). IPV has been used exclusively in many northern European countries, including Finland, Sweden, and the Netherlands, and has led to eradication in these countries. Currently, 22 developed countries use exclusive IPV, and an additional eight countries use a sequential schedule of IPV followed by OPV (World Health Organization 2003a).

The Expanded Program on Immunization of the World Health Organization recommends a schedule of four OPV doses administered at birth (zero week), 6, 10, and 14 weeks to ensure earlier protection against poliomyelitis in infants residing in the developing world. Many developing countries also recommend a dose of OPV in the second year of life.

The objective of the routine series of poliovirus vaccine is to induce humoral immunity for individual protection against poliomyelitis and mucosal immunity for community protection against its circulation. In industrialized countries, three doses of OPV or IPV result in seroconversion or seroprevalence levels of >90 percent to all three poliovirus serotypes. In developing countries, the immunogenicity of OPV is substantially lower, with median seroconversion levels of 72, 95, and 65 percent (Patriarca et al. 1991) to poliovirus types 1, 2, and 3, respectively, following the administration of three doses of OPV. The lower immunogenicity of OPV in developing countries may be due to interference by concurrent enterovirus infection, diarrhea, nonspecific inhibition, or other factors. In addition, the immunogenicity of OPV may be lower under program conditions because of suboptimal storage, handling, and administration. When given by the WHO/EPI schedule, the immunogenicity of IPV has varied widely, from 67–99 percent for type 1, 65–99 percent for type 2, and 91–100 percent against type 3 (World Health Organization 2003a). The response to early administration of IPV may be inversely affected by maternally derived type-specific antibody (WHO Collaborative Study Group 1996). Whereas OPV and IPV induce a similarly high-level humoral immune response in infants residing in industrialized countries, the intestinal mucosal immunity induced by OPV is clearly superior to that induced by IPV in limiting the replication and excretion of circulating poliovirus (Sutter and Patriarca 1993).

The widespread use of IPV, starting in 1955, led to a major reduction in the incidence of poliomyelitis in the USA, from 57 879 cases in 1952 to 5 485 cases by 1957. The widespread use of OPV led to the elimination of indigenous circulation of wild poliovirus in the 1960s. The last endemic and epidemic cases of poliomyelitis were reported in 1979. Between 1980 and 1997, aside from a few imported cases of poliomyelitis, approximately eight cases of VAPP were reported each year in the USA (Strebel et al. 1992). Of these eight VAPP cases, three each occurred in OPV recipients and in people in contact with OPV recipients and two cases in immunologically abnormal people. Since the adoption of the IPV schedule, no VAPP cases have been reported in the USA.

The occurrence of VAPP is the most serious adverse event following use of OPV and has been reported from most industrialized countries (Esteves 1988; Joce et al. 1992; Strebel et al. 1992). Among immunocompetent people, the highest risk of VAPP is in recipients of the first dose of OPV (one VAPP case per 1.5 million infants) and in unvaccinated contacts (one VAPP case per 2.2 million contacts) of recently vaccinated infants. However, the risk of VAPP is highest in the presence of immunological abnormality (either congenital or acquired), particularly people with B-cell deficiencies. In Romania, a country that had reported very high rates of VAPP for many years, a case–control study suggested

that the apparently increased incidence was primarily due to multiple intramuscular injections of antibiotics following administration of OPV (Strebel et al. 1995). An estimated 250–500 VAPP cases occur annually. An additional risk of OPV use is circulating vaccine-derived polioviruses (cVDPV), in which vaccine-derived polioviruses have reverted to wild-type virulence and developed the ability to circulate widely in the population. Since 1988, four outbreaks of cVDPV have occurred, causing between three and 30 cases of paralytic poliomyelitis (World Health Organization, 2003a). These outbreaks have generally originated in populations with low vaccine coverage, allowing vaccine viruses to circulate for long periods and reattain virulence. IPV is not known to cause serious adverse reactions.

Progress toward poliomyelitis control in industrialized and developing countries prompted the member countries of the WHO region of the Americas to adopt the goal, in 1985, of regional elimination of poliomyelitis from the western hemisphere by the year 1990. Following the implementation of key strategies, the last case of poliomyelitis associated with wild poliovirus isolation was reported from Peru in September 1991, and the region was certified free of indigenous wild poliovirus by an International Certification Commission in September 1994 (Pan American Health Organization 1994). In 1988, the World Health Assembly, the governing body of WHO, adopted the goal of global eradication of poliomyelitis by the year 2000 (World Health Organization 1988). A unique partnership of governmental and private organizations is supporting this initiative; Rotary International, a private service organization, has provided more than US$500 million and immeasurable volunteer time to achieve the goal of eradication.

The poliomyelitis eradication initiative relies on four strategies:

1. high routine coverage with OPV;
2. supplemental immunization, including national immunization days (NID) twice a year to vaccinate all children in order to eliminate the remaining poliovirus reservoirs;
3. enhanced epidemiological and virologic surveillance to detect cases immediately, institute control measures, and eventually assist in eliminating wild poliovirus circulation;
4. house-to-house campaigns to interrupt remaining chains of transmission (Hull et al. 1994). Additional house-to-house campaigns have become the key strategy in the remaining polio-endemic countries.

At present, use of IPV in developing countries is not recommended because of its inferior protection against virus transmission (mucosal immunity), potential lower response to vaccination with the EPI schedule, higher cost, and greater complexity of administration (e.g. injection, combination vaccines) (World Health Organization 2003a). This recommendation is being reviewed as progress toward eradication continues.

Progress towards eradication can be measured both by outcome evaluation (e.g. the incidence of poliomyelitis) and by process evaluation (e.g. the number of countries conducting NIDs). Worldwide, the number of polio cases has decreased by over 99 percent, from over 200 000 cases in 1980 to 1 250 in 2004. Eradication of polio has been certified in the American (1994), Western Pacific (2001), and European (2002) regions. However, the virus remains endemic in six countries (Nigeria, India, Pakistan, Niger, Afghanistan, Egypt), and in 2004 polio cases caused by wild poliovirus originating from northern Nigeria were reported in ten sub-Saharan countries in Africa and in Saudi Arabia, re-establishing transmission (for more than 6 months) in five countries bordering or near Nigeria (Vaccines and Biologicals 2004; Centers for Disease Control and Prevention 2005b). During this period, NIDs were conducted in up to 96 countries, and supplemental doses were given to 500 million of the world's children < 5 years of age during 266 rounds of NIDs, supplemental immunization days, or mopping up activities in 2002. During 2004, supplemental immunization was conducted in 23 contiguous countries in Africa, and up to 6–8 rounds of vaccination were conducted in the remaining polio-endemic countries.

The progress toward global eradication of poliomyelitis suggests that this objective may be within reach in Asia and Egypt by the end of 2005, and in Africa soon thereafter. However, increased efforts are necessary to ensure that adequate resources are made available to eliminate the remaining poliovirus reservoirs, particularly those in southern Asia and Africa.

Hepatitis B vaccine

Hepatitis B vaccines initially consisted of HBsAg particles purified from the plasma of HBV carriers. Plasma-derived vaccines were highly effective in preventing hepatitis B, were used in developed countries throughout the early 1980s, and continue to be used in a few developing countries (Szmuness et al. 1981; Kane 1993). In 1985, the first recombinant HB vaccines became available. These consist of purified HBsAg produced by recombinant DNA technology in yeast or in mammalian cells. Newer generation vaccines, which may include the pre-S1 or pre-S2 antigens, or both, in addition to HBsAg have also been developed but have not replaced the vaccines based solely on HBsAg (Hadler and Margolis 1992).

Hepatitis B vaccine is usually given as a three-dose series. The licensed schedule in developed countries includes doses at 0, 1, and 6 months, with an alternative schedule of four doses given at 0, 1, 2, and 12 months. However, schedules that vary the timing of the second

and third doses to permit integration into the routine childhood immunization schedule have been highly immunogenic (Centers for Disease Control and Prevention 1991). Dosages vary by age, vaccine, and whether the child is born to an HBsAg-positive mother; in the USA, dosages for infants and children are one-half those required for adults.

The response to a three-dose series is excellent in all age groups, with anti-HBs produced in 85–99 percent of vaccinees; response is highest in children aged 2–19 years, and decreases with increasing age (Hadler and Margolis 1992). People with immunocompromising conditions such as renal failure have poorer responses, and higher dosages are recommended. Placebo-controlled trials both in high-risk children in HBV-endemic countries and in high risk adults in the USA and elsewhere have shown short-term efficacy of 80–95 percent (Szmuness et al. 1981; Stevens et al. 1992). Long-term follow up of both children and adults for up to 14 years has demonstrated protection against serious consequences of infection (chronic carriage and chronic liver disease) in virtually all people who respond to the initial series (anti-HBs $\geqslant$10 miu/ml) (Hadler and Margolis 1992; West and Calendra 1996; Mast et al. 2004). Booster doses are not currently recommended for any age group, but the need for them continues to be evaluated.

Hepatitis B vaccine causes few adverse reactions, mainly fever and soreness at the injection site. Rarely, anaphylaxis can occur, and contraindicates additional doses of vaccine. Serious neurological injuries such as Guillain–Barré syndrome and other demyelinating conditions (multiple sclerosis, optic neuritis, and transverse myelitis) have been reported, rarely, following hepatitis B vaccination, but available information favors rejection of a causal link with multiple sclerosis, and is insufficient to accept or reject a relation between other demyelinating conditions and hepatitis B vaccine (Centers for Disease Control and Prevention 1991; Institute of Medicine 1993, 2002a).

In developed countries, including the USA and Europe, hepatitis B vaccine was initially recommended only for infants of HBV-carrier mothers and high risk adults. However, in the USA, the lack of impact on disease incidence led to implementation of a comprehensive strategy for eliminating hepatitis B transmission (Centers for Disease Control and Prevention 1991). This strategy includes: (1) universal screening of pregnant women for HBsAg, and providing hepatitis B immunoglobulin and initiating hepatitis B vaccination within 12 h of birth for infants born to hepatitis B-carrier mothers; (2) universal vaccination of all infants, preferentially beginning at birth, but at least by 2 months of age when other routine childhood vaccines are initiated; (3) vaccination of all previously unvaccinated children at 11–12 years of age; and (4) vaccination of children, adolescents and adults in high risk groups, including people who live in households with HBsAg carriers; children $\leqslant$11 years old of immigrants from areas of high HBV endemicity; people who abuse drugs parenterally; the sexually active, whether homosexual or heterosexual; and those at occupational risk. The recommendation for universal vaccination of infants was based on several considerations: the low dose of vaccine required for this age group; the feasibility of integration into the routine childhood immunization schedule; the need to prevent chronic infection in high risk children; and data showing that protection persists to the age when high-risk behaviors begin.

Vaccination of all previously unvaccinated adolescents at 11–12 years of age is the primary strategy for hepatitis B control in Canada and some countries in Europe (Committee on Infectious Diseases 2003; Hinman et al. 1999). This approach has the advantage of ensuring that adolescents will be protected before beginning high-risk behaviors, that immunity will be high and that a booster dose of vaccine will not be needed. A key challenge is providing the three-dose vaccine series to this age group in the absence of regular preventive healthcare visits. The vaccination of adolescents has been implemented successfully in British Columbia via school-based programs (Dobson et al. 1995).

The World Health Organization now recommends that all countries should include HB vaccine in their routine immunization schedules, with emphasis on routine infant immunization and prevention of perinatal HBV transmission (Vaccines and Biologicals 2003). In all developing countries, universal vaccination of infants is the recommended strategy for disease control (Kane 1993). The initial dose should be given as soon after birth as possible, particularly in countries in which perinatal disease transmission is predominant (e.g. eastern Asia). Infant immunization has been shown to be highly effective in reducing the frequency of HBV carriers among children in many high risk countries (Mast et al. 2004), and has been associated with reduced risk of liver cancer among children in Taiwan (Chang et al. 2003). Introduction of hepatitis B vaccination in the poorest countries is now supported by funding from the Global Alliance for Vaccines and Immunization, and by 2003, 151 countries had hepatitis B programs, based mainly on universal vaccination of infants (World Health Organization 2003c). A few countries with extremely low HBV endemicity (Scandinavia, UK) continue to rely only on vaccination of high-risk adults.

Varicella vaccine

Live-attenuated varicella-zoster virus vaccine was developed in Japan in the 1970s, has been available in Japan and Korea and some European countries for many years, and is now widely available throughout the world. In 1995, it was licensed for primary prevention of varicella in healthy American children and adults. Clinical

efficacy trials conducted with this vaccine, developed from the Oka strain of varicella virus, used varying vaccine potencies and formulations that were not necessarily comparable. For the formulation of vaccine most similar to the currently licensed product, the vaccine is approximately 70–90 percent effective in prevention of varicella disease and over 95 percent effective in providing protection against severe varicella disease (Centers for Disease Control and Prevention 1996; Seward 2001). Moreover, the 1–4 percent of children and adults who experience breakthrough infection annually develop mild disease with an average of $\leqslant$50 lesions, compared with 300 lesions in typical varicella (Bernstein et al. 1993). Post-exposure vaccination, if given within 5 days of exposure, appears effective in preventing or reducing severity of varicella in household contacts of cases (Salzman and Garcia 1998; Centers for Disease Control and Prevention 1999e).

For primary prevention, varicella vaccine is given as a single dose for children age either 9 or 12 months (depending on vaccine manufacturer directions) to 12 years, and two doses separated by at least 1 month for older children and adults (Centers for Disease Control and Prevention 1996; Arvin 2002). Varicella vaccine may be given simultaneously with all other childhood vaccines, but should not be administered within 4 weeks of receipt of another live, viral vaccine. For adolescents and adults, serological screening of people without a history of varicella is likely to be cost-effective, because 70–91 percent of them will be immune to varicella.

Varicella vaccine induces a mild varicelliform rash and fever in 5–10 percent of vaccinees. However, these data are from uncontrolled clinical trials. In the only two placebo-controlled trials conducted among children, one trial reported no difference in rash or fever between vaccine and placebo recipients (Varis and Vesikari 1996). The second trial found no difference in fever and a small difference in rash: 3 percent of vaccine recipients developed noninjection site rashes compared with 2 percent of placebo recipients and 1 percent of vaccine recipients developed a generalized varicella-like rash compared with no placebo recipients (Weibel et al. 1984). Among adults, rash and fever may be more common, but there are no placebo-controlled trial data available. No unanticipated rare, serious adverse effects have occurred postlicensure (Wise et al. 2000). In the USA, varicella vaccine is contraindicated in people who are immunocompromised due to cell-mediated immunodeficiency (any malignant condition, including blood dyscrasias, leukemia, lymphomas of any type, or other malignant neoplasms affecting the bone marrow or lymphatic systems), in pregnant women and in anyone who has an anaphylactic reaction to varicella vaccine or any component, including gelatin. However, vaccine is available to any physician through an investigational drug protocol for use in patients who have acute lymphoblastic leukemia (ALL) in remission who meet specified criteria) (Centers for Disease Control and Prevention 1996). Vaccination should be delayed for 5 months after the administration of immunoglobulin or blood products, because the response to vaccine administered within this interval is unknown. The risk of herpes zoster after varicella vaccination appears to be lower than after natural varicella infection.

Strategies for the use of varicella vaccine include universal vaccination of children at 12–18 months of age (with or without a catch-up program) and/or targeted vaccination for high-risk groups for severe disease or those in contact with such persons. The latter groups could include children with leukemia, as well as older susceptible children, adolescents and adults, healthcare workers, and family contacts of immunocompromised persons. Targeted programs, although they will provide protection to the individual or their close contacts, will have little impact on varicella epidemiology. Universal vaccination is intended to reduce disease transmission greatly and provide herd immunity to those who remain unvaccinated, and is the strategy adopted by the USA (Centers for Disease Control and Prevention 1996). Varicella vaccine is recommended for all children at 12–18 months of age and for all susceptible older children (with no prior history of varicella). All children who have not had natural varicella infection should be vaccinated at 11–12 years of age. Varicella vaccine is also recommended for susceptible healthcare workers and others in close contact with immunocompromised people who might experience severe varicella if infected, for susceptible adults at high risk for exposure or transmission, such as teachers, childcare center workers, and adults who live in households with children. It should be considered for any adolescents and adults with no prior history of varicella (Centers for Disease Control and Prevention 1999e).

In the USA where experience has been gained with the universal childhood program, varicella cases and hospitalizations and deaths had declined approximately 70 to 80 percent 6 years after implementation of the vaccination program (Seward et al. 2002; Davis et al. 2004; Nguyen et al. 2005). Although the greatest decline in incidence is among children 1–4 years, incidence has declined in all age groups including infants <12 months and adults indicating reduced disease transmission.

OTHER VIRAL VACCINES

Hepatitis A vaccine

Both killed and live-attenuated hepatitis A vaccines have been under development since the 1980s (D'Hondt 1992). Killed vaccines produced in cell culture, purified and inactivated with formalin first became commercially

available in 1992. Inactivated hepatitis A vaccines are highly immunogenic (94–100 percent) and over 94 percent effective in preventing hepatitis A infection when given as a two- to three-dose series to children or a two-dose series to adults (Werzberger et al. 1992; Innis et al. 1994). The duration of protection is not known but, on the basis of high antibody levels induced by the vaccine, is expected to exceed 20 years (Van Damme et al. 1994). This vaccine may also provide protection post-exposure, and has been shown to be effective in controlling hepatitis A outbreaks in well-defined populations (Centers for Disease Control and Prevention 1999h). Development of live attenuated vaccines has been impeded by difficulty in achieving an appropriate balance of attenuation and protection, but one Chinese vaccine (H-2 strain) has been reported to be both immunogenic and effective, and has been licensed and used in China since 1992. This vaccine is reported to induce high rates of seroconversion and have high efficacy when given as a single dose subcutaneously to school-age children (Mao et al. 1997).

Licensed inactivated hepatitis A vaccine is given as a two- or three-dose series, with doses at 0 and 6–12 months (or 0, 1, and 6–12 months) to children $\geqslant$2 years of age, and as a two-dose series given 6–12 months apart to adults (Centers for Disease Control and Prevention 1999h). The known adverse reactions are limited to pain at the injection site. Rare serious adverse events (e.g. Guillain–Barré syndrome) have been reported following hepatitis A vaccination, but rates of such events have not exceeded those expected in the absence of vaccination. Hepatitis A vaccine may be given simultaneously with other childhood vaccines or vaccines for international travelers. The administration of passive immunoglobulin or maternal antibody interferes with response to the first dose of vaccine, but differences in final antibody response after the multidose series seem unlikely to be of clinical importance.

In developed countries, hepatitis A vaccine is recommended for people at high risk of infection, and is most widely used in those traveling to or working in countries where hepatitis A is highly endemic. In the USA, vaccine is recommended for native Americans and other groups that experience cyclic hepatitis A epidemics, for children age 2–18 years in states that historically had high incidence of hepatitis A, as well as for others at risk such as people with clotting disorders, homosexual men, users of illicit drugs, those at occupational risk, and people who have chronic liver disease (Centers for Disease Control and Prevention 1999h). Universal vaccination of children at age 2 years, with or without catch-up vaccination of susceptible older children, has resulted in marked decline in incidence in Native Americans and in states that previously had high disease incidence. Vaccination also may be considered for the prevention or control of community-wide outbreaks, although the data on effectiveness in this situation are limited. Ultimately, universal vaccination would be the best option to reduce the burden of disease in countries with substantial clinical disease burden such as the USA; however, this will probably require a less costly preparation and its incorporation into combination childhood vaccines.

Influenza virus vaccines

Influenza viruses continue to cause considerable mortality and morbidity throughout the world on an annual basis with the potential for much greater mortality and morbidity during pandemics. The 1918–19 pandemic is estimated to have caused more than 20 million deaths worldwide, more than 500 000 of which occurred in the USA. Recent estimates of influenza-associated deaths in the USA for the seasons 1990–91 through 1998–99 range from 36 000 underlying respiratory and circulatory deaths to 51 000 all-cause deaths (Thompson et al. 2003). The increase in influenza-associated deaths since the 1970s is believed to be partly due to the aging of the US population.

INACTIVATED INFLUENZA VACCINE

Influenza virus was first isolated from humans in 1933 and the first effective vaccine was administered in studies in Pennsylvania soon after that time. Since the 1940s, influenza virus has been grown in chick embryo allantoic sacs; this medium greatly increased yield of virus and promoted vaccine production. Because of the frequent antigenic changes in influenza viruses, the antigenic content of both types of vaccine is changed annually to optimize protection against the influenza type A and B strains expected to circulate during the following winter and spring. Influenza viruses of type A (H1N1 and H3N2) and B are selected according to their immunological match with circulating strains, grown in chicken embryos, inactivated with formalin and combined into vaccine. In the USA, inactivated vaccine is either subvirion vaccine, prepared by disrupting the lipid-containing membrane of the virus, or purified surface-antigen vaccine; whole-cell influenza vaccine is no longer available. The efficacy of vaccine is related to the degree of match between the vaccine and the circulating influenza viruses, as well as age and immunocompetence of the vaccine recipient. In recent years, effectiveness has been estimated to be 70–90 percent in adults <65 years, but lower in older adults (Centers for Disease Control and Prevention 2004; Bridges et al. 2000). Protection against serious complications, including hospitalization and death, is higher than against uncomplicated influenza (Nichol et al. 1994; Gross et al. 1995). Among healthy children, inactivated influenza vaccine efficacy in various studies has ranged from 77 to 91 percent for prevention of influenza

respiratory illness and 66 percent for prevention of culture-confirmed influenza. Inactivated influenza vaccine has also been reported to reduce influenza-associated otitis media in children by approximately 30 percent (Centers for Disease Control and Prevention 2004; Neuzil et al. 2001). When major antigenic shifts occur, vaccine effectiveness may be substantially less in all age groups. Annual vaccination is necessary to ensure protection against the current strains.

For previously unvaccinated children 6 months to 8 years of age, two doses of vaccine (0.25 ml), given at 4-week intervals, are recommended (Centers for Disease Control and Prevention 2004). For other groups, only a single dose (0.5 ml) is necessary. About 3–5 percent of vaccinees experience local tenderness or fever after vaccination. The occurrence of Guillain–Barré syndrome within 6 weeks of influenza vaccination was observed in adults after the swine influenza vaccine campaign in 1976, but was not observed subsequently until 1990, when a case–control study suggested a slightly elevated risk in 18–64-year-olds, but not in those over 65 years of age (Schonberger et al. 1979; Chen et al. 1992). A similar small elevated risk was shown in adults age 18 years and older during the 1992–93 and 1993–94 influenza vaccine seasons (Lasky et al. 1998). Given the substantial benefits of influenza vaccination among the target populations, the risk of Guillain–Barré syndrome, if any, is greatly exceeded by the benefits. A previous anaphylactic reaction to egg protein is the only contraindication to influenza vaccination.

Vaccination is intended to reduce the complications and mortality due to influenza infection. Annual immunization is recommended for those at highest risk of these complications (Centers for Disease Control and Prevention 2004). In most developed countries, vaccination is recommended for people with certain chronic medical conditions, including cardiovascular and pulmonary disorders, asthma, other medical disorders such as metabolic disease (including diabetes mellitus), renal disease, hemoglobinopathies (including sickle-cell disease), and for people with immunosuppressive disorders or treatments, and children on long-term aspirin therapy. In many countries, annual vaccination is recommended for all adults aged $\geqslant$65 years. Although immunogenicity and efficacy have not been established in all these high-risk groups, the risk from vaccine virus is extremely low because vaccine is inactivated. Healthcare workers and people caring for or living with those at high risk should also be vaccinated. In the USA, annual vaccination is also recommended for women who will be pregnant during the influenza season, and for adults 50–64 years. Because children aged 6–23 months are at substantially increased risk for influenza-related hospitalizations, vaccine policy setting groups in the USA (ACIP, American Academy of Pediatrics, American Academy of Family Physicians), recommend vaccination of all children in this age group (Centers for Disease Control and Prevention 2004; Committee on Infectious Diseases 2003). Many countries have developed plans to prepare for pandemic influenza, which occurs every 10–40 years and can have devastating mortality. Such plans include the rapid production and availability of vaccine to ensure the vaccination either of people at highest risk or of the entire population.

LIVE-ATTENUATED INFLUENZA VACCINE

Cold-adapted live-attenuated influenza vaccines (LAIV) have been used in Russia since 1977 (Murphy 1993; Maassab et al. 1994). These vaccines incorporate influenza virus strains attenuated through growth at 25°C, but with reduced growth at 37°C. The genes for relevant circulating influenza strains can be incorporated into these vaccines by reassortment, and the vaccine is administered intranasally. In controled trials, these vaccines have similar efficacy to inactivated influenza vaccines in older children and adults (Belshe et al. 1998; Nichol et al. 1999; Treanor et al. 1999). In children, where the vaccine was studied during two influenza seasons, vaccine efficacy was also high (86 percent) in the season where the vaccine and circulating virus strains were not well matched (Belshe et al. 2000). In 2003, a LAIV was licensed in the USA and is currently approved for use among healthy persons age 5–49 years (Centers for Disease Control and Prevention 2004).

Japanese encephalitis vaccine

Three types of Japanese encephalitis (JE) vaccines have been developed and used to substantially reduce disease incidence in Asia where the disease is endemic. Inactivated Japanese encephalitis vaccine, currently available in Japan, Taiwan, and other developed countries, is a purified preparation of whole virus (Beijing-1 or Nakayama strain) grown in mouse brain and inactivated with formalin. When given as a three-dose series, the vaccine has 91 percent efficacy in adults (Hoke et al. 1988). Antibody persists for at least 2 years; the need for booster doses is uncertain. Primary immunization consists of three doses given at 0, 7, and 30 days; the third dose may be given at 14 days if the schedule does not permit the longer interval (Centers for Disease Control and Prevention 1993a). Vaccination schedules vary in different countries; some countries use a primary series of two doses 4 weeks apart followed by a booster dose after 1 year. The optimal interval for boosting is not defined, but some countries recommend booster doses every 3 years (Vaccines and Biologicals 2003). The dose for young children (1–3 years) is 0.5 ml, and that for older children and adults is 1.0 ml. No data are available on safety and immunogenicity in children <1 year of age. Adverse events include local reactions (20 percent) and minor systemic symptoms (10 percent). Generalized allergic reactions (angioedema, urticaria)

may occur in 1–6 per 1 000 vaccinees; more rarely, anaphylaxis, respiratory distress, and hypotension have been reported. Rare neurological events such as fatal acute encephalitis have been reported. China also produces an inactivated vaccine (Beijing P-3 strain) grown in hamster kidney cell cultures, which has 85 percent efficacy for a primary series. This vaccine has been widely used in China, but is being replaced with the live-attenuated vaccine.

A live-attenuated vaccine (SA 14-14-2 strain), produced in primary hamster kidney cells, has been developed and widely distributed in China since 1989. Recent studies have confirmed the safety in 13 000 vaccinated children, and demonstrated 80 percent efficacy of one dose and 98 percent efficacy of two doses in children in China (Chambers et al. 1997). The cost of this vaccine (US$0.06 per dose) is substantially lower than that of the inactivated vaccine, and this vaccine is being investigated as a candidate for inclusion in the Expanded Program on Immunization in JE endemic countries. Developing a vaccine schedule compatible with the EPI childhood schedule, and assuring quality of manufacturing are two challenges for this goal.

JE vaccine is recommended for travelers or residents in areas where the disease is endemic (south and east Asia), who potentially will be exposed during the transmission season particularly in rural areas when traveling for 30 or more days (Centers for Disease Control and Prevention 1993a). JE vaccine is used routinely in many of these countries, but use should be expanded to all endemic countries. Assuring a sufficient supply of effective and inexpensive vaccine will be necessary to meet these disease control objectives (Vaccines and Biologicals 2003).

Rabies vaccine

The first attenuated and inactivated rabies vaccines were developed by Pasteur from desiccated infected rabbit brains. Subsequent vaccines were developed from virus harvested from the brains of rabbits, sheep, or goats, but caused neuroparalytic disease in about one per 2 000 recipients, due to residual myelin derivatives. Nerve tissue-derived vaccines continue to be locally produced and used in many developing countries. Vaccines developed from duck embryos reduced the risk of serious adverse events about tenfold (Hattwick 1974). However, in developed countries these vaccines have now been replaced by those grown in diploid human cell lines (World Health Organization 1992). Rabies virus is harvested from cell culture and inactivated with β-propiolactone. This vaccine (human diploid cell strain (HDCS)) is highly immunogenic when given as a multidose series, either alone (pre-exposure) or with human rabies immunoglobulin (HRIG) (postexposure). The vaccine schedule for pre-exposure prophylaxis is a three-dose series at weekly intervals. For people at high continuing risk of infection (e.g. veterinarians, travelers to endemic areas), testing for the presence of neutralizing antibody should be done at 2-year intervals and booster doses given if inadequate antibody is present. Alternatively, booster doses may be given at 2-year intervals without testing. Post-exposure prophylaxis includes a five-dose series: the first dose with HRIG, half infiltrated at the site of the bite and half given intramuscularly elsewhere, followed by additional vaccine doses 3, 7, 14, and 28 days later (Centers for Disease Control and Prevention 1999i). Although episodes of rabies have rarely followed the use of HDCS alone, there have been no reports of vaccine failure with HDCS given with HRIG (Devriendt et al. 1982; Centers for Disease Control and Prevention 1999i). The WHO strongly encourages that more potent and safe cell-derived vaccines should replace nerve tissue-derived vaccines (Vaccines and Biologicals 2003).

HDCS causes few adverse events. Local and mild systemic symptoms may occur in 5–40 percent of recipients. Type III hypersensitivity similar to serum sickness can occur with repeated doses. Although cases of neurological disease, such as Guillain–Barré syndrome, have been reported following HDCS, these are not conclusively linked to the vaccine. New vaccines under investigation include recombinant vaccines containing the surface glycoprotein produced in *E. coli*, mammalian or yeast cells, or vectored into vaccinia and canarypox viruses.

Smallpox (vaccinia) vaccine

Variola virus is the causative agent of smallpox. The mortality and morbidity caused by smallpox lead to development of the first vaccine to prevent human disease. In 1796, Edward Jenner demonstrated that material from a human cowpox lesion could be inoculated into the skin of another person to produce a similar infection and this person was later protected from inoculation with smallpox virus. Smallpox vaccine was initially administered by arm-to-arm inoculation. Advances in vaccine development occurred in the 1800s when growth of vaccinia virus on the flank of a calf provided an adequate and safer supply of vaccine material (Fenner et al. 1988; Henderson et al. 2004). However, the vaccine did not remain viable for more than 1 or 2 days at room temperature. Finally, a process for production of a stable freeze-dried vaccine was perfected in the late 1940s. Though Jenner is believed to have used cowpox virus in vaccination, vaccinia virus strains are neither cowpox nor variola and neutralizing antibodies induced by the vaccine are crossprotective for other orthopoxviruses, including monkeypox virus, cowpox virus, and variola virus (Henderson et al. 2004).

Many vaccinia virus strains were used in vaccine production. In the USA, the New York City Board of

Health strain was used exclusively. Other strains used globally included Lister, Temple of Heaven, Tashkent, Copenhagan, and Patwadanger. Attempts to produce less reactogenic vaccines (e.g. Rivers, MVA (modified vaccinia virus Ankara), CVI-78, and LC 16m8) were successful, but some resulted in lowered immunogenicity. The most satisfactory attenuated strain, the LC16m8 from Japan, did produce a satisfactory immune response in humans and had markedly lower rates of adverse reactions compared with other strains. However, the eradication of smallpox precluded testing this vaccine for efficacy (Henderson et al. 2004).

Smallpox vaccine is administered by intradermal inoculation most commonly using a bifurcated needle, though high pressure jet injectors were also used during the smallpox eradication effort. The vaccine is extremely stable even when stored at extremes of temperature. When the vaccine was being used in routine vaccination programs, it was recommended for healthy infants $\geqslant$12 months of age. Adverse reactions varied by vaccine strain and included severe reactions, including generalized vaccinia, eczema vaccinatum, progressive vaccinia, postvaccinial encephalitis, and vaccinial keratitis, and mild to moderate reactions, such as inadvertent inoculation, urticarial rashes, and Steven's Johnson syndrome (Lane et al. 1970; Centers for Disease Control and Prevention 2001a). Reported complications were more common among primary vaccinees and resulted in death in approximately one per million primary vaccinees.

Smallpox was a major cause of mortality worldwide with overall mortality rates of 20–30 percent. Variola major had case-fatality rates of approximately 30 percent and people who survived the infection were commonly left with residual facial pockmarks. Other serious sequelae included blindness and limb deformities. Variola minor produced less severe illness with case-fatality rates of 1 percent or less (Fenner et al. 1988). In the 1950s, when the disease had been eliminated in developed countries, 50 million cases a year were estimated to still occur globally resulting in 6 million deaths. By the 1960s, 15 million cases and 2 million deaths were estimated to occur per year. This stimulated efforts to eradicate the disease globally which were successful; the last naturally occurring case was in Somalia in 1977 and the World Health Assembly certified global eradication in 1980. Smallpox eradication is one of the greatest public health triumphs of the twentieth century.

After smallpox eradication, the vaccine was withdrawn from routine use globally and recommended only for selected persons at high risk for exposure (Centers for Disease Control 1980). In the USA, the vaccine was recommended for laboratory workers who directly handle cultures or animals contaminated or infected with non-highly attenuated vaccinia virus, recombinant vaccinia viruses derived from non-highly attenuated vaccinia strains, or other Orthopox viruses that infect humans (e.g. monkeypox virus, cowpox virus, vaccinia virus, and variola virus) (Centers for Disease Control and Prevention, 2001a). Vaccination could also be offered to healthcare workers who have contact with contaminated materials from non-highly attenuated vaccinia viruses. In 2002–2003, because of heightened concerns over the use of smallpox virus as a bioterrorism agent, the USA and some other countries reinstituted smallpox (vaccinia) vaccination for national and state teams of clinical and public health workers who were designated to respond to and care for smallpox cases if such cases were to occur (Centers for Disease Control and Prevention 2003c) and for military personnel. Through August 2003, approximately 450 000 military personnel and 37 000 clinical and public health workers had been vaccinated. Serious adverse events following vaccination have been very rare with no cases reported of progressive vaccinia, eczema vaccinatum, or transmission of vaccine virus in a healthcare setting. This may be due to the stringent screening procedures that were in place for this vaccination program among both vaccinees and their close contacts. Unexpected serious adverse events, previously described only in occasional case reports with the NYBOH vaccine strain, have included myo/pericarditis seen among both civilian and military vaccinees (Grabenstein and Winkenwerder 2003; Centers for Disease Control and Prevention 2003d; Cassimatis et al. 2004; Eckart et al. 2004).

New generation smallpox vaccines, grown in cell culture, have been developed. Several of these vaccines have produced major cutaneous reactions (takes) and evoked neutralizing antibody and cell-mediated immune responses in the vast majority of subjects with a reactogenicity profile similar to that of Dryvax (Weltzin et al. 2003; Monath et al. 2004; Greenberg et al. 2005). Other smallpox vaccines under development include more attenuated and replication-deficient vaccinia strains including modified vaccinia Ankara and NYVAC vaccinia viruses. These vaccines hold promise as safer vaccines against smallpox or against complications from vaccinia virus and may also have application for immunization of immunocompromised persons (Belyakov et al. 2003).

Yellow fever vaccine

Yellow fever (YF) vaccine, available since the 1930s, is the live-attenuated 17D strain of yellow fever virus. A single dose, given subcutaneously, is highly effective in inducing protection that lasts for 10 or more years; booster doses are recommended only at 10-year intervals (Centers for Disease Control and Prevention 2002c). YF vaccine causes local and limited systemic symptoms in 2–5 percent of recipients 5–10 days after vaccination. Serious reactions including encephalitis are rare; the risk is highest in children <9 months of age, and the vaccine is not recommended for children <9 months of age and contraindicated in those younger than 6 months. During recent

years, serious vaccine-associated viscerotropic and neurologic adverse events have been reported globally and have resulted in deaths, primarily in the elderly (Barwick et al. 2003; Kitchener 2004; Yellow Fever Vaccine Safety Working Group 2004). Serious viscerotropic disease has been identified in 23 persons, with >60% case fatality, at an estimated rate of 3 per million vaccines. Serious neurologic disease cases, totaling 19 to present, have included encephalitis, encephalomyelitis, and Guillain Barre syndrome, with an estimated incidence of 4 per million vaccines. Both systemic and neurologic reactions are more likely after the first vaccine dose and do not appear due to mutation of the vaccine virus. Risk appears to be elevated in persons with prior thymectomy (Barwick et al. 2003). YF vaccine should not be administered to pregnant women; however, if a pregnant woman is traveling to an endemic area and cannot avoid potential exposure, YF vaccine may be given. YF vaccine is contraindicated in people with anaphylactic allergy to egg or who are immunocompromised. The response to YF vaccine can be inhibited by cholera vaccine; these vaccines should be given at least 3 weeks apart. Because cholera vaccine is rarely indicated, YF should be given first.

Vaccine is recommended for travelers 9 months of age and older going to areas where YF is endemic, and may be required for entry into such countries. Routine YF vaccination at 9 months of age is recommended in all endemic areas; vaccine may also be given in mass campaigns, which are often initiated by the occurrence of outbreaks. The incorporation of YF vaccine into the routine childhood immunization schedule at 9 months of age was initially recommended by the Expanded Program on Immunization in 1988, and its need reinforced by resurgence of yellow fever outbreaks in West Africa during the 1990s (Monath 2001). Through 2002, 26 of 44 endemic countries have implemented the recommendation, but coverage remains low in many of the highest-risk African countries (Global Programme for Vaccines and Immunization 2003).

VACCINES IN DEVELOPMENT

Rotavirus vaccines

Rotavirus is the most common cause of severe, dehydrating gastroenteritis in children throughout the world. Virtually every child becomes infected with rotavirus at least once in the first 5 years of life. Rotavirus has been estimated to cause 20 percent of all diarrhea deaths in children less than 5 years of age resulting in about 500 000 global deaths annually, most of them in developing countries. Even in developed countries, rotavirus infections cause significant morbidity and some mortality. In the USA, approximately 50 000 children are hospitalized with rotavirus gastroenteritis each year and there are 20–40 deaths due to this infection (Centers for Disease Control and Prevention 1999a). Studies in developed countries have found incidence per 100 000 children ranging from 250 (Spain) to >1 000 (Ireland) (Cunliffe et al. 2002).

Rotavirus is a double-stranded RNA virus composed of three concentric shells, the outer capsid contains two structural proteins: VP7, the glycoprotein (G protein) and VP4, the protease-cleaved protein (P protein). These two proteins define the serotype of the virus and are considered critical to vaccine development because they are the target of neutralizing antibodies that are considered important for protection. The first natural infection with rotavirus results in a predominantly homotypic response to the virus; however, subsequent infections elicit a broader, heterotypic response. After a single natural infection, 40 percent of children are protected against any subsequent infection with any serotype, 75 percent are protected against severe rotavirus infection and 88 percent are protected against severe diarrhea (Velazquez et al. 1996).

Live-attenuated rotavirus vaccines have been developed from human rotaviruses, as well as from rotaviruses of other species (rhesus, bovine, and lamb). All rotavirus vaccines in development are live, orally administered vaccines that aim to mimic the protection acquired from naturally occurring rotavirus infection (Cunliffe et al. 2002). Vaccines based on animal viral strains are developed using a Jennerian approach enhanced with modern virological techniques. Animal rotaviruses are considered naturally attenuated for humans. Human rotaviruses recovered from children with acute rotavirus infection have been attenuated by passage in tissue culture and rotaviruses isolated from asymptomatic neonates are considered to be less virulent and have also been tested in clinical trials.

Taking advantage of the segmented genome of rotavirus, reassortants have been developed that retain most of the genome of the parent virus, but include one or both of two key surface glycoproteins, VP7 and VP4, of the human viruses. Multivalent vaccines were developed following the recognition that rotavirus disease is caused by four major serotypes (G1, G2, G3, G4, and P1a). Monovalent vaccines also appear to confer protection against other serotypes (Offit 2002).

In 1998, a tetravalent, rhesus-human reassortant rotavirus vaccine (RRV-TV) was licensed and recommended for routine childhood immunization in the United States (Centers for Disease Control and Prevention 1999a). However, within a year of use, the recommendations for vaccine use were withdrawn due to the risk of a rare but serious adverse event, intussusception, that occurred in approximately 1 in 10 000 infants vaccinated (Centers for Disease Control and Prevention 1999f; Kramarz et al. 2001; Murphy et al. 2001). WHO has strongly encouraged the rapid development of new and safe rotavirus vaccines (World Health Organization 2003b) and the Global Alliance for Vaccines and Immunization (GAVI)

and The Vaccine Fund have supported a project to accelerate development of rotavirus vaccines for the developing world (McCarthy 2003).

In January 2005, a new vaccine for prevention of rotavirus infections was licensed in Mexico. This monovalent live-attenuated human rotavirus vaccine (G1) produced by GlaxoSmithKline (derived from strain 89–12 which was isolated from a rotavirus-infected child in Cincinnati, Ohio, USA) is administered to infants using a two-dose schedule six to ten weeks apart. The first dose is administered between 6 and 14 weeks of age and the second dose between 14 and 24 weeks of age. Vaccine efficacy data from Finland and Latin America show 70–73 percent protection against rotavirus gastroenteritis, 85–86 percent protection against severe rotavirus gastroenteritis and 93 percent protection against rotavirus illness requiring hospitalization (Bernstein et al. 2002, De Vos et al. 2004, Vesikari et al, 2004). Vaccine efficacy was observed against severe rotavirus gastroenteritis caused by G1 and non-G1 types including the emerging G9 type in Latin America. Safety data available on 5024 immunized infants was reassuring with no increases in any solicited symptoms (including fever, vomiting, diarrhea) compared with placebo, however, the sample size from the combined trials was not intended to draw conclusions about the risk for intussusception which was 0.05 percent in the vaccine group and 0.08 percent in the placebo group (De Vos et al. 2004). The other licensed rotavirus vaccine is a lamb rotavirus vaccine, which is available for use in China, however there are few data available on efficacy and safety of this vaccine.

Several other rotavirus vaccines are currently in development. A pentavalent vaccine based on a bovine rotavirus strain (WC-3) reassorted with the common *VP7* and *VP4* genes of human rotaviruses (G1, G2, G3, G4, and PIa) has been well tolerated in phase I and phase II studies (World Health Organization 2003b). Various bovine reassortant vaccines have been studied as three-dose series in infants; a monovalent WC3 reassortant vaccine was 64–100 percent effective and a quadrivalent WC3 reassortant vaccine was 67 percent protective against all rotavirus disease with essentially complete protection against more serious disease (Clark et al. 1996). This protection is similar to that afforded by RRV-TV, which, when given during infancy in trials in the USA, Finland, and Venezuela, had demonstrated 49–68 percent efficacy against any rotavirus diarrhea and 69–91 percent efficacy against severe diarrhea (Rennels et al. 1996; Joensuu et al. 1997; Perez-Schael et al. 1997). The bovine pentavalent vaccine is currently undergoing large-scale safety trials to examine risks for intussusception, the rare serious adverse event of primary concern. Bovine rotaviruses do not replicate well in the infant small intestine and have lower first dose side-effects than the RRV-TV vaccine. Other vaccine candidates under development include human neonatal RV strains and other human-bovine reassortant vaccines. Additional approaches to the development of rotavirus vaccines include DNA vaccination and subunit vaccines (Barnes et al. 1997; Cunliffe et al. 2002; World Health Organization 2003b).

Other viral vaccines

Vaccines for prevention or treatment of human papillovirus (HPV) infections, herpes simplex virus infections (types 1 and 2), and cytomegalovirus (CMV) are in various stages of development and testing. An Institute of Medicine committee to assess vaccine needs for the twenty-first century placed two viral vaccines in its highest priority category (cost savings and QALYs) for vaccine development in the USA: CMV vaccine administration for 12 year olds and influenza virus vaccine administered to the general population and four viral vaccines in the second priority category for vaccine development (costs <$10 000 per QALY saved): hepatitis C virus vaccine for infants, herpes simplex virus vaccine for 12 year olds, HPV vaccine for 12 year olds and RSV vaccine for infants and 12-year-old females (Institute of Medicine 2000). Among these, HPV and HSV are in the late stages of development and with stage III clinical efficacy trials already conducted.

HUMAN PAPILLOMAVIRUS

HPV infection is the most common sexually transmitted disease; the spectrum of disease caused by this virus ranges from benign anogenital warts to cervical and anal cancer. Cancer of the uterine cervix is the third most common cancer in women. Worldwide, approximately 450 000 new cases are diagnosed each year with a 50 percent mortality rate. More than 100 types of HPV have been identified, approximately 30 of these infecting the anogenital region and about 15 of these types causing almost all cervical cancer. HPV-16 accounts for 50 percent of cases of cervical cancer. Thus effective vaccines to prevent and/or treat HPV infection would have enormous global public health impact.

Prophylactic vaccines are designed to prevent infection; the most common type of prophylactic vaccine is made up of viruslike particles (late structural proteins that make up the viral capsid) which are easily synthesized. Animal studies have provided convincing evidence that neutralizing antibodies can block new infection. A number of prophylactic HPV vaccines have been developed and are currently being tested in phase II and phase III trials, including monovalent HPV-16 and HPV-11 vaccines, multivalent HPV-16 and HPV-18 vaccine and a quadrivalent vaccine against types 6, 11, 16, and 18. Titers achieved following vaccination have frequently been 50 times higher than the titers seen in natural infection (Harro et al. 2001; Berry and Palefsky 2003; Schiffman and Castle 2003; Galloway 2003; Kahn and Bernstein 2003). A large placebo-controlled trial of

a HPV-16 L1 VLP vaccine with aluminum hydroxyphosphate sulfate adjuvant administered as three doses at 0, 2, and 6 months in >2 000 young adult HPV-16 seronegative women followed for a median duration of 17.5 months demonstrated 100 percent efficacy for prevention of persistent HPV infection (Koutsky et al. 2002). All nine cases of HPV-related cervical intraepithelial neoplasia occurred among the placebo recipients. The authors concluded that immunizing HPV-16-negative women may eventually reduce the incidence of cervical cancer. Large phase III trials of vaccines targeted against multiple oncogenic types are under way.

Therapeutic vaccines are designed to eradicate or reduce infected calls and are therefore aimed at stimulating cytotoxic T lymphocytes and are directed against early proteins (E6 and E7) which are thought to be responsible for the oncogenic potential of HPV. HPV theraupeutic vaccines have been tested in phase I and phase II trials against cervical cancer and anal dysplasia and include subunit, recombinant vaccinia virus, recombinant fusion protein, and plasmid DNA vaccines (Berry and Palefsky 2003; Stanley 2003).

HERPES SIMPLEX VIRUS

The herpes simplex virus has two biologically distinct serotypes, HSV-1 and HSV-2. HSV-2 infection is acquired either by sexual contact causing herpes genitalis (300 000 new infections per year in the USA) or may be vertically transmitted from a maternal genital infection to a newborn resulting in severe neurological sequelae and death (Morrison 2002; Schleiss 2003; Koelle and Corey 2003; Cunningham and Mikloska 2001). Vaccines to protect against or modify established genital herpes infections have been under development for decades. Many types of vaccines have been evaluated in clinical trials of immunogenicity and prophylactic and therapeutic efficacy (Morrison 2002; Koelle and Corey 2003). Two similar subunit vaccines prepared from recombinant glycoproteins with different adjuvants have completed phase III trials using a three-dose schedule at 0, 1, and 6 months. The HSV-2 glycoprotein B and D subunit vaccine combined with MF59 adjuvant was immunogenic, but not effective in preventing HSV-2 infections (Corey et al. 1999). In contrast, a glycoprotein D-subunit vaccine with alum and MPL adjuvant was 73–74 percent effective in prevention of HSV-2 infections among women who were seronegative for both HSV-1 and HSV-2. The vaccine was not efficacious in women who were seropositive for HSV-1 and seronegative for HSV-2 prior to the study or in men (Stanberry et al. 2002). A prophylactic plasmid vaccine using the gene for gD of HSV-2 has completed phase I studies. Other prophylactic and therapeutic HSV-2 vaccines are in various stages of development and preclinical and clinical testing. Several therapeutic vaccines (plasmid, subunit, and live replication-deficient virus (DISC)) have completed phase I and phase II trials (Koelle and Corey 2003; Morrison 2002).

CYTOMEGALOVIRUS

Cytomegalovirus (CMV) is the most important cause of congenital viral infection, affecting 0.5–1.5 percent of births in the USA. Though most babies with congenital CMV infection have no abnormalities detected at or after birth, 15–25 percent of affected births have abnormalities with sensorineural hearing loss, mental retardation, cerebral palsy, or impaired vision detected at birth or on follow up (Pass and Burke 2002). A vaccine to prevent congenital CMV infection has been designated a top priority for development in the USA by the Institute of Medicine of the National Academy of Sciences (Institute of Medicine 2000). For vaccine development, the major barrier has been the knowledge that naturally acquired infection does not prevent reinfection with a new strain of CMV and that immunity acquired before conception does not always prevent transmission to the infant. These and other issues relevant to development of an effective CMV vaccine have been reviewed (Plotkin 2004b).

An effective vaccine will need to stimulate high levels of neutralizing antibody and cytotoxic lymphocytes and would ideally also stimulate mucosal antibodies (Plotkin 2004b). Vaccines tested to date in phase 1 or phase 2 trials or preclinical studies include various formulations of a live-attenuated vaccine (Towne strain) (phase 1 and phase 2 trials), a recombinant glycoprotein B subunit vaccine (phase 1 and phase 2 trials), chimeric live virus vaccine (Towne and Toledo strains, phase 1 trials), a canarypox vector vaccine with recombinant gB or pp65 (phase 1 trials) and DNA vaccines (preclinical studies) (Pass and Burke 2002; Temperton et al. 2003; Plotkin 2002).

VZV zoster vaccine for prevention of herpes zoster and its complications

Herpes zoster and its complications including postherpetic neuralgia cause a significant public health burden among the aging population in the USA and other developed countries. The incidence of herpes zoster increases with age and it is estimated that about 20 percent of people will develop herpes zoster during their lifetime, resulting in about 600 000 cases of herpes zoster in the USA each year (Hope-Simpson 1965; Schmader 2001). Declines in VZV-specific cell-mediated immunity are associated with increased risk and severity of herpes zoster (Arvin 1996; Oxman 1995). Early studies on administration of a live VZV vaccine (with higher titers than the licensed varicella vaccine) to older adults 55+ have shown that vaccinated persons experience increased VZV-specific cell-mediated immunity responses to levels typical of those observed in younger

persons, in whom the incidence and severity of herpes zoster are lower (Levin 2001). A booster dose of VZV vaccine administered ⩾5 years after the first dose resulted in boosting in VZV-specific cell-mediated immunity (Levin et al. 2003). A large (ca. 37 000) placebo-controlled clinical trial has been conducted in the USA to test whether a VZV 'zoster' vaccine in persons ⩾60 years will prevent or reduce the risk or severity of herpes zoster and its complications. Results of this trial are expected in late 2005. This may lead to a future zoster vaccine to reduce the incidence of herpes zoster or reduce/attenuate the severity of post-herpetic neuralgia and other herpes zoster complications.

SOURCES OF INFORMATION ON VACCINES

Important sources for information on vaccines include the following:

World Health Organization. Provides extensive information on vaccines, vaccine preventable diseases, and global and national statistics on immunization programs and vaccine preventable diseases. Additional information about the World Health Organization and international vaccine programs may be found at www.who.int/vaccines/. Training materials may be found at www.who.int/vaccines-diseases/epitraining.

United Nations Children's Fund. Provides information about state of the world's children and women of child-bearing age, including statistics on immunization coverage and progress of initiatives to eliminate neonatal tetanus and measles, and eradicate polio. Websites include www.unicef.org/ and www.childinfo.org.

Global Alliance for Vaccines and Immunization. Information on the Global Alliance for Vaccines and Immunization may be found at the website www.vaccinealliance.org.

National Health Service, UK. Provides information about immunization recommendations for the UK (www.immunisation.nhs.uk or www.immunisation.org.uk).

National Immunization Program, Centers for Disease Control and Prevention, Atlanta, GA 30333, USA. Extensive resources provide specific information on immunization and vaccine preventable diseases (www.cdc.gov/nip/).

The Report of the Committee on Infectious Diseases of the American Academy of Pediatrics (Red Book). The full report containing recommendations on all licensed vaccines is usually updated every 3 years. The most recent *Red Book* was published in 2003. It can be ordered from the American Academy of Pediatrics, 141 Northwest Point Blvd., PO Box 927, Elk Grove Village, IL 60009-0927, USA or from the AAP website (www.aap.org).

Morbidity and Mortality Weekly Report. This report is published weekly by the Centers for Disease Control and Prevention (CDC) and contains vaccine recommendations, reports of specific disease activity, policy statements, and regular and special recommendations of the ACIP. The MMWR is available online at www.cdc.gov/mmwr/ or www.cdc.gov/nip/acip.

Allied Vaccine Group. A partnership of six independent websites providing science-based, reliable information about immunization (www.vaccines.org).

Immunization Action Coalition. The Immunization Action Coalition promotes physician, community, and family awareness of and responsibility for appropriate immunization of all children and adults against all vaccine-preventable diseases. This US-based site has a wealth of education materials (www.immunize.org).

Official Package Circular. Manufacturers provide product-specific information for each vaccine. Some of these are reproduced in their entirety in the *Physicians' Desk Reference* (PDR) and are dated.

Control of Communicable Diseases in Man. The American Public Health Association publishes a manual at approximately 5-year intervals. The 18th edition (2004) is currently available. The manual contains valuable information concerning infectious diseases; their occurrence worldwide; immunization, diagnostic, and therapeutic information; and up-to-date recommendations on isolation and other control measures for each disease presented. It can be ordered from the American Public Health Association, 800 St. NW, Washington, DC 20001, USA.

Viral vectors for gene therapy

R. MICHAEL LINDEN AND KENNETH I. BERNS

Introduction	1	Adeno-associated virus vectors	9
Retroviral vectors	2	Conclusion	13
Adenoviral vectors	5	References	13
Herpes simplex virus (HSV) vectors	8		

INTRODUCTION

Our increased knowledge of the human genome and the understanding that a large number of human illnesses have a genetic basis have led to a desire to correct the genetic defects underlying these diseases. Human gene therapy has two basic requirements: 1) the wild type gene sequence, and 2) a means of delivering the wild type sequence to the cell so that it may be expressed in an appropriate manner. In the case of a deleterious mutation, which is dominant when heterologous, the therapeutic gene may encode a product which selectively inactivates the deleterious mutant product. While we know and have in hand large numbers of potentially corrective genes, development of successful delivery vehicles or vectors is still at a relatively early stage. To be successful, a vector should be able to introduce the corrective gene (transgene) into the target cell, in most cases transport it to the nucleus, establish a stable state in the nucleus, and express the desired levels of the product encoded by the transgene for extended periods of time. (The latter need not be the case when the intent of the therapy is to engender a protective immune response, i.e. a vaccine or a product intended as a lethal, anticancer agent.) Finally, the vector should not elicit an inflammatory or immune response against the cells that contain the vector.

A variety of delivery systems have been tried including viruses, artificial lipid envelopes, and direct injection of naked DNA (e.g. via the 'gene gun'). Viruses have been the favored instrument since they naturally deliver genes into human cells. The viral genes are expressed in a regulated manner and in many instances persist for extended periods of time. However, there have been only a moderate number of clinical trials and only one has offered good evidence of therapeutic benefit (see below). Several significant problems have been encountered. Either the level of transgene expression has been inadequate or of insufficient duration. The latter is a common problem and is thought to relate to the host immune response to the vector. An immune response to structural proteins in the vector virion leads to inhibition of successful vector delivery on subsequent administration. However, often there is an immune response to expression of the viral genes remaining in the vector. This leads to cell death and frequently is an inflammatory response. It was such a response which led to the only death of a patient in a gene therapy clinical trial after administration of a high dose of an adenovirus vector (see below). Thus, development of vectors which allow sustained expression of the transgene is a common goal; success in this implies the absence of deleterious host response. As an aside, if the patient has a null mutation, it is conceivable that expression of the wild type gene product would elicit an immune response. This is of concern and must be carefully monitored in each case. Another potential concern of gene therapy is the location of the vector within the nucleus. If it remains extrachromosomal and is not able to replicate in synchrony with cell DNA, then it is likely to be diluted out if the cell divides; extrachromosomal vectors are not useful if the goal is introduction of the transgene into progenitor cells. Thus, it would be advantageous to develop vectors that can integrate into the

cell genome so that the transgene can be replicated in synchrony. Almost all of the current vectors do integrate to an extent; retroviral-based vectors do so frequently, other current viral vectors integrate at a low frequency. However, of great significance is the possibility of insertional mutagenesis. If the vector integrates into an important cellular gene, it may inactivate the gene or convert its product into one that is deleterious to the cell. As indicated below, in the only clinically successful use of gene therapy a retroviral vector derived from Moloney murine leukemia virus was used to treat patients with severe combined immunodeficiency disease. However, two of the patients developed a leukemia-like disease because of the site of integration of the vector. While these two have been successfully treated for the complication, the risks inherent in vector integration at random sites remain (Hacein-Bey-Abina et al. 2003).

Although human gene therapy is in its infancy, significant progress has been made in the development of viral vectors. In this chapter we will describe such work with the four viruses that are most commonly used as vectors: adenovirus, herpes simplex virus, retrovirus, and adeno-associated virus.

RETROVIRAL VECTORS

Both in vitro and in vivo gene delivery strategies were pioneered using retroviral vector systems. In the early 1970s the concept of gene transfer using retroviruses for a variety of purposes had been put forward. Although nearly 35 years have passed since, the successful application of this system has mainly been limited to a range of laboratory uses. Only recently has clinical investigation resulted in unambiguous evidence that a therapeutically beneficial result can be achieved. Notwithstanding the long development phase, it must be noted that retroviruses have served as a guiding frontrunner in the development of a range of vector systems that are built on many different animal viruses.

Due to the large amount of research involving retroviruses the aim of this section is not to represent a comprehensive review of the virus and all possible applications, but rather to limit the discussion to those characteristics of retroviruses that are essential to understanding the complexities inherent in this promising gene transfer system.

Retrovirus Biology

The *Retroviridae* represent a large group of viruses that are widely distributed throughout the vertebrates (Coffin et al. 1997). The taxonomy of this virus family has recently been adjusted to reflect our understanding of the molecular biology of the different genera. In general, retroviruses can be divided into two groups, the 'simple' retroviruses among which the alpha-, beta-, and gamma retroviruses are counted and the 'complex' retroviruses with the genera delta-, epsilon-, spuma-, and lenti-retroviruses. Representative members of the retrovirus genera are avian leukosis virus (ALV) for alpha viruses, *Mouse mammary tumor virus* for beta-, and *Murine leukemia virus* (MLV) for the gamma retroviruses. The genera of complex viruses are represented by human T-lymphotropic viruses (HTLV) (delta virus), *Human foamy virus* (spumaviruses) and human immunodeficiency virus (HIV) (lentiviruses). Epsilon viruses are exclusively found in fish and reptiles and will not be further discussed. Based on the observation that the alpha-, beta-, and gamma retroviruses have oncogenic potential these genera have been also collectively called onco-retroviruses. There are several potential mechanisms that can contribute to the transforming potential of these viruses (Suzuki et al. 2002; Mikkers et al. 2002; Lund et al. 2002). First, these viruses are known to undergo recombination at high frequencies resulting in the generation of defective genomes that can be complemented by wild type retroviruses. These contaminating defective genomes have been shown to be able to acquire host cell sequences that, in very rare events can be biologically active. Among those sequences that have been identified to have a significant (detectable) effect on the cell cycle are a number of proto-oncogenes. A second mechanism is inherent to the viral life cycle through the retroviral strategy of integrating a copy of the cDNA into the host genome in a manner that is nonspecific with respect to the chromosomal locus (Stocking et al. 1993). Theoretically the viral cDNA can integrate into or close to a tumor suppressor or a proto-oncogene, respectively. We will discuss the events that have made this theoretical possibility a reality which, in the context of gene therapy, needs consideration.

The members of all retrovirus genera share three coding regions, *gag* (group-specific antigen), *env* (envelope), and *pol* (polymerase) (Goff 2001). The *env* region encodes the envelope protein, the *pol* region the reverse transcriptase, integrase, and a viral protease, and the *gag* region encodes the nucleoproteins as well as the matrix and capsid proteins. The complex retroviruses distinguish themselves from the 'simple' viruses by the presence of additional accessory genes that significantly alter the viral life style.

In general, retroviruses are diploid in that they contain two identical copies of the viral single-stranded RNA. The sizes of positive-strand virus genomes range from seven to 13 kb. As the retrovirus genome is generated by cellular transcription complexes it resembles cellular RNA through the presence of both a 5′ cap and a poly(A) sequence. Additional sequences that are essential to the viral life cycle include the packaging signal (ψ) and the *att*-sites that are required for provirus integration.

Retrovirus life cycle

The life cycle of retroviruses is somewhat complex and in addition to receptor binding, fusion, and uncoating involves reverse transcription (hence *Retro*viruses), nuclear import (either passive through cell division for onco-retroviruses or active in the case of lentiviruses), and integration of the proviral DNA. In order to generate daughter virions, the integrated provirus is transcribed by cellular proteins, followed by splicing and nuclear export. The cytoplasmic RNA is then translated into precursor proteins, and the life cycle is concluded by packaging of full length RNA into the assembled virions. A new round of infection can commence after budding of the virion and proteolytic processing and maturation of the virion. Each of these steps had to be taken into account for the development of retrovirus-based gene transfer strategies. Early problems with this vector system included the contamination by replication competent virus (in this class of viruses a certainly significant concern), low titers of the vectors, only low levels of expression by the transgene, and promoter down-regulation after successful transduction. Overall, the retrovirus gene therapy field has been able to overcome these hurdles to a large extent through many variations of vector design and production. One of the hurdles was the efficiency of receptor binding by retroviruses. All retroviruses that are used for gene therapy purposes are enveloped by a glycolipid membrane. This envelope contains proteins that are responsible for receptor binding and thereby defines the tropism of the viruses and vectors. In general, this receptor-mediated fusion triggers all of the subsequent steps in the viral entry process that are necessary for successful transduction. However, the viral glycoproteins of the envelope also define – and in some cases restrict – the efficiency of gene transfer. A significant development in this regard was the introduction of pseudotyping, a strategy that allowed for the replacement of the native glycoprotein with one of a broader tropism. In the early clinical trials that utilized retroviruses and that were aimed at the transduction of hematopoietic stem cells (HSC), the vectors were pseudotyped with the MLV amphotropic envelope (Chien et al. 1997). A disadvantage of these amphotropic viruses, however, is the relatively low amount of this specific receptor on HSCs. This observation possibly explains the relatively low efficiency transduction of HSCs by amphotropic retroviruses. The protein of choice for the expansion of the tissue tropism was the glycoprotein G from vesicular stomatitis virus (VSV-G) (Yang et al. 1995). While only replacing a single envelope protein, this variation shifts the mode of vector uptake from receptor-mediated fusion to endocytosis that, in addition, requires endosome escape as a result of vesicle acidification. The advantage of this pseudotyping strategy is several-fold. First, the receptor for VSV-G is believed to be a membrane lipid that is ubiquitous in all cells. Second, VSV-G itself mediates pH-dependent endosome escape in addition to its receptor attachment function (Yamada and Ohnishi 1986). As a result, this simple envelope modification conferred a broad tissue tropism and efficient cellular trafficking to many retroviruses, including the increasingly utilized lentiviruses. Conceptually, the introduction of pseudotyping has opened the door to many applications ranging from the broadening of tissue tropism to strategies aimed at the targeting of specific cell types.

Subsequent to membrane fusion, or endocytosis and endosome escape, are several steps that are of importance with respect to retrovirus gene transfer and vector production. Several viral gene products are required for these steps, including reverse transcriptase, integrase, and protease. Although in current vectors the genes encoding these proteins are not present, these, as well as other proteins, are part of the virion and, therefore, do not need to be encoded by the recombinant transfer vector genome.

The reverse transcriptase step during viral replication is of importance with respect to vector design and quality control based on its biochemical properties. The enzyme is characterized by a comparatively slow incorporation rate of <100 nucleotides per second, a poor processivity, a relatively low fidelity with a mis-incorporation rate of approximately one in 104 and the absence of a proof-reading activity (Kerr and Anderson 1997; Oude Essink and Berkhout 1999; Harrison et al. 1998). Although these values have been determined in vitro they do correspond somewhat to the high mutation rate in vivo of ca. one mutation per genome (Burns and Temin 1994). This error rate has been associated to the unique capacity of lentiviruses to evade either host cell responses or the effects of antiviral pharmaceuticals and is therefore biologically significant. With respect to vectors, however, the mis-incorporation rate is somewhat problematic, particularly since it has been documented that the error rate is template-dependent and can therefore not be predicted (Bebenek et al. 1993). An additional characteristic of retroviruses is their diploid genome that, theoretically, could provide a certain genetic stability to the viruses. It has, however, been documented that when genetically different genomes are present the reverse transcription process utilizes both RNA strands resulting in a high degree of recombination.

Nuclear import

In the field of retrovirus gene transfer a frequently discussed ‘roadblock’ is the transport of the viral cDNA into the nucleus. The onco-retroviruses do not encode for a machinery that would actively facilitate nuclear import. On the level of gene transfer application this

reliance on passive import translates into the requirement for cell division prior to transduction (Roe et al. 1993; Lewis and Emerman 1994). Although the majority of applications to date focus on HSC this dependency defines a limitation for the ultimate usefulness of 'simple' retroviruses as it has been demonstrated that even primitive HSC cells are predominantly in a quiescent, nondividing state. This roadblock has been central to the efforts of developing vectors that are based on the complex retroviruses such as the spumavirus human foamy virus (HFV) and, most importantly, lentiviruses. Possibly the most widely explored lentivirus remains HIV-1 (Weinberg et al. 1991; Blomer et al. 1997). Although it might appear counter-intuitive that a virus with such devastating effects on human health would be pursued as an ultimately nonpathogenic gene transfer vector, it has been exactly this phenomenon that resulted in the accumulation of an impressive body of information about the biology of the virus, which has allowed the accelerated development of this class of gene transfer vectors. Among the viruses explored in this class are both HIV-1 and 2, simian immunodeficiency virus (SIV), feline immunodeficiency virus (FIV), bovine immunodeficiency virus (BIV), and equine infectious anemia virus (EIAV) and visna virus. Despite this reorientation of the field towards the complex retroviruses that is mainly based on their nuclear import potential, the underlying mechanisms have not yet been identified and the subject is somewhat plagued by controversy. Similarly, foamy virus nuclear import is not understood, although a pathway that involves different cellular components (and is therefore distinct from lentiviruses) has been proposed (Saib et al. 1997). It must be pointed out that aspects of these unknown mechanisms possibly underlie the observation that in some differentiated tissue in vivo transduction by lentiviruses might require cell division (Park et al. 2000).

Provirus integration

The subsequent step in viral infection, cDNA integration, is one of the clearly attractive features of retroviruses. This step is an essential component of the viral life cycle and it is thus not surprising that the mechanism is quite efficient. Consistent with the life cycle of retroviruses in vivo the integration allows persistence of the viral genome in dividing cells.

Mechanistically, after formation of the double-stranded cDNA and nuclear import, the generation of circular molecules has been observed. To date, it is believed that the presence of certain circular species can be used to detect nuclear import, but it also has become clear that these molecules are poor substrates for the integration process (Lobel et al. 1989). This leaves unanswered the question of function of these circularized retroviral genomes. It is reasonable to assume that these structures represent a side product of integration rather than an essential part of the mechanism. However, of some concern is the possibility that the circular molecules can – transiently – contribute to transduction efficiency thereby skewing the estimated gene transfer rate (Haas et al. 2000).

A key concern, however, with respect to retroviral gene transfer, has been the potential of insertional mutagenesis. In general, the risk for tumor transformation as a result of a single insertion event could be estimated to be rather low in light of the well-documented notion that the establishment of malignancy in differentiated tissue requires multiple 'hits'. Nevertheless, the application of vectors that integrate in a nonspecific manner into the genome in rapidly dividing cells adds the additional level of selection to the consideration. That is, if virus genomes randomly integrate in cells that are first expanded (either in vivo through growth advantage over nontransduced cells or ex vivo through selective pressure) and then differentiated, it is feasible to hypothesize that cells with integration events into a tumor suppressor gene or close to a proto-oncogene are likely to be enriched. In this 'selection' scenario, a single-hit, vector-induced mutation might be sufficient to contribute to the subsequent establishment of malignancies. In this context it must be emphasized that in nearly 15 years of clinical experimentation with retroviruses, no integration-related cancer has been reported. Recently, however, in what might represent the first clinically successful gene therapy trial to date, two patients developed a T-cell leukemia that was correlated to the insertion of the retroviral vector. The trial was designed to treat X-linked severe combined immunodeficiency (X-SCID) using an MLV-based vector expressing the γ-c chain cytokine receptor. In the affected children the absence of this receptor function results in the inability to respond to cytokine signaling and therefore the absence of functional T- and natural killer (NK) cells (Hacein-Bey-Abina et al. 2002; Fischer 2000; Soudais et al. 2000). Approximately 30 months after the engraftment of retrovirally transduced cells, two of the patients developed a leukemia-like condition that required chemotherapeutic treatment. Since, it has been determined that in both patients the retroviral cDNA had integrated into and close to the LMO2 locus, respectively. Understandably, these adverse side effects have caused considerable anxiety within the gene therapy community, the government regulators, and beyond (Hacein-Bey-Abina et al. 2003; Check 2002a,b). However, this case, that was characterized by the unique willingness of the investigators to share the pertinent information with the scientific community and the public, deserves further analysis. First, among the more than ten treated patients, only two have fallen ill with leukemia. Second, a third patient is said to have insertion into the *LMO2* locus but did not develop leukemia within a comparable time frame. Third, within the

context of numerous clinical and preclinical experiments employing retroviruses these are the first serious adverse effects documented to result from insertional mutagenesis by a retrovirus. Taken together, these observations indicate that several parameters came together in this case. It is unlikely that random integration (in these cases into the *LMO2* oncogene that has previously been reported to play a role in leukemia development) by the vectors alone caused the development of the malignancies. It is more likely that the cancer in these two patients has resulted from a combination of factors that include the *LMO2* alterations, the unregulated transgene expression (note that the γ-chain of the cytokine receptor for IL2, 4, 7, 9, 15, and 21 naturally confers a selective advantage for the transduced cell) and the nature of this particular treatment strategy that is based on the proliferation of a few cells to repopulate this component of the hematopoietic system. Therefore, the importance of these events to retrovirus-mediated gene therapy in general is unclear and will likely only be assessed through further pre-clinical and clinical trials.

The further steps in the retroviral life cycle, transcription of the provirus, packaging and maturation are mainly important for considerations regarding the vector production and purification. Although most clinical trials to date have been conducted ex vivo, increasingly efforts are underway to develop strategies that employ in vivo delivery. These approaches confront the retrovirus gene therapy with issues related to anti-virus immunity. For example, it has been shown that the glycoprotein G of VSV can serve as an efficient antigen through which the vector can be inactivated (DePolo et al. 2000) by human serum. In order to address this concern, alternative envelopes or PEGylation of these vectors have been proposed (Croyle et al. 2004).

Vector design strategies

Both simple and complex retrovirus vector development have undergone numerous generations, including many variations in the strategy to provide the helper functions necessary to generate infectious virions (for a review of these developments see Brenner and Malech (2003)). Of particular concern in this regard has been, and still are, the attempts to minimize and exclude the risk of generating replication-competent viruses through recombination events. In brief, the approaches can be summarized by two different strategies: first, the use of stable cell lines that contain the genes encoding all necessary helper functions stably integrated within the genome of the producer cell line. A construct containing the transfer vector is then transiently transfected into the producer cell line and the recombinant virus is shed into the medium. Notably, only the essential retrovirus components are retained within the transfer vector, including the packaging signal ψ and the viral LTRs. In lentiviruses these elements also include the rev responsive element (RRE). The second strategy, transient transfection of both the helper functions and the transfer vector has been more employed during the development of lentivectors. The overall theme during this development process, that has now undergone more than three generations, has been to delete as many of the accessory factors as possible. This was particularly important since some of these factors are toxic to cells and enhanced the likelihood of eliminating the generation of replication competent virus. In exchange, however, both titers and transgene expression levels after gene transfer have been reduced. This problem has then been addressed by the addition of different promoters driving the transgene and the incorporation of post-transcriptional regulatory elements such as the one identified in Woodchuck hepatitis B virus (WHV). An additional safety element has been introduced through the use of self-inactivating (SIN) vectors (Zufferey et al. 1998). In these vectors there is a deletion in the 3′LTR including the TATA box. This deletion is transferred to the 5′ LTR resulting in its inactivation. While this modification does not result in lower titers or reduced transduction efficiency it considerably adds to the safety of these vectors.

Finally, retrovirus based systems have been the frontrunners of viral vector development and are likely to contribute significantly to both experimental and therapeutic gene transfer in the future. Several hurdles, however, will need to be overcome. These include the moderate titers achieved with current production schemes as well as regulatory restrictions with regard to the use of a vector that is derived from a serious human pathogen.

ADENOVIRAL VECTORS

The development of gene transfer for the future treatment of a variety of diseases has been accompanied by a number of breakthroughs and prominent setbacks. Due to their early presence in the gene therapy field, adenovirus-based vectors have been at the center of some of the most widely publicized events. In the following section we will outline the basic aspects of adenovirus biology, the early contributions to gene transfer, the culmination of extensive research, and vector-development efforts in the serious adverse effects leading to the death of Jessie Gelsinger and the redefinition of the entire gene therapy field as a direct result.

Adenovirus biology

Adenoviruses were discovered in the 1950s as pathogenic agents found in human adenoid tissue (Rowe et al. 1953) and from military recruits suffering from respiratory illness (Hilleman and Werner 1954). Soon thereafter, these agents were named *adenoviruses.* Since then

many viruses with similar characteristics have been isolated from humans and animals resulting in more than a hundred members of this virus group, 47 of which are classified as human adenoviruses. To date the family of *Adenoviridae* is divided into four genera, the *Mastadenoviruses* to which the human viruses belong, those limited to bird infections, the *Aviadenoviruses* (Norrby et al. 1976), the ovine *Atadenoviruses* (Both 2004), and the *Siadenoviruses* that are found in frogs and turkey (Davison 2000). During the early studies on adenovirus biology a key observation was made in 1962 when Trentin found that a human serotype of adenovirus (Ad12) could induce tumors in newborn hamsters (Trentin et al. 1962). Although to date no evidence has been found that adenoviruses are capable of inducing cancer in humans, this first notion of DNA viruses as tumor-inducing agents set precedence for numerous subsequent discoveries in the field of DNA tumor viruses. Furthermore, the use of adenoviruses as model systems to study cellular phenomena led to a number of highly significant findings related to cell cycle regulation, DNA replication, and gene expression. The most prominent discovery was made by Sharp and colleagues and, independently, the laboratory of Roberts who demonstrated the presence of spliced mRNA segments in adenovirus late genes (Berget et al. 1977). This discovery led to the identification of introns and ultimately to our current understanding of splicing and was awarded the Nobel Prize in 1993.

The capsids of adenovirus are not enveloped and form an icosahedral structure of approximately 100 nm in diameter. Each capsomer (one of 252 capsid subunits) contains hexons (at the six-fold axis), pentons (at the five-fold axis), a penton base, and an extending fiber that gives adenoviruses their characteristic appearance (Table 1).

The genome of adenoviruses (Shenk 2001) is flanked by inverted terminal repeats (TR) of approximately 160 nucleotides that contain origins of DNA replication. The TRs are covalently attached to terminal protein that is essential to the virus replication cycle. In addition, the left-end DNA contains a number of signals between nucleotides 200 to 400 that are essential for the packaging of the viral genome into preformed empty capsids (Grable and Hearing 1992; Hearing et al. 1987). Together, the packaging elements, the TRs and the 5′ covalently attached terminal proteins are sufficient *cis* elements for efficient packaging. This has enabled the development of a new generation of adenoviral vector (gutless vectors) that contain only these minimal *cis* elements flanking the gene cassette of interest (potential therapeutic gene). The viral genome is divided into two regions, the early region (encoding the E1, E2, E3, and E4 transcription units) with two delayed early transcripts (IV and IX) and the late region (L1–L5). In addition, the only RNA polymerase III product, VA, from the adenovirus genome is also expressed in the late phase. In general, the transcription units of adenovirus encode proteins of related functions. E1 units encode proteins involved in transcription (E1A) and the inhibition of apoptosis (E1B), while E2 products are involved in DNA replication. E3 products have functions involved in overcoming host defense mechanisms. It might be noteworthy that a generation of viral vector constructs has omitted the E3 region in order to gain larger capacity for transgene cassettes. The exception to the functional unity within the transcriptional units is provided by the E4 region that encodes proteins that are involved in a range of different functions, including transcription, replication, RNA trafficking, and apoptosis (Leppard 1997). Finally, the family of late genes is responsible for the generation and maturation of the viral capsids.

Vector design strategies

The rich history in adenovirus research has left us with a wealth of tools for the generation of recombinant Ad-based vectors. Strategies have been developed that allowed the generation of mutated and deletion variants

Table 1 *Selected characteristics of the most frequently used gene delivery vectors*

Vector	Genome capacity	Tropism	Immune response	Genome persistence	Limitations
Onco-retrovirus	8 kb RNA	Dividing cells	Limited	Integrated, long-term	Require cell division, insertional mutagenesis
Lentiretrovirus	8 kb RNA	Dividing and arrested cells	Limited	Integrated, long-term	Limited titers and some applications, insertional mutagenesis
Herpes virus	40–150 kb dsDNA	Particularly suited for neurons	Strong	Episomal, long-term possible in neurons	Immune rejection of infected tissue (except neurons)
Adenovirus	8–30 kb dsDNA	Broad	Strong	Episomal, transient	Innate and cellular immunity
AAV	5 kb ssDNA	Broad	Limited	Episomal, long-term	Limited packaging capacity, slow onset of transduction

of the adenovirus genome that could still be grown to appreciable titers of recombinant viruses. One of the essential reagents to this end is the human embryonic kidney cell line 293 (HEK293) (Graham et al. 1977). This cell line contains the E1 genes of Ad5 and thus allows the production of high titer stock of E1 deleted adenoviruses. Many of the recently employed recombinants simply replaced the E1 region by the transgene of interest. A corollary of the E1 deletion is, that because of the transcriptional activation functions of E1A, the remaining genes of the Ad-vectors cannot be expressed to appreciable amounts. A second aspect of adenovirus biology that has facilitated the development of viral vectors is the capacity of the virus for genome recombination and thus the possibility for insertion of transgenes into the approximately 36 000 bp genome. Wild type adenovirus undergoes recombination at high efficiency in cells that are co-infected with different serotypes (Williams et al. 1975). The precise mechanism of these recombination events is not entirely dissected to date. However, it has been demonstrated that DNA replication is required for these events to occur (Young et al. 1984). This requirement hints at DNA replication intermediates as likely substrates for the extraordinarily efficient recombination reaction. The proposed model for adenovirus DNA replication predicts that replication initiates at both origins within the TRs and proceeds in a unidirectional manner resulting in the displacement of the strand that is opposite of the replicated strand. This strand displacement mechanism results in generation of a single-stranded genome that can form a panhandle structure through hydrogen bonds between the terminal repeats (Lechner and Kelly 1977). It is this single-strand replication intermediate that is hypothesized to be involved in recombination with other serotypes through either strand-invasion of double-stranded genomes or simple annealing to single-strand intermediates of the other serotype followed by DNA repair (Flint et al. 1976). In order to conclude the DNA replication cycle, both products generated in the first round of replication, the double-stranded genome as well as the single-stranded displaced strand, can serve as templates for further replication.

Adenovirus pathogenesis

Much is known about the pathology and pathogenesis of adenovirus infection in humans and it would exceed the purpose of this chapter to summarize the extensive literature addressing these aspects. However, in view of the application of adenovirus as a gene transfer tool, several observations are noteworthy. With respect to preclinical evaluation of the safety of recombinant adenovirus, a key feature is the species dependent replication cycle of these viruses. Although there is some cross-permissivity in closely related species, no frequently used animal model is suited, e.g. to evaluate the replication of human adenoviruses. This species specificity is illustrated by the requirement of SV40 co-infection to achieve productive replication of human adenovirus 2 even in monkey cells (Klessig and Anderson 1975). Possibly the only model that was able to faithfully replicate the clinical consequences of wild type adenovirus infection in both the respiratory tract as well as in the eye was the cotton rat (Prince et al. 1993; Tsai et al. 1992). Host range mutants have also been described that allow replication of Ad2 and 5 in simian cells (Klessig and Grodzicker 1979; Klessig and Hassell 1978). Although it appears of limited importance with respect to toxicity evaluation of replication deficient recombinant adenoviruses, the availability of faithful animal models would facilitate the evaluation, e.g. of contaminating wild type particles.

An additional aspect of the infectious cycle of adenovirus is the general absence of toxins. Possibly the only exception to this rule is the capsid component penton. It has been demonstrated that, when added to cells in culture, penton leads to a clear cytopathic effect, even though the mechanism of this phenomenon is not yet fully understood (Pettersson and Hoglund 1969; Seth et al. 1984).

A more complex phenomenon of adenovirus infection is the host immune response to infection. Although a comprehensive description of the immunity to adenoviruses is certainly beyond the scope of this chapter, certain aspects deserve further elaboration in light of the death of Jessie Gelsinger, a patient at the University of Pennsylvania who died of the consequences of adenovirus mediated gene transfer that resulted in an overwhelming immune response and ultimately fatal multiple organ failure. It should be pointed out that this event resulted in profound and lasting changes in the then emerging field of gene therapy research.

Much like many viruses, wild type adenovirus encodes a number of immunomodulatory functions and it must be highlighted that recombinant adenoviruses that are devoid of the expression of viral genes are consequently vulnerable to the effects of capsid-mediated host responses. It has been known for more than a decade now that non-permissive infection by adenovirus results in an activation of cytokine networks (including IL1, IL6, and TNF responses) (Ginsberg et al. 1991; Ginsberg and Prince 1994). Immediately after infection the product of the early gene E1A inhibits interferon-controlled gene regulation while VA-RNA blocks PKR activity. Subsequently, the products of the early region 3 counteract apoptosis and the pro-inflammatory actions of TNF-α. Due to the deletion of E1 (involved in the regulation of both cellular and viral gene expression) in most recombinant adenoviral vectors, there is no controlled expression of the adenovirus 'stealth factors' that in fact make up approximately one third of the wild type genome. It can therefore be of no surprise that the

high-dose delivery of recombinant adenovirus (deleted for E1 and E4) could result in severe adverse effects observed in one of the patients enrolled in the study.

In general, a major hurdle in the development of future gene therapy is represented by the multifaceted host responses against viral infections. Adenovirus vectors have demonstrated this problem starting from the observation that transgene expression in all tissues was of transient nature in immune competent animals and culminating in the death of Jessie Gelsinger that is now understood to have resulted from the innate immunity to the viral vector (Marshall 1999, 2002).

Adenovirus vectors

To date, several strategies have been employed to engineer adenovirus vectors. It is noteworthy that most of the more recent strategies were designed to minimize the immune-mediated toxicity of the vectors. While first-generation vectors were deleted for E1 and E3 in order to both prevent late-gene expression and to allow for deficient cloning capacity, subsequent modifications such as the deletion of E2 and E4 were designed to lower the toxicity in animal models (Marshall 1999, 2002). The most recent variation on adenoviral vector design represents a more conceptual development in that all of the adenoviral genes are deleted, leaving only the terminal repeats and a packaging signal. These vectors are termed 'gutless' or helper dependent (HD) adenovirus vectors and clearly resemble the design of first-generation adeno-associated virus vectors (Morsy and Caskey 1999; Cregan et al. 2000; Zhou et al. 2002; Palmer and Ng 2003; Imperiale and Kochanek 2004; Mitani et al. 1995; Parks et al. 1996). Although a number of studies clearly demonstrated that transgene expression as a result of HD-adenovirus delivery, it has become evident that transduction is not persistent for the life span of the animal. It remains to be addressed whether the, albeit delayed, loss of transgene expression is due to vector genome loss, residual immune response to capsid components or to contaminating replication competent helper adenovirus. Although a number of strategies have been designed in order to purify the HD vectors, the biophysical similarity between HD-vectors and their helper virus have made this attempt challenging (Palmer and Ng 2003).

Finally, a different strategy takes advantage of the toxicity of replicating adenoviruses and has been proposed for use in cancer gene therapy. The first strategy proposed involved ONYX015, an adenovirus vector that was deleted in E1B (Bischoff et al. 1996). It was hypothesized that the deletion of the inactivating p53 binding partner would render this virus conditionally permissive in p53 deficient cells. Preclinical studies using this construct were sufficiently promising for clinical studies to be conducted (Nemunaitis et al. 2000; Lamont et al. 2001; Nemunaitis and O'Brien 2002a,b). This study, however, that is in progress in patients suffering from head and neck cancers, has not yet been able to demonstrate a clinical benefit although tumor-specificity was documented (Lamont et al. 2001). It is not clear what additional, possibly cellular, factors are required in order to convert tumor selectivity into clinical benefit. A number of current preclinical and clinical studies are underway to address this question and to validate this promising approach.

HERPES SIMPLEX VIRUS (HSV) VECTORS

Herpes simplex virus is a large DNA virus that has been well characterized (Roizman and Knipe 2001). It has a predilection for infection of neural tissue; for this reason it has been of special interest as a potential vector for gene therapy of the central nervous system. The genome is a linear, double stranded DNA composed of 152 kb which contains two unique segments, each bounded by an inverted terminal repeat. The two segments can be arranged in either orientation with respect to one another so that there are four possible sequence arrangements. The overall genome is bounded by two short terminal repeats. The capsid is icosahedral and enveloped in a trilaminar lipid membrane into which are embedded ten virally encoded glycoproteins, some of which are involved in cellular attachment. A protein matrix, the tegument, separates the nucleocapsid from the envelope. Functions of proteins in the tegument include regulation of induction of viral gene expression and the shutoff of cellular protein synthesis.

HSV life cycle

HSV gene expression is temporally regulated. Induction of immediate early (IE) gene expression requires VP16, a structural protein in the virion tegument. Only two (ICP 4 and 27) of the five IE proteins are required to turn on later gene expression, the other three (ICP 0, 22, and 47) are not required for productive infection of cell cultures. (One of the non essential genes, ICP 47, is involved in immune evasion in the intact host.) Early (E) gene expression products are required for viral DNA replication, while late (L) genes encode the structural proteins. Overall, the HSV genome encodes 84 proteins (Roizman and Knipe 2001). While deletion of the nonessential early genes helps reduce potential pathogenicity in the intact host, deletion of the required IE genes renders the mutant virus unable to replicate and, therefore, absolutely defective. In this manner it is possible to construct HSV vector viruses which should be nonpathogenic, as long as they do not elicit a toxic immune response in the host. The ability to delete significant regions of the genome and the overall large size of the DNA means that the space available for transgene insertion is large. Vector production can be

carried out in cell lines which constitutively express the IE genes which have been deleted from the vector construct. In practice, high titer preparations of recombinant HSV can be made (Advani et al. 2002).

The HSV life cycle is notable for the ability of the virus to establish persistent infections in various ganglia. Primary infection occurs through the skin or mucosal surface where the initial round of viral replication occurs. Progeny virions enter neural axons and are transported in a retrograde manner to the cell body where the virus can establish a latent state in which the viral genome is maintained as an extrachromosomal, duplex circular molecule. Latency can be maintained for periods of months or years until activation, usually induced by some form of stress to the host (e.g. superinfection or exposure to toxic stimuli). Activation leads to production of infectious virus, an event typically manifested in the case of HSV as a cold sore. To the extent that persistent infection can be maintained without the threat of multiplication during the primary infection or during reactivation, HSV represents a good potential vector for human gene therapy.

HSV vectors

An alternative approach to the construction of HSV-based vectors, known as amplicons, is to create plasmids which contain both bacterial and HSV origins of DNA replication, viral genomic packaging, and cleavage signals. All of the HSV functions which are required for DNA replication, structural proteins, etc. can be supplied in trans. If the complementing genes have none of the signals required for replication or packaging and no sequences homologous to the amplicon sequences, only the amplicon should be replicated and packaged into vector virion particles. Thus, amplicons are potentially capable of containing extremely large transgenic sequences. However, despite the lack of homology between amplicon and the HSV helper sequences, in practice it has proven difficult to produce vector preparations devoid of wild type virus.

All of the IE genes, with the exception of ICP 47, are cytotoxic; thus deletion of the other four would be desirable. However, it is difficult to achieve high titer preparations if all of the IE genes are deleted. ICP 0, which is a potent transactivator, appears to greatly facilitate vector production. ICP 0 is metabolized differentially in neurons and glial cells; it appears to be degraded in the former. If so, it is possible that vectors containing ICP 0 could have two potential benefits. They could be used for persistent infection of neurons without toxicity, yet they would retain cytotoxic properties which would make them of value in the treatment of central nervous system tumors of glial cells.

There is extremely limited transcription of the HSV genome during a latent infection. Overlapping transcripts are produced from two promoters, LAP1 and LAP2. One approach to vector construction is to create hybrid promoter enhancers which would incorporate a latency promoter so that expression would occur in the latent state. This has proven possible to do. Transgenes inserted into the latency transcript have been found to be expressed in dorsal root ganglia and motor neurons, as well as in the brainstem motor nuclei of mice.

In a primary HSV infection, virus enters at an epithelial surface and undergoes a round of replication before entering the axon and being transported to the body of the neuron in a ganglion. A consideration was whether replication-defective vectors could be expected to get to the axon and be transported in a retrograde fashion. The potential requirement for an initial round of replication at the site of entry can be overcome by introducing a sufficient amount of the vector. Another way of enhancing vector uptake by axons is to inject the vector intramuscularly in which case it is in proximity to the synapse between the axon and muscle. Of course, it is possible to inject virus directly into the brain in cases where the severity of the disease (i.e. glial cell tumors) would warrant a neurosurgically mediated method of introduction of the vector.

ADENO-ASSOCIATED VIRUS VECTORS

The human parvovirus adeno-associated virus (AAV) has been appreciated to have considerable promise as a vector for human gene therapy (Samulski 2003). AAV is a small, nonencapsidated, icosahedral virus with a linear single-stranded DNA genome (Linden and Berns 2000). The virion has a diameter of ~26 nm. The species type virus AAV2 genome contains 4.68 kb. Although the small size of the genome presumably constrains the size of any transgene, the biological properties of the virus have prompted its development as a gene therapy vector. Additionally, recent experiments have suggested that the constraints on transgene size may be overcome (see below). AAV is widespread in nature throughout vertebrate species. There are at least six human serotypes. The most common are the closely related AAV2/3; about 90 percent of adult humans are seropositive (Blacklow et al. 1971). In spite of this evidence for very common infection by the virus, there has been no evidence of association of the infection with any human disease. Indeed there have been several studies which suggest that infection by AAV may protect women against developing cervical carcinoma (Georg-Fries et al. 1984; Mayor et al. 1976; Sprecher-Goldberger et al. 1971).

AAV life cycle

AAV does not undergo productive infection in healthy cells in culture unless there is concomitant infection with

a helper virus, such as an adenovirus or a herpesvirus (Berns and Linden 1995). Several types of the latter have been shown to help AAV multiplication. It is possible to render cells permissive for low levels of AAV replication by treatment of the cells with various genotoxic agents (e.g. UV or gamma irradiation, or various chemical carcinogens) (Yakobson et al. 1987). If AAV infects a healthy cell in the absence of a helper virus coinfection, the viral DNA is uncoated, but undergoes minimal, barely detectable conversion into the double-stranded form and is then integrated into a specific site on the q arm of chromosome 19. As long as the cell remains healthy the viral genome remains relatively quiescent in the integrated form; rescue and replication seems to be inhibited by a very low level of expression of a viral regulatory protein. If the cell is stressed by superinfection with an adenovirus or a herpesvirus or by exposure to certain genotoxic agents, the integrated genome is 'activated,' rescued, replicated, and infectious virus made. As described here, AAV is close to a perfect parasite in that it uses the host to perpetuate the viral genome while doing no harm to the host. If, for unrelated reasons, the host is stressed, the virus activates its genome to form infectious particles to find a new host to infect. The facts that AAV causes no apparent disease, yet can persist for extended periods of time in an integrated state, were significant in alerting investigators to the potential use of AAV as a vector for human gene therapy (Hermonat and Muzyczka 1984).

AAV genetics

The linear, single stranded DNA genome contains two open reading frames bounded by inverted terminal repeats (ITR) of 145 nucleotides (nt). The outer 125 nt constitute an overall palindrome which contains two smaller palindromic sequences, one on either side of the midpoint of the overall palindrome (Lusby et al. 1980). Thus, when the terminal 125 nt sequence is folded on itself to maximize potential base pairing, a T- or Y-shaped structure is formed. The open reading frame in the left half of the genome encodes four regulatory proteins (Rep 78, 68, 52, 40) which have overlapping sequences and which regulate all phases of the AAV life cycle. The four proteins are the consequence of two promoters (P5, P19) and an intron (Lusby and Berns 1982; Mendelson et al. 1986). Both spliced and unspliced forms of the two mRNAs are translated, hence four Rep proteins.

The open reading frame in the right half of the genome encodes three structural proteins (P85, P75, P60), again with overlapping sequences (Srivastava et al. 1983). The three coat proteins are the consequence of alternative splicing and the use of an unusual ACG start codon for translation of the middle protein (Muralidhar et al. 1994).

Site specific integration

AAV integration into the human genome is unique in that it is the only known example of a human virus integrating at a specific site (Kotin et al. 1990, 1992; Samulski et al. 1991). The site (at 19q 13.4) is just upstream from the gene for one of the myosin binding proteins (MBS85) and downstream from the troponin I gene (Dutheil et al. 2000, 2004). The integration site sequence has been dubbed *AAVS1* and is a potential promoter. It is likely that the sequence has a relatively open chromatin structure that would render it susceptible to AAV integration. Within the AAV ITR there is a Rep binding site (RBS) and a terminal resolution sequence (TRS) that is nicked by Rep in a sequence-specific manner. A similar sequence arrangement is present in *AAVS1*. Genetic analyses have shown that both the RBS and the TRS are required for site-specific integration (Linden et al. 1996a,b). Interestingly, the length of the intervening sequence is not absolutely fixed, but the sequence significantly influences the frequency of integration (Meneses et al. 2000). About half of the junctions between viral and cellular DNA occur within the viral ITR; the other half occur just upstream of the viral promoter for Rep at map position 5 (p5 promoter) on the genome (Samulski et al. 1991; Giraud et al. 1995). This is of potential significance because studies of plasmid based integration suggest that the sequence from the end of the ITR to the p5 promoter greatly facilitates the frequency of site specific integration. In model systems where *AAVS1* is on a plasmid, the specific integration site clusters around the *AAVS1* RBS. Integration into the genome does not appear to be as tightly clustered. At the cellular level, integration into the q arm of chromosome 19 has been estimated to occur with a relative frequency of 70–100 percent. More recent studies have trended toward the higher figure. At the cellular level the AAV genome is integrated as a tandem repeat which undoubtedly facilitates rescue. Both head-to-head and head-to-tail repeats have been reported (Cheung et al. 1980; McLaughlin et al. 1988). Whether the tandem arrangement is the consequence of limited viral replication or recombination has not been determined.

AAV vectors

Despite the fact that one of the attractive features of the AAV life cycle, which suggested its use as a vector for human gene therapy, was its ability to persist in a latent form by site-specific integration, all of the AAV vectors which have been tested to date lack the Rep gene. The typical AAV vector consists of the transgene(s) with appropriate regulatory sequences flanked at the ends by the AAV ITR. Omission of Rep has been a consequence of two considerations: 1) the Rep gene occupies

half of a small genome, so omission doubles the transgene capacity of the vector; 2) Rep is a potent regulatory protein which might be toxic under certain conditions. Since almost all vectors also lack the p5 promoter sequence which has been found to enhance the frequency of site specific integration (Philpott et al. 2002), the current AAV vectors do not have a propensity for site specific integration and most often persist as extrachromosomal elements. The extrachromosomal elements are quite stable and can persist for a year in the mouse model. It seems likely that structures, which can be assumed by the AAV ITR protect the vectors from exonucleolytic degradation. One year after introduction of AAV vectors into skeletal muscle in the mouse a significant fraction of the vector DNA was found to be integrated at apparently random sites in the SCID mouse genome (Song et al. 2001).

AAV virion vector production requires three elements: 1) the vector construct, a transgene flanked by AAV ITRs within a plasmid vector; 2) the AAV genes for Rep and the structural proteins, either in a plasmid or integrated into the genome of a cell line; 3) required adenovirus helper functions, again either on a plasmid or integrated into the genome of the cell line. The appropriate combination of plasmids are transfected into cells in culture to produce vector virions. The major concern is vector production without contamination with either wild type AAV or adenovirus. Using only the adenovirus helper genes, which constitute a small fraction of the adenovirus genome, means that contamination with adenovirus is not a significant concern. Contamination with wild type AAV, on the other hand, is a major concern. Recombination between the vector construct and the AAV helper construct can occur readily if any homology remains between the two DNAs. Even in the absence of overlap homology illegitimate recombination can occur; hence, it is difficult to produce AAV vectors in which no contamination with wild type virus is detectable. In the past it was difficult to generate high titer preparations of AAV vectors. However, development of new cell lines, better helper plasmids, the use of cell factories, and column-based methods of purification have greatly improved the ability to generate sufficient amounts of clinical grade virus so that human gene therapy trials are feasible.

Several AAV serotypes have been tested with respect to their relative abilities to transduce various tissues. Hybrid vectors have been used in which an AAV2 vector genome is packaged into capsids of various AAV serotypes. Striking differences have been observed with respect to the frequency of transduction observed with the different hybrids. Rabinowitz et al. (2002) observed that in vivo Type 1 was the most efficient in transducing liver and muscle, followed by types 5, 3, 2, and 4, in that order. However, when transduction of the rat retina was attempted, types 4 and 5 were the most efficient, followed by type 1. Although others have found some relative differences in the ability of specific serotypes to transduce various tissues, the general principle is that there are significant differences and that these differences should be taken into account when it is desirable to transduce a specific tissue. All of the available data are consistent with the notion that the differences in efficiency of transduction reflect the fact that different AAV serotypes use different cell receptors. No evidence has emerged to suggest that the differences reflect regulatory variability within the transfected cells. Additional efforts to modify tissue specificity have involved chemical linkage of cell-specific ligands to vector virions or genetic modification of the coat proteins. Limited success has been achieved so far and, with the ever-increasing number of AAV serotypes which are becoming available, the need for specificity may be able to be met naturally. One likely exception to this conclusion would involve vectors designed to kill tumor cells. In this case, a likely vector would be linked to a monoclonal antibody to a specific tumor surface antigen.

Animal models

There have been numerous reports of successful transductions by AAV vectors in animal models. Most often these have been rodent models, especially genetically defined mice, but other species have been tested, including dogs, rabbits, and nonhuman primates. Among the many genetic lesions reported to have been corrected in mice or rats are a model for asthma, hemophilia B, retinopathy of prematurity, erectile dysfunction, phenylketonuria, diabetes, obesity, a model for acute macular degeneration, and Fabry's disease (Samulski 2003). The hemophilia B model is of particular interest because part of the transgene was in one AAV vector and the other was in a second vector construct. Apparently the two polypeptides were able at either the RNA or protein level to come together to form a functional protein (Duan et al. 2001). In the canine model, AAV has been used to correct Factor IX hemophilia and Leber's disease. The latter is of particular interest. Leber's disease, which also occurs in people, involves a defect in a protein, RPE65, affecting the retinal pigmented epithelium, so that puppies are born blind (as are the human patients). However, the disease is potentially reversible if treatment is instituted early enough. Acland et al. (2001) were able to treat blind puppies with an AAV vector containing a wild type RPE gene by injection into the eye. The treated eye gained visual function, but the contralateral eye did not.

A genetic disease which is relatively common, cystic fibrosis (CF), has been modeled in mice and safety tested in both rabbits and nonhuman primates. The AAV vectors have persisted for a long time and there has been no significant toxicity noted.

There have been several general conclusions noted from these animal studies. The first is regarding the relative safety of the vectors. There has been one report of tumor formation subsequent to AAV-mediated liver transduction (Daly et al. 2001), but analysis of the tumors did not reveal the presence of vector sequences and such tumor formation has not been observed in other experiments (Nakai et al. 2003). The affected animals had a specific genotype. The immune response elicited by the vectors has been limited. There has been at least one report of an immune response to the transgene product, but again this is a rare occurrence. Different strains of mice show variable immune responses to the vector coat proteins, thus the ability to re-administer the original vector is also variable. Recent reports of novel serotypes isolated from nonhuman primates (Gao et al. 2004) opens the possibility of a large increase in the number of vector serotypes, so that immune resistance to readministration may be largely mitigated. Various routes of administration have been used, in part depending on the target tissue. All of the routes, including direct injection, iv injection, and inhalation have been successful in specific cases. Of particular note are the high levels of transgene expression achieved in many instances, of ten at therapeutic levels, and the length of time which expression persists. In many cases the duration of expression has approached the normal life span of the mouse.

Clinical trials

Clinical trials using an AAV vector have been carried out with a limited number of diseases. The first studies concerned patients with CF with moderate symptoms. The first trial involved bronchoscopic administration to 19 patients (Flotte et al. 2003). The major finding was the lack of any detectable toxicity over a wide range of dosages. No significant enhancement in clinical status was noted. A second Phase I trial involving 12 patients was conducted by another group who administered the vector by an aerosolized spray. The experiment was monitored by bronchoscopy to gather experimental samples. Vector transfer was dose related: after nebulization involving 1 013 infectious particles, 0.6 copies per brushed cell were noted after 14 days and 0.1 vector copies were found after 30 days. No vector could be detected by 90 days. Vector was noted to the fourth airway generation after the nebulization administration. Although the conclusion from this experiment was that the protocol had been safe, there were six 'serious' adverse events, three of which might have been related to the vector. In a Phase II trial involving CF patients, vector was administered by spray to the maxillary sinus on one side, the other side serving as the control. No statistically significant differences were noted when relapse of clinically defined sinusitis was measured, or when sinus transepithelial potential difference, histopathology, or sinus fluid IL-8 measurements were made. Only the level of IL-10 was significantly increased at day 90. However, again the safety of the vector was noted. Trials have been carried out on three patients with Factor IX hemophilia. Since adequate serum levels of Factor IX are the goal, the site of protein synthesis is not critical. In this trial intramuscular injection was used. No evidence for toxicity was noted. Vector sequences were detectable in muscle and there was immunohistochemical evidence for expression of Factor IX, along with evidence for a moderate increase in serum levels (Margaritis et al. 2004). A clinical trial has been announced to test the use of AAV to deliver the aspartoacylase gene to patients with Canavan Disease, a neurodegenerative disease characterized by failure to cleave N-acetyl-aspartate leading to inhibition of normal myelination in the central nervous system. Finally, a clinical trial to see whether an AAV vector can lead to therapeutic levels of alpha-1-antitrypsin in serum is close to initiation. It seems likely that an increasing number of trials involving AAV will take place in the near future.

AAV has demonstrated significant promise as a vector for human gene therapy. To date, in both animal and human studies there has been minimal toxicity observed. The major question has been the extent to which humoral antibody to the virion coat might inhibit subsequent administration of the original vector. Occasional reports of possible AAV vector toxicity in animal models either have not been reproducible or have not been demonstrated to have been caused by the vector. There have been no reports of significant toxicity in several human trials. On the positive side, high levels of transgene expression have been noted in a large number of animal trials. This has not yet been achieved in any of the human trials, although lower levels have been observed. In the animal models, expression occurs rapidly and is sustained at potentially therapeutic levels for more than a year in several instances (essentially the life span of the mice used). This is in distinction to the results observed for either retrovirus or adenovirus vectors. The reason for this difference is not known, but may be a reflection of the fact that there is no expression of AAV genes.

Results to date are highly encouraging for the potential of AAV to be used as a vector for human gene therapy. However, before its utility in this context can be considered established, there are a number of questions that need to be answered. Long-term safety will have to be ascertained. The propensity for the vector to integrate in an apparently random manner after long periods of time raises the question of insertional mutagenesis and its potential consequences. Will the results using a Moloney murine leukemia virus-based vector to treat children with severe combined immunodeficiency (i.e. a leukemoid reaction similar to leukemia which was observed more than a year after therapy) occur? Would

it be better to develop AAV vector systems which involve Rep expression like that seen with wild type infection so that site-specific integration would occur? Would such systems have toxicity associated either directly with Rep expression or as a consequence of site-specific integration? If the experience with natural infection is a reasonable model, neither of these concerns would appear to have a high probability, but until there is direct testing of vectors, one cannot be sure. A related question is whether integration into *AAVS1* leads to expression at levels comparable to those observed with the vector as an extrachromosomal element. Another issue to be resolved is whether there is a preferred route of administration or does the optimal route depend upon the specific use of the vector. While the latter would seem to be the more likely answer, the extent to which there may be a preferred general route of administration remains to be determined. Animal models have shown that different AAV serotypes have differing levels of effectiveness depending on the cells to be infected. While this stands to reason, the details of tissue and cell specificity remain to be worked out. Also to be refined is the extent to which vector coat proteins can be selectively modified to both enhance and narrow the specificity of tissue or cellular susceptibility to infection by the vector.

Thus, while the effective application of AAV to human gene therapy has not yet been achieved, AAV remains one of the most promising of the viral vectors.

CONCLUSION

Considerable progress has been achieved in the development of viral vectors. After an early rush to clinical trials with an attendant lack of success, it has become clear that the key to success in human gene therapy is a detailed understanding of the basic biology of the viruses relevant to their use as vectors. Areas of continuing concern include tissue and cell specificity, persistent expression, host response, the possibility of insertional mutagenesis, and maintenance of the vector in dividing cells. Because use of gene transfer for therapeutic purposes is not a major philosophical concern, but altering the germ line is, vectors are monitored for their presence in germ cells. Although most viral vectors cannot replicate and often are delivered locally, systemic spread might be considered to be infrequent; but this is not the case. Much of the time at least some of the vector does reach the circulation and is distributed throughout the body. One way to avoid the possibility of germ line contamination would be to develop viral vectors whose tissue tropism was sufficiently narrow that infection of germ cells would not occur. Another concern stated above is insertional mutagenesis. Potentially, it would be possible to minimize this problem by designing vectors which would integrate at specific sites in the human genome which would not be deleterious. Wild type AAV is the only human virus which is known to do this. However site-specific integration in this case requires the *rep* gene product and cis-active sites on the vector DNA. Work is proceeding to develop such vectors. Another approach would be to develop a system that can lead to efficient homologous recombination between the resident gene and the transgene to correct the inherent defect. Work is progressing in this direction as well. Each of the viruses discussed in this chapter has inherent drawbacks. Three of the four are significant human pathogens. The challenge is to modify such viruses so that they are no longer virulent but retain the capabilities required of a vector. Although not known to be a pathogen, AAV has a limited transgene capacity and the Rep protein required for site specific integration is a powerful transactivator. Hence it must be demonstrated that AAV-based vectors designed to integrate site-specifically are both safe and effective. A similar issue bedevils retrovirus vectors; we have already seen one instance where the use of what was thought to be a 'disarmed' retroviral vector led to the development of a leukemia-like disease of the type naturally caused in mice by the virus used.

In summary, use of viral vectors for human gene therapy retains its considerable promise. We do have one instance in which a lethal disease has been 'cured,' albeit with some therapeutic complications. However, it is clear that a greater understanding of the biology involved with vector administration and more sophisticated engineering of vectors will be required.

Antiviral chemotherapy

HUGH J. FIELD AND RICHARD J. WHITLEY

Introduction	1	Problems in antiviral chemotherapy	28
Discovery and assessment of new antiviral compounds	2	Combination chemotherapy for viral infections	35
Mechanism of action of important antiviral compounds	6	Conclusions and future prospects	35
		References	35

INTRODUCTION

The science of antiviral chemotherapy has developed over the last 40 years; in the last two decades the rate of progress has accelerated markedly and more new chemical therapeutics to treat viral diseases have been introduced since 1990 than during the whole of the preceding 30 years. Viruses are obligate intracellular parasites that are completely dependent on an intact host cell to provide the ribosomal machinery for protein synthesis. As such, many scientists claimed that 'selective toxicity' towards viruses was unattainable and that the cost of interfering with virus replication would necessarily be unacceptable damage to the host. Historically, lack of susceptibility to antibiotics was considered to be one of the hallmarks of a virus. This gloomy prospect was transformed by a series of discoveries that has now led to effective and safe systemic chemotherapy for many different virus infections. The mechanisms of action and mode of application of some of the best known are covered in this chapter.

Achieving selective toxicity against human viruses

Although the potential toxicity of antiviral compounds remains important, over the last three decades the prescription of safe, systemic antiviral chemotherapy has gradually come to be taken for granted. This revolution was largely brought about by the development of the nucleoside analogue, acyclovir (also known as aciclovir), which became one of the world's best known medicines with more than 33 million patients treated by the end of the millennium (Darby 1995). Such is the confidence in its safety that it has been administered prophylactically for over 20 years to individuals, apparently without ill-effects, to suppress recurrences of genital herpes (Whitley and Gnann 1992; Tilson et al. 1993). The confidence generated by this one compound provided a completely new background to our current thinking about the development of antiviral chemotherapy and the encouraging prospects for future therapeutic strategies. The emergence of human immunodeficiency virus (HIV) during the 1980s provided a monumental stimulus to the antiviral field; driving research which led to the many new antiretroviral drugs currently available or in clinical development. Herpesviruses, which were historically the most important targets for chemotherapy are currently attracting less interest (Field and Fitzmaurice 2001), while alternative virus targets such as influenza and hepatitis viruses have come to the fore.

The importance of specific diagnosis and early therapy

Useful inhibitors are generally specific for one family of virus and, in some cases, to individual members of that family (e.g. particular members of the *Herpesviridae*). Initiating the appropriate therapy therefore depends on rapid and accurate diagnosis. In fact, often, significant tissue damage occurs before the etiology of virus infection is determined. For many acute respiratory infections

that have both short incubation periods and similar clinical signs early in the infection (e.g. caused by rhinoviruses, myxoviruses, or paramyxoviruses) there is a narrow window of opportunity for intervention by chemotherapy following specific diagnosis and this is an important barrier to the development of new compounds. However, experience with aciclovir demonstrated that therapy can be beneficial, even when the infection has progressed for several days, although, as defined below, early therapy is of paramount importance in determining the outcome when treating herpes zoster, herpes simplex encephalitis, and the complications of cytomegalovirus infection. With several virus infections, however, the slow development of clinical signs over many weeks or months allows ample opportunity, following specific diagnosis, to provide benefit to patients with such diseases as HIV, hepatitis B virus (HBV), hepatitis C virus (HCV) and Papillomavirus (HPV). Furthermore, rapid 'bedside tests' to confirm diagnosis of many different virus infections are becoming available and will be increasingly reliable.

The importance of an intact immune system

Another widely held view at the outset of antiviral chemotherapy was that an intact immune system would be a prerequisite for clearing infection. Experience with several excellent inhibitors of viral replication has shown that this is untrue. Indeed, some of the most spectacular successes with antiviral chemotherapy and prophylaxis have been obtained using aciclovir in severely immunosuppressed patients suffering from herpesvirus infections (Meyers et al. 1982) and subsequently highly active antiretroviral therapy (HAART) administered to HIV-infected patients who have severely compromised immunity (Jain et al. 2003). A particular problem in such patients, however, is their tendency to develop infections resistant to antiviral drugs and the approaches to countering this problem are discussed below.

DISCOVERY AND ASSESSMENT OF NEW ANTIVIRAL COMPOUNDS

Molecular targets for inhibition

The obligate intracellular parasitic mode of viral replication determines that it must pass through a series of stages common to all viruses: adsorption; entry; uncoating of the nucleic acid; expression of the genome; transcription and translation of proteins; replication of nucleic acids; assembly and release of mature progeny (Figure 1).

So far, almost all the useful inhibitors of viral replication are targeted to one or other of these steps. The mechanism of action of many compounds in current use involves interference with nucleic acid metabolism; they include the many nucleoside analogues that inhibit herpesviruses and nucleoside and nonnucleoside analogues that interact with HIV reverse transcriptase (reviewed by De Clercq 1992). Several of the early influenza virus inhibitors affect the disassembly of particles by blocking a virus protein complex that acts as an ion channel (Wang et al. 1993). Most viruses induce one or more proteases involved in processing virus polypeptides into functional components. The HIV protease was the first such enzyme to be targeted, and novel inhibitors of the proteases of other viruses are now being developed (Mills 1993). Finally, a series of inhibitors of picornaviruses act by binding directly to the virion capsid, thus blocking the interaction between the virion and the receptor on the cell surface that facilitates its entry and disassembly (Rossmann 1990).

Now that many compounds have been discovered that possess potent selective toxicity against particular viruses, it is ironic that there is renewed interest in compounds that appear to depend upon a cellular function that has a role in virus replication, e.g. the cyclin-dependent kinases as targets for the inhibition of herpes simplex virus (HSV) (Schang 2001). Furthermore, there is considerable interest in compounds that modify the host response to virus infection such as the induction of cytokines or the accelerated apoptosis of virus-infected cells. Examples of such immune response modifiers are imiquimod, which is reported as a treatment for HSV (Harrison et al. 1988) and HPV (Beutner et al. 1998), and resiquimod, which is also used to treat HSV (Tomai et al. 1995).

Drug discovery

SERENDIPITOUS DISCOVERY

In the early days, most new antiviral compounds were discovered by chance (often referred to as serendipity); indeed, several of the earliest antiviral compounds (e.g. idoxuridine) originated from cancer research where there was an interest in using nucleoside analogues to interfere with DNA synthesis and hence to inhibit the rapid division of tumor cells (Darby 1994).

RATIONAL DRUG DESIGN

With thorough understanding of the molecular basis of the replication of many important viruses, the availability of the entire nucleotide sequences of their genomes and the three-dimensional protein structure derived from X-ray diffraction analysis, compounds can be designed to interact with specific targets involved in the virus replication cycle. Among the first molecular targets were virus-induced enzymes which have properties differing from those of counterpart enzymes induced by the host cell. The best known examples are neuraminidase (NA) induced by orthomyxoviruses;

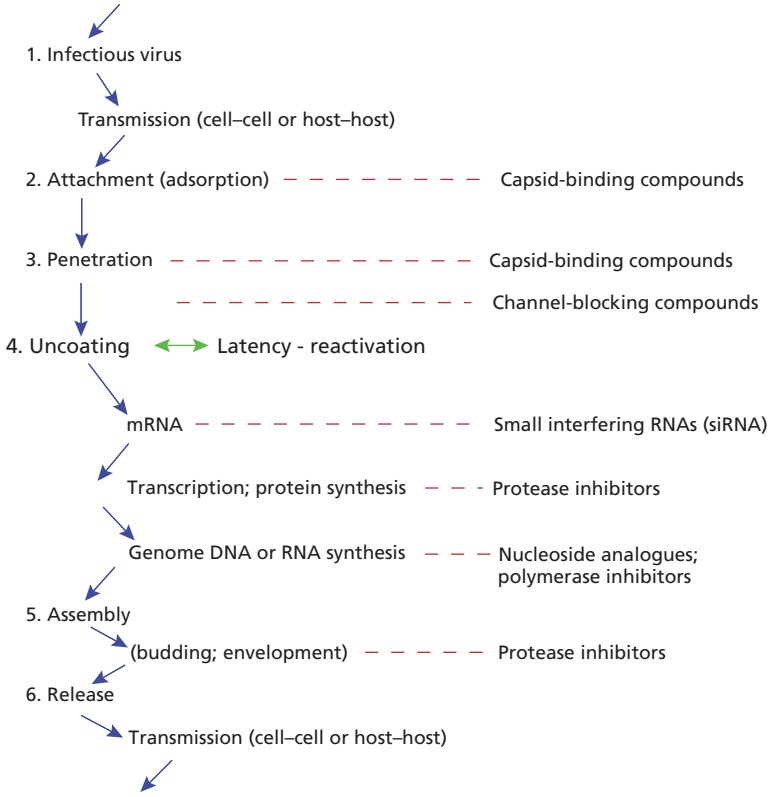

Figure 1 *Sites of action for several important classes of virus inhibitors. The classical progression of the virus replication cycle is denoted by the blue arrows. The sites at which the current successful antiviral compounds act are indicated by red dashed lines.*

thymidine kinase (TK) and DNA polymerase (DNApol) induced by some herpesviruses; transcriptase and reverse transcriptases induced by hepadnaviruses and retroviruses; and proteases induced by retroviruses and herpesviruses. Knowledge of such enzymes enables the establishment of biochemical screens to test hundreds of thousands of potential inhibitors and to develop structure–activity relationships. When the enzyme concerned can be crystallized and its three-dimensional structure solved, the synthesis of appropriate molecules to interact with particular sites on that enzyme can be attempted (Laver and Air 1990). For example, the crystal structure of two members of the herpesvirus proteinase family (human cytomegalovirus (CMV) and varicella-zoster virus (VZV)) revealed that they belong to a new class of proteinase with a completely novel protein fold and catalytic site. In some cases, potent inhibitors have been discovered that bind in a region away from the enzyme active site. Such is the case with several useful inhibitors of HIV, the so-called nonnucleoside reverse transcriptase inhibitors (NNRTI) and these will be elaborated on in the HIV section below. This molecular approach to the rational design of new inhibitors is being pursued in relation to HIV reverse transcriptase and protease; influenza neuraminidase and some potential nonenzymatic virus targets, e.g. the picornavirus capsid-binding molecules (Jones 1998).

Although the discovery of future antiviral compounds will rely heavily on these methods, the development of successful drugs still depends on finding molecules with the appropriate pharmacokinetic properties and lack of toxicity, and which can be synthesized inexpensively in large quantities from available precursors; thus, even with the best efforts of the medicinal chemist, relatively few new antiviral agents are likely to become successful antiviral drugs.

Methods for detecting the inhibition of molecular targets directly

STRATEGIES FOR ANTIVIRAL DRUG DISCOVERY

The methods for discovering new antiviral drugs have evolved over the past half century to a high degree of sophistication. The general principles, however, are unchanged. The first or most promising member of a family of related chemical structures that shows antiviral activity is referred to as a ‘lead’ compound. The overall process of developing an antiviral compound for clinical evaluation can be broken down into the stages of lead generation, lead optimization, and lead development. The virus genome sequence and the study at a molecular level of virus proteins and their functions enables potential molecular targets for attack to be identified.

Methods have been developed in the pharmaceutical industry for screening literally hundreds of thousands of compounds against particular targets. Much use is now made of X-ray crystallographic data obtained from target-inhibitor complexes in drug design and the optimization of lead compounds, in particular the ever-expanding databases of chemical structures such as the Cambridge Structural Database (CSD) for small organic and metallo-organic compounds and the Protein Database (PDB) for polypeptides and polysaccharides. To date, virus-induced enzymes have been particularly useful targets for attack by this means.

VIRUS ENZYME SCREENS

Viruses induce enzyme activities in the infected cells and there are now many examples of the assay of such enzymes in vitro and the screening of potential inhibitors for activity (Öberg 1983b). DNA and RNA polymerases were originally the best-studied systems, particularly in herpes and retroviruses, respectively. The herpesvirus TK was one of the earliest viral enzymes to be studied, because, as well as being a target for inhibition itself (Wright 1994), it is responsible for the phosphorylation of many nucleoside analogues that then become virus DNApol inhibitors. HIV research has largely been responsible for revolutionizing the study of enzyme-inhibitors at the molecular level and the classes of enzyme under investigation has extended beyond the conventional nucleic acid polymerases. In recent years the list of virus-induced enzymes to become targets for effective inhibitors includes retrovirus protease, herpesvirus protease, and helicase primase and orthomyxovirus neuraminidase, and there is no doubt that these will soon be joined by many others.

EFFECTIVE CONCENTRATION (EC_{50}) AND TOXIC CONCENTRATION

Antiviral compounds are usually assessed at an early stage for their ability to inhibit viral growth in tissue culture. The virus is generally titrated by means of cytopathic effect, plaque production or some other measure (e.g. infectious center assay). The percentage reduction is usually plotted against the $\log_{10}$ of the drug concentration. The concentration of compound that reduces the titer of virus by 50 percent is measured and is usually expressed as the effective dose 50 concentration (ED_{50}), inhibitory concentration (IC_{50}) or something similar (Figure 2). Although the ED_{50} provides the most reproducible value, in some cases the ability to reduce virus yield by 90 percent (ED_{90}) is regarded as a more realistic measurement and is sometimes quoted. When expressing results it is important to state the type of cell culture used for the test and the multiplicity of infection because the species of origin, the tissue from which the cells are derived, and whether the cells are resting or dividing can all influence the result. The multiplicity of infection may also be important: plaque reduction tests

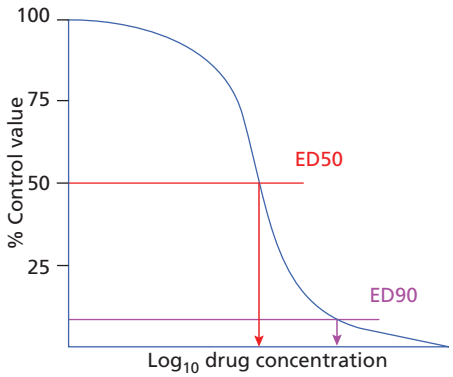

Figure 2 *Determination in cell culture of effective dose (ED_{50}; ED_{90}) for an inhibitor*

are necessarily conducted at low multiplicity but those based on reduction of cytopathic effect or virus yield may be carried out at different multiplicities and this can profoundly affect the result (Harmenberg et al. 1980; Harmenberg et al. 1985b).

A number of important human viruses that are targets for chemotherapy are extremely difficult to grow in convenient tissue culture systems, presenting a major hurdle in the identification and early development of inhibitors. Examples are HPV (Stanley 1993; Stanley et al. 1997; Phelps et al. 1998) and HBV and HCV (Murphy 1993; Main et al. 1998; Walker et al. 2003; Yuen and Lai 2003).

The quantification of compound toxicity is very much more difficult to assess in tissue culture and many methods have been employed (Dayan and Anderson 1988; Newton 1988). They include effects on cell division; cell generation time over several rounds of replication (Field and Reading 1987); cell replication measured by thymidine uptake; cell volume; and various other more subjective measurements of cytopathic effect. Several assays employ vital dyes to assess cell viability, and in these cases colorimetric apparatus can be used to automate the readings (McLaren et al. 1983). Further tests have been devised to assess genetic damage (Evans 1983) and effects on DNA repair systems (Collins et al. 1984) The problems of assessing potential long-term genetic damage by nucleosides is reviewed well by Wutzler and Thust (2001).

An important consideration for both toxicity and antiviral activity in cell culture is that cells from species other than humans are often employed and may give different results (Harmenberg et al. 1985a). Furthermore, cells adapted for tissue culture may provide misleading data in comparison with those actually involved in the natural pathogenesis (Perno and Calio 1994). Experimental work with differentiated cells (e.g. human macrophages or neuroblastomas) or organ fragments (e.g. tracheal rings or ganglion explants) have been used in attempts to circumvent these difficulties. Two important examples of the latter exist. For HPV,

raft cultures have been developed Similarly, the trimeric mouse has been utilized to study compounds directed against HCV. Although these methods can provide additional information the results may be difficult to interpret (Bartenschlager 2002a, b; Bartenschlager and Lohmann 2001)

Structure–activity relationships

Having established that a particular chemical inhibitor (lead compound) has a useful selective index against a particular virus or family of viruses, many closely related chemical analogues are synthesized, if possible. These are then screened for antiviral and toxic activity. It often emerges that particular features of the molecule are important and further modifications may be attempted in order to improve or refine the properties of the leading drug for further development. The analysis of such series led to the concept of structure–activity relationship (SAR) and this has been most important in the development of many new drugs. Examples of such series are the 5-substituted 2′-deoxyuridine inhibitors of herpesviruses (De Clercq et al. 1982) and the non-nucleoside reverse transcriptase inhibitors and peptidomimetic protease inhibitors of HIV (Roberts et al. 1990).

ANIMAL MODELS

Animal infection models were essential to the programme of development of most major antiviral compounds in clinical use. This is less true of compounds active against HIV because there is a paucity of suitable models (Koch and Ruprecht 1992).

Infection models for HSV dating back to the 1920s (Goodpasture and Teague 1923) have been developed in mice, rabbits, and guinea-pigs. There is thus a very large amount of published information on the pathogenesis of experimental infections, which aids the interpretation of the different models and the extent to which the results can be extrapolated to human disease (reviewed by Field and Brown 1989). Table 1 indicates some of the most important models for studying HSV as a cause of labial, genital, and ocular lesions, and of encephalitis and disease in the immunocompromised host. Such models have been used to provide further evidence of efficacy, to compare different compounds and to study therapeutic regimens. However, their particular strength is the ability to investigate complex features of pathogenesis and their interaction with potential inhibitors. For example, the effects of antiviral compounds on the establishment, maintenance, and reactivation of latency are extremely difficult to study in humans (reviewed by Darby and Field 1984).

Many viruses, including other herpesviruses (e.g. human cytomegalovirus (HCMV) and VZV), have a restricted host range and cannot establish infections in laboratory animals comparable with those in humans. It is, however, sometimes possible to do so using a different member of the same family of viruses, for example murine CMV (Sandford et al. 1985) and feline immunodeficiency virus (North et al. 1993). Clearly, the range of questions that may be asked of such models may be limited, but they can provide powerful systems for studying both the dynamics of drug resistance developing during therapy and counter-measures (e.g. the use of combinations or alternations of drugs).

Table 1 *Examples of the many animal models used to study and evaluate inhibitors of herpes simplex virus*

Type of disease	Animal species	Route of inoculation
Orofacial herpes	Guinea-pig	Flank
	Mouse	Ear pinna
		Flank
		Lip
		Foot pad
	Hairless mouse	Flank
	Nude mouse/human skin	Skin
Genital herpes	Guinea-pig (female)	Vagina
Ocular herpes	Rabbit	Cornea
	Mouse	Cornea
Herpes encephalitis	Mouse	Nares
		Vagina
		Cerebrum
		Tail vein
		Peripheral nerve (sciatic)
		Peritoneal cavity
	Rabbit	Olfactory bulb
Disease in immunocompromised host	Mouse (X-irradiated, cyclosporin-treated; nude transgenic knockout, etc.)	Various routes

Animals also play a vital role in the study of toxicity, and a number of statutory tests, both short and long term, are performed in several species in attempts to evaluate the risks of side effects before new compounds enter clinical trials. An important component of evaluation of any drug in animal species, generally two, is the assessment of adsorption, distribution, metabolism and elimination.

Selective index and therapeutic index

The ratio of the 50 percent toxic concentration to the 50 percent virus inhibitory concentration for the compound is often termed the *selective index*. When this is close to unity, the compound is generally taken to be toxic and is very unlikely to become useful. Conversely, a high selective toxicity index suggests a potentially useful compound. It should be stressed, however, that this ratio can be extremely misleading. For example, trifluorothymidine (Kaufman and Heidelberger 1964) has a selective index close to unity yet has been licensed as a topical agent against ocular HSV, for which it has enjoyed some success (Kaufman 1979). There are, of course, many compounds with high selective indices in vitro that demonstrate toxicity only when tested in vivo. Thus, when possible, compounds are tested in animals infected with the target virus itself or a suitable relative for comparison. If inhibition of virus growth and of clinical signs are observed with doses that are tolerated by the host, an estimate of *therapeutic index* (the ratio of the toxic dose to the therapeutic dose) can be made (Field 1988a). This value is generally obtained in suitable animal models; it may remain theoretical for humans.

CLINICAL TRIALS

The evaluation of a potential antiviral drug in humans generally proceeds through several phases, numbered I to IV (Rees and Brigden 1988). Although the boundaries are not always exact, this terminology is widely employed.

Phase I studies

The evaluation begins with the administration of the drug to a limited number of healthy volunteers. It is normally given in small single doses at first, increasing by stages to multiple doses in an attempt to mimic the probable clinical use of the compound. During these studies the pharmacokinetics, pharmacology, and metabolism of the compound are closely monitored. If these results are favorable the investigation may proceed to studies on virus-infected patients.

Phase II studies

The compound is administered to patients with disease, and data similar to those in phase I are collected. This is important because the metabolism of the drug in patients with disease may differ from that in healthy subjects. Phase II studies usually employ controls in order to provide 'proof of principle' data. These data are essential in order to estimate the extent of the drug's effect – information essential for the design of Phase III trials. Limited numbers of patients (<100) are utilized. One should be wary of claims of therapeutic benefit derived from such studies.

Phase III studies

Phase III studies are designed for registration whereby the drug is usually compared against placebo or standard licensed therapies. The main aim is to establish the therapeutic spectrum of the drug and the benefits to be gained from therapy compared with the risks associated with its use (the risk/benefit ratio). These studies require 100–1000 patients.

Phase IV studies

These are generally defined as investigations conducted after obtaining marketing approval. Phase IV studies increase experience of treating patients and provide more information about safety and efficacy. Different formulations, dosages, durations of therapy, drug interactions, and comparisons or combinations with other drugs may be evaluated and special problems such as the selection of drug-resistant mutants detected.

There are many reports of antiviral compounds that demonstrate good selective indices against particular viruses in cell culture and, in some cases, high therapeutic indices in animal models. However, in the absence of appropriate pharmacokinetic properties in humans, only a minority have proved clinically useful.

In practice, most compounds described during the preclinical investigation as active in enzyme screens, cell culture, and animal models, fail to pass through all the phases of clinical studies and many are withdrawn during these evaluations. Nevertheless, for severe and life-threatening diseases, the degree of toxicity allowed to certain compounds may be quite high, including zidovudine for therapy of HIV infections and ganciclovir for treating CMV in immunosuppressed patients.

The remainder of this chapter is confined to the relatively small, but rapidly growing, group of compounds that are currently used for chemotherapy of virus infections or are likely to become clinically useful in the near future.

MECHANISM OF ACTION OF IMPORTANT ANTIVIRAL COMPOUNDS

Of the innumerable compounds known to inhibit one or other of the viruses, only very few have proved useful for treating human infections. The early antiviral

compounds that were licensed for use in one or more indications were dominated by those for use against herpesviruses, especially HSV. Subsequently, this emphasis moved to the many new therapies for patients infected with HIV. Currently, the viruses attracting most attention for novel therapies include not only HIV but especially those causing hepatitis. Renewed interest exists for antiviral therapy for influenza. Interest in herpesviruses has, of course, continued in the background and there has been particular progress with the development of treatments for HCMV in immunocompromised patients and newborns.

Inhibitors of herpesviruses

HSV offered one of the most attractive targets for chemotherapy, and thousands of compounds have been discovered that inhibit it selectively. The infections are extremely common and a 1997 survey showed that 62 percent and 16 percent of adolescents in the USA were seropositive for HSV-1 and HSV-2, respectively (Rosenthal et al. 1997). Latent infection is lifelong and is associated with both symptomatic and asymptomatic recurrences with viral shedding on between 15 percent and 25 percent of all days (Wald et al. 1997). With this disease, clinical signs are characteristic, and specific diagnosis (including self-diagnosis) is possible and in many but not all cases can be made when prodromal symptoms occur (Griffiths 1995; Whitley and Roizman 2001). Ocular lesions offer the possibility of topical application. In the normal host, mucocutaneous lesions are almost always self-limiting; thus, it can be difficult to prove a clinical benefit or, indeed, a lack of benefit from a particular therapy.

ACYCLOVIR; ACICLOVIR; A PARADIGM FOR SELECTIVE TOXICITY

Acyclovir (first published under the name acycloguanosine and now as aciclovir (ACV), Zovirax) is a nucleoside analogue structurally related to the natural nucleoside guanosine (Figure 3) (Elion et al. 1977; Schaeffer et al. 1978, reviewed by Elion 1993). To become active, the nucleoside must be converted by three phosphorylation steps to ACV monophosphate (ACV-MP), ACV di- and then ACV triphosphate (ACV-TP) (Figure 4) (Fyfe et al. 1978).

ACV is a poor substrate for cellular enzymes, and uninfected human cells convert very little ACV to its triphosphate (ACV-TP). In contrast, the HSV-induced enzyme TK can, albeit with relatively low efficiency, convert ACV to ACV-MP. Thus the HSV TK recognizes ACV as thymidine but the fact that cellular enzymes convert ACV-MP successively to the di- and triphosphate only within virus-infected cells accounts for the extremely high selective index of the compound (Darby 1995). ACV-TP enters the cellular nucleotide pool where it competes with guanosine triphosphate as a substrate for HSV DNApol. ACV-TP is a particularly potent inhibitor of HSV DNApol (the inhibition constant, K_i, versus the natural substrate, deoxyguanosine, is ca. 0.01 μm) and this appears to provide further selectivity, because cellular DNApols are much less sensitive to

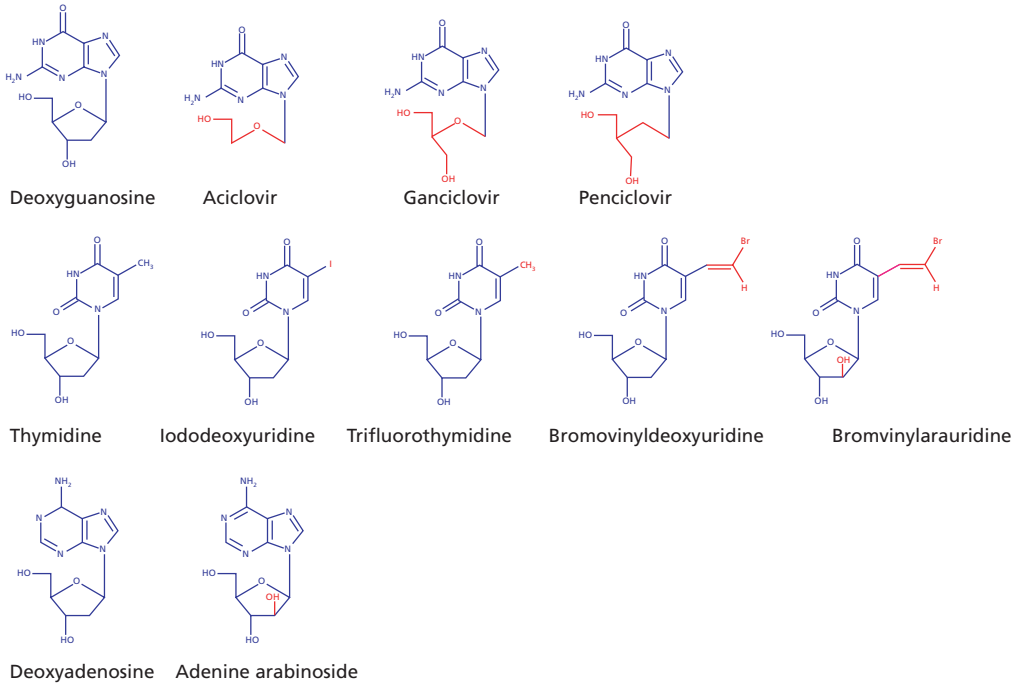

Figure 3 *Nucleoside analogues related to the natural nucleosides, deoxyguanosine, thymidine, and deoxyadenosine. The natural molecules are shown in blue. Red denotes those parts of the synthetic compounds that vary from the natural structures.*

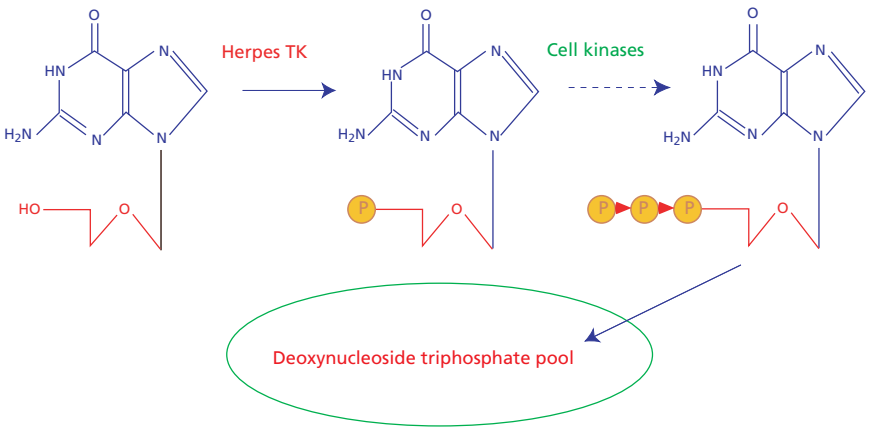

Figure 4 *The mechanism of action of aciclovir: activation*

inhibition. As the ACV residue is linked to the growing chain of virus DNA, it forms a chain terminator since there is no 3′-OH group on the ACV sugar moiety to link to the next residue in the growing chain of virus DNA (Figure 5) (Furman et al. 1979). ACV may thus be described as an obligate chain terminator.

In summary, ACV is taken up and phosphorylated in significant amounts only by HSV-infected cells and inhibits virus DNA synthesis, thus preventing the production and release of infectious progeny virus.

Clinically, ACV is licensed worldwide in topical, oral, and intravenous formulations. Generally, the drug is effective when given systemically for primary and recurrent genital HSV infections (Bryson et al. 1983; Mertz et al. 1984; Goldberg et al. 1993), mucocutaneous HSV in immunocompromised hosts and life-threatening infections, e.g. encephalitis and neonatal disease (Whitley et al. 1986, 1991). It is also an effective therapy for chickenpox (Balfour et al. 1990; Dunkle et al. 1991; Wallace et al. 1992) and herpes zoster in normal (Crooks et al. 1991) and immunocompromised hosts (Griffiths 1995).

NUCLEOSIDE ANALOGUES RELATED TO ACV

Following the discovery and development of ACV, many other nucleoside analogues with similar modes of

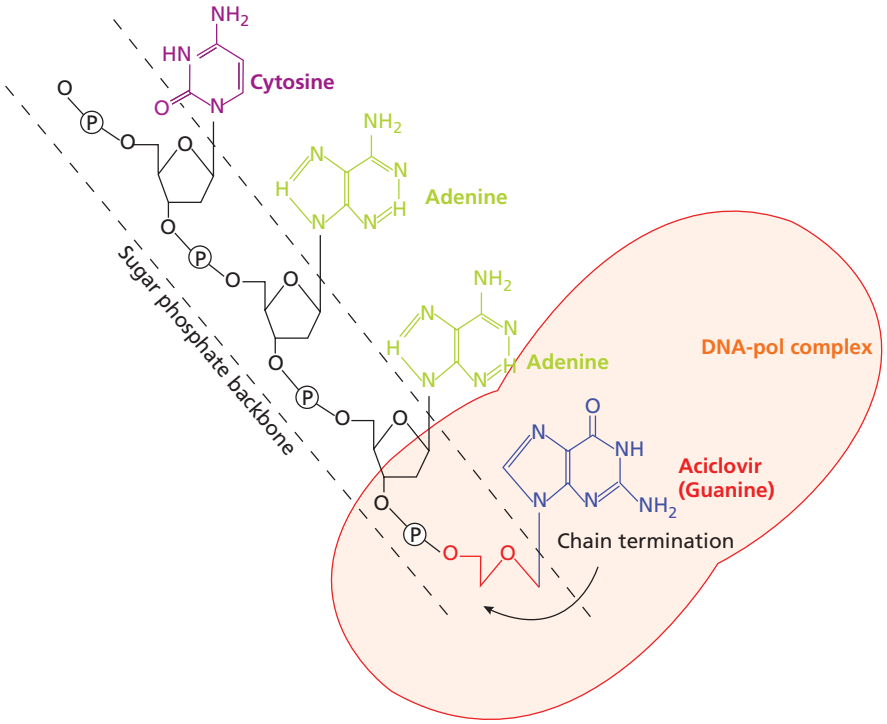

Figure 5 *The mechanism of action of aciclovir: inhibition of DNA synthesis and chain termination*

action were described. Some have high selective indices similar to or higher than that of ACV and several have been developed for clinical use. Each new compound, even those with close structural similarities with ACV (e.g. ganciclovir and penciclovir), has individual properties that differ from those of ACV, although the differences may be very subtle (Darby 1995). It is most important that this is kept in mind when comparing the antiviral efficacy and potential toxicity of such compounds with those of ACV (Wutzler and Thust 2001).

Ganciclovir

Figure 3 shows that ganciclovir (GCV), Cymevene or Cytovene has a structure similar to ACV, with an additional carbon atom in the sugar moiety and the presence of a 3′-OH group (Smee et al. 1983). The compound therefore differs from ACV in that further extension of the DNA chain is possible after incorporation of GCV triphosphate (GCV-TP). Although the compound shows significant toxicity in humans, its spectrum of action is broader than that of ACV and includes HCMV (Freitas et al. 1985; Matthews and Boehme 1988). Unlike HSV, HCMV does not encode a TK. Studies of viruses with acquired resistance to GCV have, however, revealed that a previously unsuspected virus enzyme is responsible for the metabolic conversion from GCV to GCV monophosphate (GCV-MP) (Littler et al. 1992; Sullivan et al. 1992). The enzyme is a product of CMV gene *UL97*, a discovery that focused attention on this gene which codes for a protein with close homology to several eukaryotic protein kinases. The precise function of the virus enzyme is thought to concern export of HCMV nucleocapsids from the nucleus (Krosky et al. 2002). Once formed in the CMV-infected cells, GCV-TP inhibits CMV DNApol and virus replication is prevented.

Clinical use of GCV has focused on patients at high risk for CMV disease (Fan-Havard et al. 1989; Levinson and Jacobson 1992; Balfour 1999). Thus, individuals with AIDS benefit from GCV therapy of retinitis and gastrointestinal disease. Oral administration of GCV delays onset of end-organ disease in patients with AIDS who have CD4 counts <200/μl. Similarly, GCV delays the onset of CMV disease in organ transplant recipients. Poor bioavailability and the problem of toxicity limit the value of the compound. The prodrug of GCV, val-ganciclovir (Figure 6), has been proven to provide higher oral bioavailability and is now licensed for the treatment of CMV retinitis. However, toxicity remains a problem.

Recently, intravenous GCV has been shown useful for the treatment of symptomatic congenital CMV infection (Kimberlin et al. 2003).

Penciclovir

Penciclovir (PCV), Vectavir or Adenovir, is another nucleoside analogue in which the base, guanine, is normal but the sugar moiety has a structural modification (Boyd et al. 1987). The structural similarity to ACV is apparent (see Figure 3); there is, however, no oxygen atom in the acyclic 'sugar' moiety although an OH group exists in the position equivalent to that of the 3′-OH group in the normal nucleoside, guanosine. Like

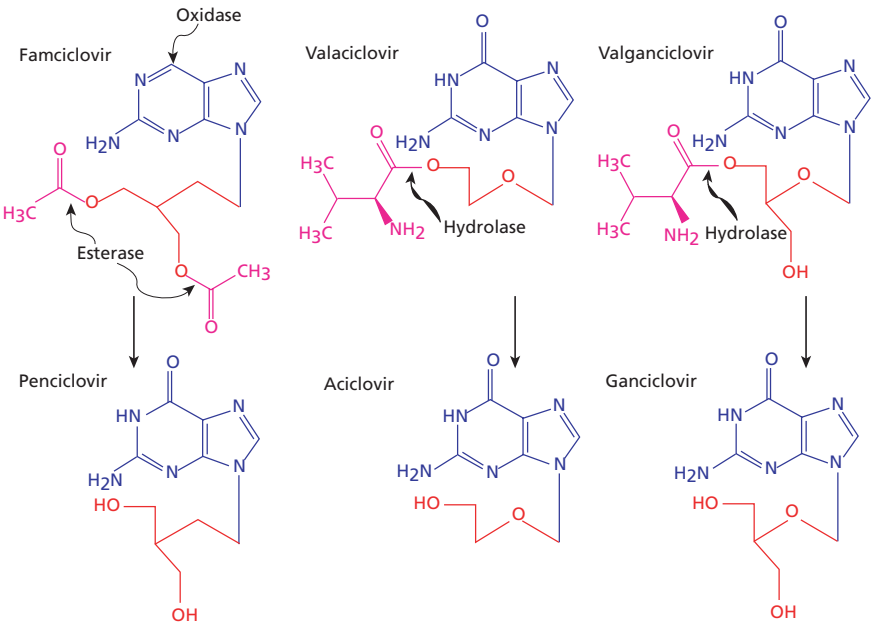

Figure 6 *The nucleoside analogue prodrugs famciclovir, valaciclovir, and ganciclovir showing their conversion to the active metabolites,* penciclovir, *aciclovir, and ganciclovir, respectively. The modifications that are subject to enzyme attack in vivo, providing oral bioavailability are shown in purple*

ACV, PCV is converted to PCV-monophosphate (PCV-MP) by the HSV or VZV TK (Vere Hodge and Cheng 1993), and PCV-triphosphate (PCV-TP) inhibits the viral DNApol but with the possibility of internal incorporation of PVC residues into viral DNA and further chain extension (Vere Hodge and Perkins 1989). The initial conversion of PVC to PCV-MP is more efficient than the phosphorylation of ACV, but the PCV-TP formed in infected cells is less active than ACV-TP as an inhibitor of HSV DNApol (Table 2) (Earnshaw et al. 1992).

PCV-TP has a significantly longer intracellular half-life than ACV-TP (Vere Hodge and Perkins 1989). Although the full implications of this observation have yet to be elucidated, it does seem that the compound may have more long-lasting inhibitory effects in infected tissues; this supposition is supported by tests in animals that compared famciclovir (FCV) and valaciclovir (VACV) (Sutton and Kern 1993; Field et al. 1995). It remains to be seen whether this biochemical feature translates into clinical benefit in humans. Although the compound seems to have a very high selective index, the bioavailability is poor (<5 percent in man) and the drug chosen initially for clinical development is a prodrug of PCV termed FCV, increasing the bioavailability of PCV to >70 percent.

As well as good activity against members of the *Herpesviridae*, PCV has limited activity against HBV (Boker et al. 1994; Locarnini et al. 1994). Thus far, no mechanism of action for this unexpected activity has been reported; it is, however, likely to involve specific inhibition of the HBV-induced DNApol although there is no explanation as yet for the phosphorylation of PCV in the infected hepatocytes.

Brivudin; bromovinyl deoxyuridine

Historically, brivudin, or bromovinyl deoxyuridine (BVDU), Helpin or Zostrex was discovered at about the same time as ACV (De Clercq et al. 1979) and, in vitro, appeared to be even more active than ACV against HSV-1 and VZV (De Clercq et al. 1980). However, the drug proved less useful than was anticipated. It is much more closely related to the natural substrate for TK (i.e. thymidine) with the modification of the bromovinyl group at the five position of the pyrimidine ring (see Figure 3).

The mechanism of action resembles that of ACV except that the conversion of BVDU-monophosphate (BVDU-MP) to BVDU-diphosphate (BVDU-DP) seems also to be achieved by the HSV TK (Descamps et al. 1982). The virus (but not cellular) TK thus possesses a thymidylate kinase activity. BVDU is significantly less active against HSV-2, probably because of the lack of conversion of BVDU-MP to BVDU-DP by the HSV-2 TK (De Clercq et al. 1981). A limitation of the compound in vivo is attack by phosphorylases that convert BVDU to bromovinyl ara-uracil, which is inactive. This, and concern about toxicity, has limited the development of the compound for clinical use; even so, the principles discovered during the development of this drug and SAR studies have led to several compounds (e.g. bromovinyl ara-uridine) that seem more promising. For a comprehensive review of brivudin see De Clerq (2004).

Sorivudine; bromovinylarabinosyl-uracil; brovavir

The mechanism of action of sorivudine, or bromovinylarabinosyl-uracil (BVaraU), Usevir (see Figure 3), seems similar to that of BVDU (Yokota et al. 1989; Machida 1990); its spectrum of action is, however, different and it seems to be some 2 000-fold more active than ACV or BVDU against VZV replication in cell culture (ED_{50} = 0.001 μm, compared with 14 μM for ACV) (Machida and Nishitani 1990). Like BVDU, however, the compound is poorly active against HSV-2. It is an extremely good substrate for VZV TK and its antiviral activity is attributed to the inhibition by BVaraU-TP of VZV DNApol; the compound is thought not to be incorporated into virus DNA. Unfortunately, one of the metabolites is bromovinylarabinosyl-uracil (BVU), a potent inhibitor of dihydrothymine dehydrogenase which is responsible for degrading drugs such as 5-fluorouracil that are used in cancer chemotherapy. Although this interaction was predicted, a number of deaths have occurred as a result of co-administration of the two drugs (Meeting Report 1995) (see section entitled The problem of toxicity of antiviral compounds). As a consequence, the compound will not be licensed in the USA. However, clinical benefit has been demonstrated against VZV disease in a

well-controlled clinical trial in comparison with ACV (Gnann et al. 1998).

Vidarabine; adenine arabinoside

Vidarabine, or adenine arabinoside (AraA), was an important landmark in the development of antiviral chemotherapy (Schabel 1968), being among the early compounds that achieved proven clinical benefit with relatively little acute toxicity, particularly in the systemic treatment of severe HSV infections (Whitley et al. 1977). The compound is a close analogue of adenine except that the OH group in the 2′ position on the 'sugar' moiety is in the unnatural 'arabinosyl' configuration (see Figure 3). The nucleotides formed from the phosphorylation of AraA have the potential to interfere with many different steps in the metabolism of DNA and its precursors, for example blocking of S-adenosyl homocysteine hydrolase (Hersfield 1979). The relative importance of these effects is unknown but, as with the other nucleoside analogues, the primary target for AraA-triphosphate (AraA-TP) seems to be the HSV-induced DNApol. The compound has low toxicity and may be used systemically, but its poor solubility necessitates the intravenous administration of large quantities of fluids. Secondly, its activity in vivo is limited by rapid deamination of AraA by adenosine deaminase, yielding arabinosyl-hypoxanthine which has no antiviral activity (Whitley et al. 1980a). Attempts to circumvent this problem by the administration of AraA-monophosphate (ARA-MP) have enjoyed little success (Whitley et al. 1980b). Today, vidarabine has largely been replaced in the physician's armamentarium for systemic therapy by more active and less toxic medications.

Idoxuridine

The pyrimidine analogue, idoxuridine (IDU), (e.g. Herpid, Kerecid, Virudox, Idurin, Stoxil) was the first specific antiviral compound to be discovered (Prusoff 1959). and is the best known example of the 5-substituted thymidine series; it is similar to BVDU. However, IDU does not possess the high selectivity associated with the more modern drugs. This 'first generation' nucleoside analogue is readily phosphorylated by cellular enzymes and thus can be converted to the active nucleotide in normal, as well as in virus-infected, cells although the conversion is much more efficient in the latter. The IDU triphosphate (IDU-TP) inhibits viral (and cellular) DNA synthesis, but a major part of the antiviral action may be due to incorporation of the analogue into viral nucleic acids and subsequent perturbation of virus gene expression (De Clercq 1982). The exact mechanism of action is unknown but some selectivity is assumed to result from the comparatively greater accumulation of IDU-TP in infected cells. IDU is, however, severely toxic upon systemic administration and is useful only as a topical agent, for which it continues to be useful both for herpes zoster and HSV keratitis. Skin penetration is a problem for topical administration. While formulations have been prepared in dimethyl sulfoxide (DMSO) for treating zoster (Dawber 1974; reviewed by Spruance 1994), they have been replaced by oral therapy with ACV, VACV, and FCV. Notwithstanding its traditional use for treating HSV in humans, the potential long-term genetic toxicity of this compound remains a major concern.

Trifluridine; trifluorothymidine

Like IDU, trifluridine (TFT), or trifluorothymidine Viroptic, (see Figure 3), synthesized in 1964 (Heidelberger et al. 1964), is also highly toxic and is unsuitable for systemic use. Even to demonstrate its selective antiviral effect in cell culture requires the use of cells lacking TK that are resistant to its toxic effects (Field et al. 1981). However, the compound is very soluble and has found a particular use in the topical treatment of ocular infections (Wellings et al. 1972). The very rapid hydrolysis of TFT to harmless metabolites probably accounts for the lack of toxicity in this application (Dexter et al. 1972). It is the treatment of choice for HSV keratoconjunctivitis (reviewed by Bigar 1979). The compound is reported to be effective against drug-resistant strains and remains in the armoury of anti-herpes drugs despite its toxicity in vitro.

NUCLEOSIDE ANALOGUE PRODRUGS

An important limitation of many nucleoside analogues is their poor bioavailability following oral administration. The development of orally bioavailable compounds that are converted in vivo to yield the relevant nucleoside analogues thus represents a major advance. The first compounds of this type were developed for herpes chemotherapy and the first to be licensed for use in humans were derived from ACV and PCV. Following this paradigm, a similar strategy has now been successfully applied to many different compounds including nucleosides active against alternative virus targets. Note that, technically, ACV itself is a 'prodrug' since the mechanism of action involves conversion of absorbed ACV to the active metabolite (ACV-TP) in vivo. However, in the antiviral field, the term prodrug is usually reserved for compounds where the first chemical conversion in vivo is primarily concerned with significantly improving bioavailability.

Valaciclovir

VACV Valtrex, Zelitrex is the L-valine ester of ACV (Figure 6) which, following oral administration, is cleaved in the gastrointestinal tract by an enzyme referred to as VACV hydrolase to yield ACV and the natural amino acid L-valine, little VACV being detected

in plasma (Beauchamp et al. 1992). Multiple oral doses of VACV (>1 g four times daily) result in plasma ACV concentrations similar to those achieved with intravenous ACV (5 or 10 mg/kg three times daily) but without the sharp peak concentrations (Carrington 1994; Crooks 1995). Once formed and distributed to the infected tissues, the mode of action is, of course, identical to that of simple ACV. This compound offers a formulation that is more convenient to administer for the treatment of herpes zoster than ACV (Murray 1995).

Famciclovir

The concept that led to VACV also resulted in FCV (Vere Hodge et al. 1989), the diacetyl ester of 6-deoxy-penciclovir (Figure 6). In this case two enzymes are involved, first in removing one ester preferentially, then the second, followed by oxidation by aldehyde oxidase to yield PCV (Vere Hodge 1993). The only degradation products from this reaction are harmless carboxylic acid and PCV and, as with VACV, little FCV is detected in plasma. Ease of administration provides a distinct advantage over ACV in the treatment of herpes zoster (Carrington 1994).

Have the nucleoside analogue prodrugs VACV and FCV met the clinical challenge? Following a decade of clinical experience with these nucleoside prodrugs, have the hoped-for improvements in antiviral efficacy been realized? The consensus is that both compounds do offer significant clinical benefits over oral ACV (Field 1996; Baker and Eisen 2003). However, the relative merits of the two new compounds in comparison with one another remain controversial (Carrington 1994, 1997). The disruption to the preclinical and clinical development teams associated with these drugs caused by the merger of the two giant pharmaceutical companies, GlaxoWellcome and SmithKlineBeecham, in the year 2000 may help to explain why there is still a paucity of data from clinical trials on the relative advantages and disadvantages of the two compounds under circumstances where they may be compared directly (Field and Fitzmaurice 2001).

NUCLEOTIDE ANALOGUES

A series of acyclic purine and pyrimidine nucleoside phosphonates was first described in 1986 (De Clercq et al. 1986). Several of these compounds showed a broad spectrum of activity against viruses, including both DNA and RNA viruses. Unlike the natural nucleotides, the acyclic nucleoside phosphonates (ANP) resist phosphorolytic cleavage by cellular esterases. The negative charge on the phosphate moiety impairs their cellular uptake which may occur by an endocytosis-like process. Once inside the cells, the ANP compounds need to be activated by cellular enzymes to catalyse their conversion to di- and tri-phosphorylated forms. The virus inhibitory effects then result from a selective interaction of their diphosphate metabolites with virus DNA pol (Votruba et al. 1987), thus their ultimate antiviral target is the same as that described above for the regular nucleoside analogues. A general feature of ANPs is the long intracellular half-life of the diphosphate metabolite, which may help to explain their long-lasting antiviral effects allowing infrequent dosing. The mechanisms of action of this series of compounds are thoroughly reviewed by De Clercq (1997)

Cidofovir (Vistide)

Cidofovir, (S)-1-(3-hydroxy-2-phosphonylmethoxypropyl) cytosine (HPMPC, Forvade) (Figure 7). As mentioned above, HPMPC viz. has a very long tissue half-life; it has been shown in many animal models that long intervals between doses can be allowed without loss of antiviral effect. Thus, once weekly dosing is employed in humans with apparent success (Snoeck et al. 1993). The compound has significant toxic side effects, particularly nephrotoxicity, although this can be minimized by co-administration of probenecid (which competitively inhibits the transport of drugs through the glomeruli) and intravenous hydration. Intravenous HPMPC is licensed for treatment of HCMV retinitis and topical gel used for the treatment of refractory HSV lesions in AIDS patients. Its spectrum of action extends beyond herpesviruses and includes poxviruses, HPV and HBV (see below). Other important compounds in this series include 9-(2-phosphonylmethoxyethyl) adenine (PMEA) (adefovir), which is active against herpes- retro- and hepadnaviruses, and R-9-(2-phosphonylmethoxypropyl) adenine (PMPA), which is active against retro- and hepadnaviruses. Following the prodrug strategy outlined above for the guanosine nucleosides, the oral prodrug of PMEA, bis(pivaloyloxymethyl) PMEA or adefovir dipivoxil (Naesens et al. 1996) is a very promising compound for the treatment of HBV (see section entitled Inhibitors of hepatitis viruses below)

PYROPHOSPHATE ANALOGUES

A series of compounds has been known for many years whose members interact directly with herpesvirus DNApol at the pyrophosphate binding site. This was first shown with phosphonacetic acid (Purifoy et al. 1977), a compound too toxic for humans. However, the closely related compound phosphonoformate (Figure 8) has been developed for use in man in the treatment of CMV disease in immunocompromised hosts. Its administration is associated with toxicity as evidenced by electrolyte imbalances (reviewed by Öberg 1983a).

Phosphonoformic acid

Phosphonoformate (PFA), foscarnet, foscavir (Figure 8) seems to have a relatively simple mode of action, being a

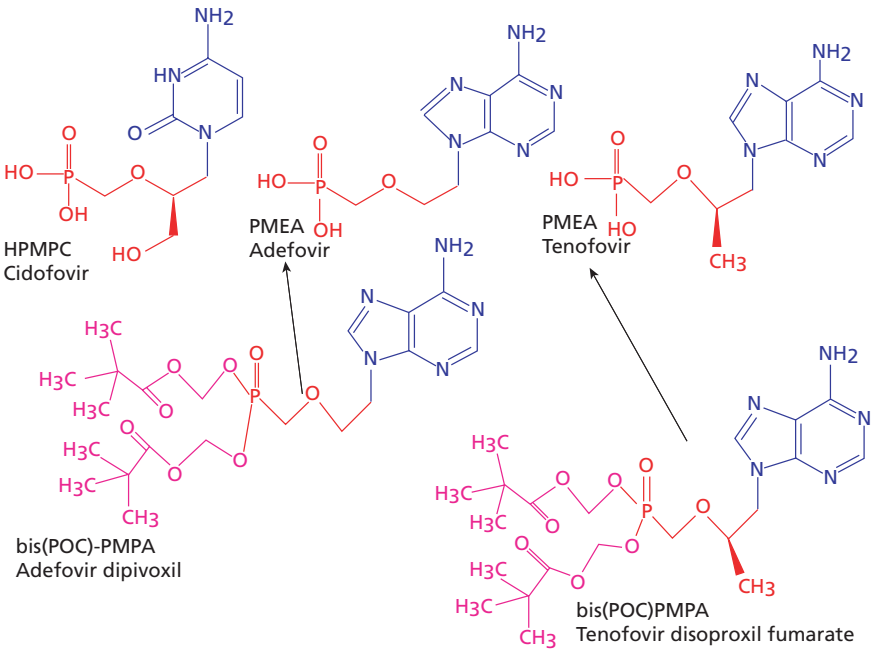

Figure 7 *Examples of effective inhibitors of virus polymerase: phosphonyl compounds cidofovir, adefovir, and tenofovir and two prodrugs that yield adefovir and tenofovir, respectively. The modifications to the compounds that provide oral bioavailability are shown in purple.*

direct inhibitor of HSV DNApol (Leinback et al. 1976). The compound suffers from some toxic features, and its tendency to accumulate in bone (Crisp and Clissold 1991) is of particular concern. It does, however, offer an alternative strategy for treating both infections with ACV-resistant strains of HSV and CMV retinitis in AIDS patients (Fanning et al. 1990).

ALTERNATIVE ENZYME TARGETS FOR HERPESVIRUS INHIBITORS

Most of the successful antiherpetic agents, to date, target the virus DNApol. Among the more than 80 distinct genes in the HSV genome, there are several other obvious enzyme targets for inhibition including ribonucleotide reductase (RR), protease, and helicase primase. There has been much effort to target herpes RR including synthetic oligopeptides directed to the enzyme active site. To date, none of these approaches has resulted in useful therapies. Given the success of compounds directed to the HIV protease (see section entitled Inhibitors of human immunodeficiency virus, below). It is likely that compounds designed to interfere with the herpes proteases will be effective (reviewed by Waxman and Darke 2000), but to date, none have been developed for clinical use. Another function that has been exploited is the HSV helicase primase. This is a virus enzyme that promotes the ATP-dependent unwinding of the DNA duplex during replication and it appears that compounds directed to it can inhibit virus replication at nanomolar concentrations.

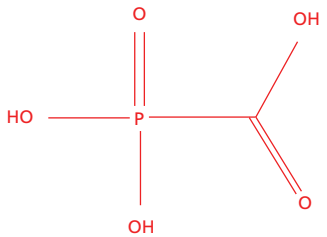

Figure 8 *An inhibitor of herpes DNA polymerase: the pyrophosphate analogue, foscarnet*

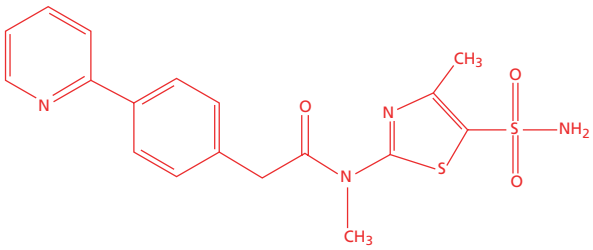
BAY-57-1293

The thiazolylsulfonamide, BAY-57-1293 (N-[5-(aminosulfonyl)-4-methyl-1,3-thiazol-2-yl)-N-methyl-[4-(2pyridinyl)phenyl]acetamide) (Figure 9) is an example of an inhibitor of herpes helicase primase (Kleymann et al. 2002, 2004). The compound is highly selective and extremely active in vitro with an IC_{50} concentration of approximately 20 nM (i.e. some 500-fold more active than ACV), furthermore, it is reported to be remarkably effective in several different laboratory animal HSV infection models. Other similarly potent molecules from different chemical series have also been described (Field and Fitzmaurice 2001). Although these particular compounds may not progress to the clinic, the experimental data clearly show that inhibition of this target has considerable potential and it is likely that effective



BAY-57-1293

Figure 9 *An inhibitor of the herpes simplex virus enzyme, helicase primase: BAY-57-1293*

compounds suitable for clinical development will emerge in the foreseeable future (Kleymann 2003, 2004).

DRUG COMBINATIONS TO MANAGE HERPESVIRUSES

Historically, there has been little enthusiasm for the use of drugs in combination against herpesviruses. Recently, the introduction of combination therapy has revolutionized the management of HIV and viral hepatitis (see sections below). Given the success obtained with different viruses, the possibility of this approach for HSV is currently being assessed – it is the turn for herpes virologists to learn from the younger areas of antiviral research! Actually, there is a long history of anti-inflammatory agents being used in combination with specific antiviral agents to manage severe lesions in recurrent herpes keratitis. One problem with this approach is that some effective anti-inflammatory agents also up-regulate and prolong virus shedding. This can be controlled by using a specific virus inhibitor (Harmenberg et al. 2003), thus a recent trial reported beneficial effects in patients with experimentally induced cutaneous HSV lesions using a combination of topical 5 percent ACV and 1 percent cortisone (Evans et al. 2002). There is no doubt that the further use of combinations of two or more specific antiviral drugs will be the subject of future studies and are likely to become more common in the future.

IMMUNOMODULATORS AS ANTIVIRAL TREATMENTS FOR HERPES

Compounds have been discovered that inhibit HSV replication by interference with a cellular target involved in virus replication (e.g. cyclin-dependent kinases) yet appear to behave as selective inhibitors of virus replication (Schang 2002). It remains to be seen whether such compounds will have a value either alone or in combination with conventional inhibitors of virus functions. Another approach is to stimulate the host to react more effectively to the reactivating virus so as to minimize the clinical signs generally referred to as immunomodulators.

Resiquimod

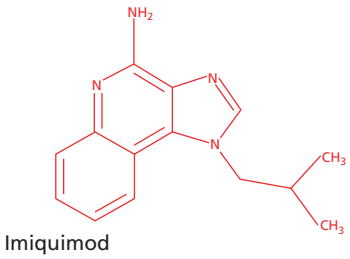
One compound of this type that is claimed to be effective is known as resiquimod (4-amino-2-ethoxymethyl-α,α-dimethyl-1H-imidazo[4,5-c]quinoline-1-ethenol). The compound (Figure 10) is described as an immune response modifier which induces cytokines including interferons (Tomai et al. 1995), however clinical trials as a topical therapy for genital herpes were recently abandoned.

HCMV INFECTION

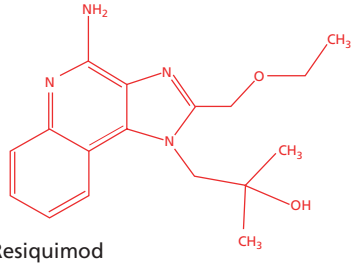
HCMV is another member of the *Herpesviridae* that is very widespread among human populations worldwide. Infection is rarely associated with clinical signs in otherwise healthy individuals except when primary infection occurs during pregnancy when congenital disease can result. However, when the immune system is compromised, e.g. associated with allograft transplantation, clinical signs of infection often become apparent and may be extremely damaging. The coming of HIV heightened awareness of the condition and HCMV retinitis became one of the most feared complications of the retrovirus infection. The introduction of highly active antiretroviral therapy has decreased the incidence of this complication substantially, but this and other manifestations of HCMV infection still account for considerable morbidity and there is much interest in developing improved drugs to treat or prevent these conditions (Field 1999). Currently there are five compounds that have been officially licensed for the treatment of HCMV infections. These are ganciclovir and phosphonoformic acid and cidofovir (see above) and two further compounds.

Formivirsen

There have been many unsuccessful attempts to employ antisense oligonucleotides in an effort to block or



Imiquimod



Resiquimod

Figure 10 *Examples of antiviral compounds whose primary activity is thought to be as immunomodulators: imiquimod and resiquimod*

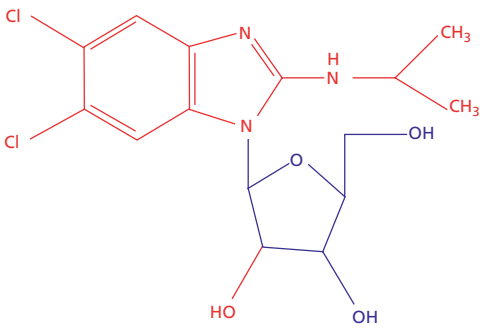
attenuate virus replication. There have been some more optimistic results, however, and formivirsen (ISIS 2922), vitravene is an antisense oligodeoxynucleotide (Figure 11) comprising 21 phosphorothioate-linked nucleosides that is complementary to the RNA of the HCMV major immediate–early region (Azad et al. 1993) and is one of the most promising compounds of this type.

Valganciclovir

Using the same oral prodrug strategy that led to valaciclovir and FCV, the orally bio-available valine ester of ganciclovir was synthesized and found to be effective. Valganciclovir (Valcyte) (Pescovitz et al. 2000; Reusser 2001) (Figure 6), when administered orally (two 450 mg tablets twice daily), gives equivalent systemic ganciclovir levels as intravenous ganciclovir at 5 mg/kg twice daily. Oral valganciclovir is expected to replace intravenous ganciclovir in both the therapy and prevention of CMV infections.

1263W94, Maribavir

There are currently many new compounds in development to combat HCMV (briefly reviewed by De Clercq 2003). Currently, one of the most promising of these is 1263W94 or maribavir. This is a novel benzimidazole compound, 5,6-dichloro-2-(isopropylamino)-1,β-L-ribofuranosyl-1-*H*-benzimidazole. (Figure 12). The compound has been demonstrated to potently selectively inhibit HCMV in vitro and to have favorable safety profiles in animal species and it is currently undergoing



1263W94 Maribavir

Figure 12 *A new inhibitor, 1263W94,* maribavir, *which targets the human cytomegalovirus protein kinase*

trials in man (Wang et al. 2003). Its mechanism of action is mediated through inhibition of the protein kinase activity of the *UL97* gene product (Wang et al. 2003). The precise function of this virus product has recently been elucidated, it is thought to concern export of HCMV nucleocapsids from the nucleus (Krosky et al. 2002) and it is the same gene product that is responsible for phosphorylation of ganciclovir to its monophosphate (see above).

Inhibitors of human immunodeficiency virus

NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS (NRTI)

The emergence of HIV as a major pathogen resulted in an unprecedented effort to develop new antiviral agents. The earliest compounds to enjoy limited therapeutic success were all nucleoside analogues; the first to be widely prescribed was 3′-azido-3′-deoxythymidine (azidothymidine).

Zidovudine; azidothymidine

Zidovudine, or azidothymidine (AZT), is an analogue of thymidine (Figure 13) (Mitsuya et al. 1985), and is readily phosphorylated in actively dividing cells. The drug is initially phosphorylated by cellular TK, the rate-limiting step being its conversion to AZT diphosphate (AZT-DP) by cellular thymidylate kinase. AZT triphosphate (AZT-TP) competitively inhibits HIV reverse transcriptase with respect to thymidine triphosphate (TTP) and, because the 3′-azido group prevents the formation of 5′,3′-phosphodiester linkages, AZT-TP acts as a chain terminator of DNA synthesis (Darby 1995). The compound, via its metabolites, also inhibits a variety of cellular enzymes, including DNA-polymerase-γ, which undoubtedly contributes to the range of toxic effects associated with prolonged clinical use of the drug (Fischl et al. 1987). It was the first drug to be used to treat HIV, and is still accepted as conferring at least transient benefit.

Stavudine; didehydrodideoxyuridine

Stavudine, or 2′,3′-didehydro-2′-deoxythymidine (D4T), is similar to AZT in that it is a thymidine nucleoside analogue (Figure 13) (Baba et al. 1987). It readily enters cells but, in contrast to AZT, the rate-limiting step is the initial phosphorylation by cellular TK. Once formed, D4T triphosphate (D4T-TP) is rapidly converted to D4T diphosphate (D4T-DP) and triphosphate derivatives. The mechanism of action at the level of reverse transcriptase seems to be similar to that of AZT (reviewed by Hitchcock 1991); toxicity in the form of peripheral neuropathy is, however, more common. The clinical use of D4T is variable worldwide.

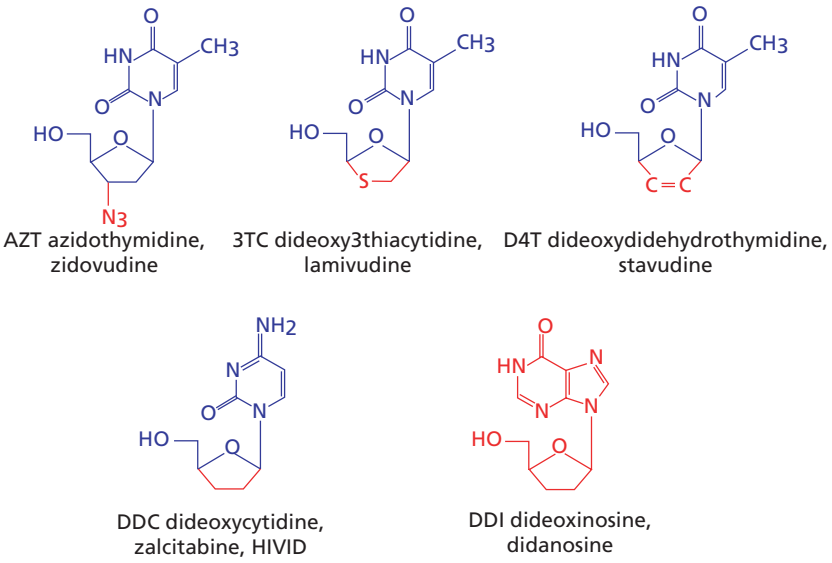


Figure 13 *Nucleoside analogue inhibitors of HIV reverse transcriptase (NRTI)*

Didanosine; dideoxyinosine (Videx)

Didanosine, or 2′,3′-dideoxyinosine (DDI), is a purine nucleoside analogue (Figure 13) (Mitsuya and Broder 1986) which is taken up intracellularly and converted by 5′ nucleotidase to DDI monophosphate (DDI-MP) and further metabolized by cellular enzymes to DDA triphosphate (DDA-TP), which has a prolonged intracellular half-life (8–24 h). Again, the molecular target for the drug action is the HIV reverse transcriptase (reviewed by McLaren et al. 1991). Clinical trials have been conducted in AIDS patients (Darbyshire and Aboulker 1992; Kahn et al. 1992) but the clinical use of DDI has been limited by its oral formulation which may cause gastrointestinal discomfort.

Zalcitabine; dideoxycytidine (HIVID)

Zalcitabine, or 2′,3′-dideoxycytidine (DDC) (Figure 13), is active against HIV-1 and 2 and against some strains that are resistant to AZT (Mitsuya and Broder 1986). The drug seems to be similar in potency to AZT (Bozzette et al. 1995).

Lamivudine; thiacytidine (Epivir)

Next, in this series of nucleoside analogue inhibitors of reverse transcriptase, lamivudine, or 2′-deoxy-3′-thiacytidine (3TC) (Figure 13), is synergistic with AZT in vitro and is active against HIV-resistant strains (Soudeyns et al. 1991). It seems to be relatively nontoxic but is less active than AZT in monotherapy. This drug is of particular interest for combination studies with AZT and a protease inhibitor. Lamivudine is also an active inhibitor of HBV DNApol in vitro (Doong et al. 1991) and against HBV infection in vivo (Honkoop and de Man 1995). Lamivudine has been coformulated with AZT and marketed as combivir.

Carbovir, Abacavir (Ziagen)

Abacavir is a carbocyclic synthetic nucleoside analogue (Figure 14). Intracellularly, abacavir is phosphorylated by cellular enzymes to its active metabolite, carbovir triphosphate, which is an analogue of deoxyguanosine-5′-TP. Carbovir-TP then inhibits the activity of HIV reverse transcriptase both by competing with the

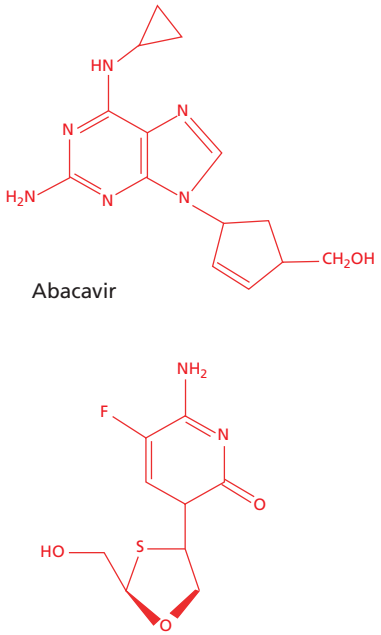

Figure 14 *Further examples of HIV nucleoside reverse transcriptase inhibitors: NRTI*

natural substrate dGTP and by its incorporation into viral DNA. The lack of a 3′-OH group in the incorporated nucleoside analogue prevents the formation of the 5′ to 3′ phosphodiester linkage essential for DNA chain elongation, producing chain termination. Abacavir is often used in combination with lamivudine and zidovudine, as well as with either a nonnucleoside reverse transcriptase inhibitor or protease inhibitor.

Adverse reactions associated with abacavir therapy include nausea, headache, stomach pain, diarrhea, insomnia, rash, fever, and dizziness. Importantly, fatal hypersensitivity reactions have been associated with abacavir use.

Abacavir resistance is conferred by mutations in the HIV reverse transcriptase gene that resulted in amino acid substitutions at positions K65R, L74V, Y115F, and M184V. M184V and L74V are the most frequently observed mutations among clinical isolates. Multiple reverse transcriptase mutations conferring abacavir resistance exhibit cross-resistance to lamivudine, didanosine, and zalcitabine in vitro.

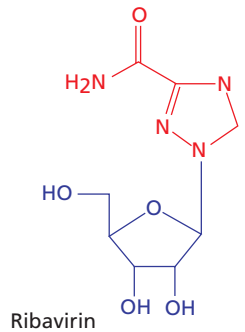
Emtricitabine (FTC) (Emtriva)

Emtricitabine is a synthetic nucleoside analogue of cytosine (Figure 14) active against the reverse transcriptase of HIV-1. Following triphosphorylation by cellular enzymes, it competes with the natural substrate deoxycytidine 5′-triphosphate and, following incorporation into the nascent viral DNA, results in chain termination.

Other related compounds, e.g. Entecavir, have been found to be more useful against HBV infection and are under investigation for the treatment of chronic HBV infection (see section on Inhibitors of hepatitis viruses, below). Entecavir is a promising new drug that has entered a Phase III clinical trial for efficacy. The compound is a cyclopentile guanosine nucleoside analogue (Figure 15) with selective activity against hepatitis B viral DNApol. It is orally bioavailable, and due to a long terminal elimination half life of approximately 110 h, is clearly suitable for once daily therapy. Similarly, a series of L-nucleosides is advancing through Phase II and III clinical trials. Hepatitis viruses are considered in more detail and a description of further inhibitors is dealt with in the section entitled Inhibitors of hepatitis viruses.

NONNUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS (NNRTI)

The intensive screening of compounds for anti-HIV activity led to the discovery of several families of inhibitors that, although they differ from one another in structure, share the property of inhibiting reverse transcriptase by binding to sites other than that which normally interacts with the nucleosides. Some act at concentrations in the nanomolar range and are cytotoxic only at 10 000- to 100 000-fold higher concentrations. HIV-1 (but, notably, not HIV-2) reverse transcriptase is



Ribavirin

Figure 15 *The broad spectrum nucleoside inhibitor, ribavirin, entecavir, and the synthetic peptide, T-20 which is anti-HIV fusion inhibitor*

the target sensitive to inhibition. Enzyme studies, however, indicated that such compounds inhibit reverse transcriptase in a noncompetitive fashion (De Clercq 1992). The site on the enzyme at which these compounds bind has been termed the TIBO site (Pauwels et al. 1990) and certain other compounds (e.g. HEPT, an acyclic uridine derivative) seem to interact with the same site (Baba et al. 1989) (TIBO and HEPT are discussed below). These compounds have been collectively described as allosteric inhibitors. The rapid selection of drug-resistance seems to be a major limitation of the success of these compounds, which, however, are likely to have an important role when used in combination both with other nonreverse transcriptase inhibitors and with other classes of inhibitor.

TIBO, nevirapine and HEPT

A series of nonnucleoside inhibitors was discovered that are tetrahydro-imidazo[4,5,1-jk][1,4]-benzodiazepin-2H (1H)-thione derivatives (Figure 16) (Debyser et al. 1991). This almost unpronounceable name is usually shortened to TIBO. This benzodiazepine-like drug was the first of the NNTRI to be identified (De Clercq 1992). Early trials showed a large but transient reduction in viral

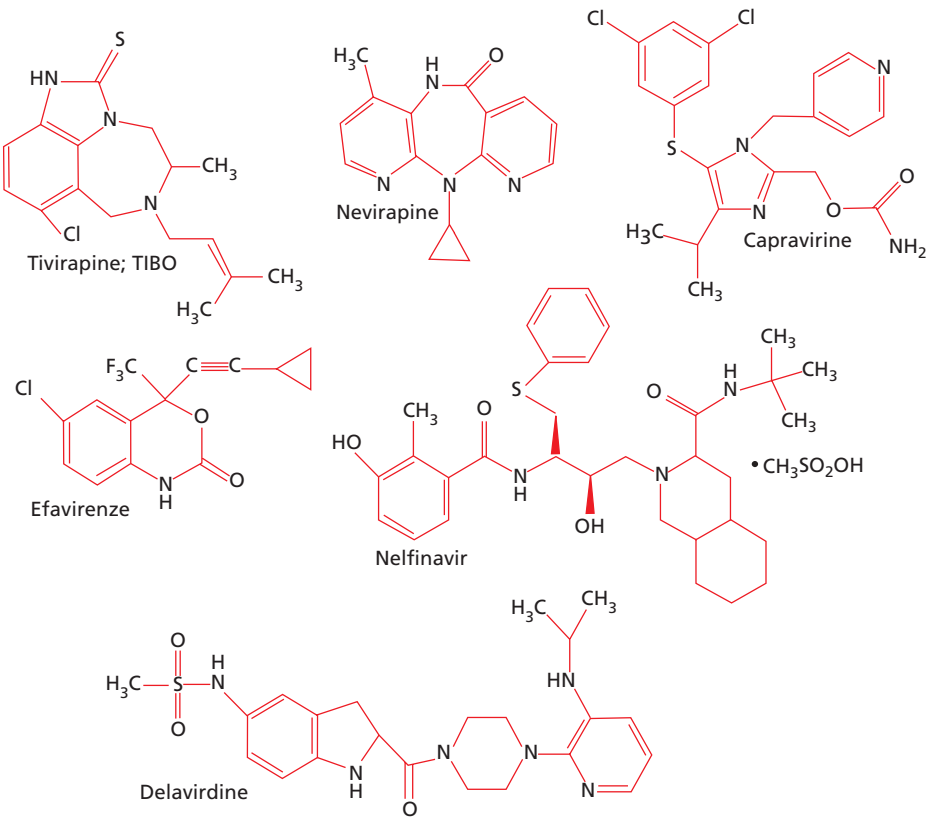

Figure 16 *Nonnucleoside analogue inhibitors of HIV reverse transcriptase (NNRTI)*

load. The drug is of relatively low toxicity but its oral bioavailability is poor. Nevirapine (Figure 16) is another noncompetitive inhibitor of reverse transcriptase that interacts with tyrosine residues on the enzyme (Merluzzi et al. 1990) and yet another series of compounds of this general type, hydroxyethoxymethylphenylthiothymine derivatives, has been given the acronym HEPT (Figure 16) (Miyasaka et al. 1989).

Nevirapine (Viramune)

Nevirapine is a nonnucleoside (dizyridodiazepinone) reverse transcriptase inhibitor that is structurally similar to benzodiazepines (Figure 16) (Merluzzi et al. 1990). Binding of nevirapine to reverse transcriptase is noncompetitive. It selectively inhibits HIV-1, but not HIV-2, reverse transcriptase without significant inhibition of other cellular polymerases. It is currently used in combination with nucleoside reverse transcriptase inhibitors and/or protease inhibitors. Because of the rapid and certain appearance of resistance, it is not used as monotherapy. The major side effect of nevirapine is the development of a cutaneous rash including 'Stevens Johnson syndrome' which is a severe rash, often drug-induced. Other less common side effects include altered liver function tests, fever, and myalgia. Since nevirapine is metabolized by the liver, there is the potential for interaction with other hepatically metabolized medications metabolized by this organ, including rifabutin, rifampin, ketoconazole, and the protease inhibitors.

Resistance to nevirapine occurs at codons 181, 188, 103, 106, 108, and 190, all of which result in a significant reduction in nevirapine susceptibility to treatment. A nevirapine-associated mutation at codon 181, concurrent with the presence of the most common zidovudine resistant mutation (codon 215), appears to restore susceptibility to zidovudine.

Delavirdine (Rescriptor)

Delavirdine binds directly to reverse transcriptase and blocks RNA-dependent and DNA-dependent DNApol activities (Figure 16). HIV-2 reverse transcriptase and human cellular DNApol are not inhibited by delavirdine. In addition, HIV-1 group O, a group of highly divergent strains that are uncommon in North America, may not be inhibited by delavirdine. Delavirdine is frequently used as combination therapy with two nucleoside reverse transcriptase inhibitors, such as zidovudine and didanosine, with or without a protease inhibitor. Adverse reactions associated with delavirdine therapy include rash (which may be maculopapular or pruritic), headache, increased transaminases, nausea, diarrhea, fatigue, and, rarely, Stevens Johnson syndrome. Delavirdine increases concentrations of the protease inhibitors saquinavir, nelfinavir, and indinavir when given in combination.

Mutations conferring resistance to delavirdine occur predominantly at position 103 and less frequently at positions 181 and 236. Combination therapy with delavirdine and zidovudine may result in increased zidovudine sensitivity of patient isolates after 24 weeks on therapy. Mutations at positions 103 and 181 have been associated with resistance to other NNRTI.

Efavirenz (Sustiva)

Efavirenz is mediated predominantly by noncompetitive inhibition of HIV-1 reverse transcriptase (Figure 16). HIV-2 reverse transcriptase and human cellular DNApol are not inhibited by efavirenz. Efavirenz is frequently used in combination with two or more nucleoside reverse transcriptase inhibitors, with or without a protease inhibitor. Side effects include headache, dizziness, diarrhea, skin rash, impaired concentration, anxiety, visual disturbances, nausea, vomiting, insomnia, fatigue, and flulike symptoms. Efavirenz has produced numerous birth defects in animal models, and is contraindicated in pregnancy. No clinically significant drug interactions occur between efavirenz and nucleoside reverse transcriptase inhibitors. Efavirenz decreases indinavir concentrations, necessitating an increase in indinavir dosing when given concomitantly with efavirenz. Saquinavir concentrations are diminished to such a degree by efavirenz that the two should not be used in combination.

Mutations at the reverse transcriptase amino acid positions 98, 100, 101, 103, 106, 108, 188, 190, and 225 confer efavirenz resistance. The mutation at position 103 (lysine to asparagine) is the most frequently observed. Efavirenz-resistant isolates are frequently resistant to others in the same class.

Capravirine

Capravirine (Figure 16) is the last of this series of NNRTIs currently under investigation. It has potent activity in vitro against HIV variants but RT substitutions are detected including K103N that confer broad cross resistance to the other drugs in this class.

PROTEASE INHIBITORS

HIV encodes an enzyme that specifically cleaves protein precursors in the maturation of gag and pol polyproteins (Pearly and Taylor 1987). Inhibition of this enzyme results in the production of noninfectious virus (Kohl et al. 1988). This virus-induced enzyme has no known cellular function, but a number of highly specific inhibitors of HIV whose action is based on inhibition of the HIV protease have been reported (De Clercq 1995).

Saquinavir (Fortovase, Invirase)

This was the first active virus protease inhibitor to be described. It is a peptide-based transition-state mimetic of an Asn.Phe.{ }Pro. substrate sequence, in which { } indicates the cleavage site (Roberts et al. 1990).

Saquinavir (Figure 17) is an extremely active inhibitor of HIV replication in cell culture, with a very high selective index and was the first licensed protease inhibitor worldwide. Its pharmacokinetic properties are, however, not ideal for use in vivo (Roberts 1995). Furthermore, viruses of many other families encode proteases, including pathogens as diverse as polio, HCV, influenza, and HSV, against which a similar approach is being directed. The potential for these compounds to be valuable inhibitors seems to be great but their ultimate success in clinical use cannot yet be predicted. Adverse reactions include diarrhea, abdominal discomfort, and nausea. Photosensitization can occur. Saquinavir is metabolized by the liver enzyme system: cytochrome P-450; thus, ketoconazole and itraconazone increase the plasma levels of saquinavir, as does ritonavir, a fact that has been utilized in the development of combination protease inhibitor therapies.

Saquinavir-resistant HIV occurs most commonly at the HIV protease L90M site. Saquinavir is effective against ritonavir- and indinavir-resistant mutants.

Ritonavir (Norvir)

Ritonavir (Figure 17) is a peptide-like inhibitor of HIV proteases and one that renders them incapable of processing the gag–pol polyprotein precursors required for assembly of progeny virions. Ritonavir is used in combination with NRTI and/or NNRTI. Ritonavir is also metabolized by the cytochrome P450 system, as is saquinavir. Ritonavir increases plasma levels of macrolides, particularly clarithromycin and erythromycin, anticonvulsants, tricyclic antidepressants, and the azole antifungals. Ritonavir also increases levels of saquinavir, and, as such, low doses of ritonavir are sometimes used in combination with saquinavir to achieve higher saquinavir concentrations. Adverse reactions include nausea, vomiting, anorexia, abdominal pain, taste perversion, and circumoral and peripheral paresthesia. Furthermore, there are alterations in triglyceride metabolism and elevation of liver function tests have also been described. Clinically, fat redistribution can appear.

Ritonavir resistance occurs with mutations in HIV protease at codons 84, 82, 71, 46, 54, and 36. The development of mutations is stepwise, occurring first at codon 82. Cross-resistance with indinavir but not saquinavir is common.

Indinavir (Crixivan)

Indinavir (Figure 17) binds to cleavage sites of HIV protease; thereby, it prevents cleavage of viral polyprotein precursors into individual proteins required for progeny virions assembly. Adverse reactions associated with indinavir therapy include nephrolithiasis, hematuria, and occasionally hyperbilirubinemia.

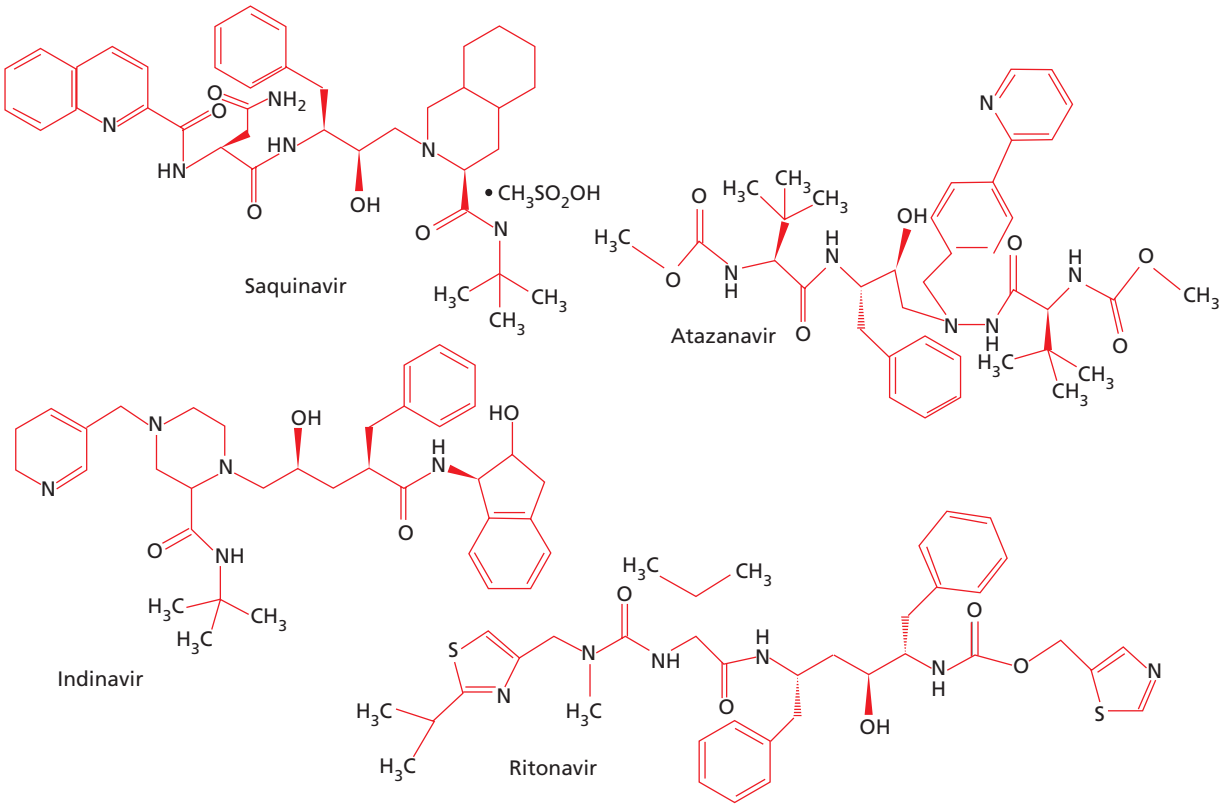

Figure 17 *Highly active inhibitors of the HIV protease (PI)*

Administration of indinavir selects for resistant mutants with alterations in HIV protease at a variety of different amino acid sites. Increased resistance is a function of stepwise acquisition of multiple mutations in HIV protease.

Nelfinavir (Viracept)

Nelfinavir (Figure 18) is a nonpeptidic inhibitor of HIV protease that inhibits or interferes with processing of viral polyprotein precursors, resulting in noninfectious progeny virions. It is given in combination with NRTI and/or NNRTI. Nelfinavir is metabolized by the cytochrome P450 system. Adverse events associated with nelfinavir administration include diarrhea, rash, leukopenia, and neutropenia.

Resistance to nelfinavir occurs by mutations in HIV protease, particularly at codons 30, 35, 36, 46, 71, 77, and 88. Importantly, these sites are all different from those that confer resistance to other protease inhibitors. However, once resistance to a protease inhibitor develops, it is likely that cross-resistance will occur.

Amprenavir (Agenerase)

Amprenavir (Figure 18) acts by binding to the active site of HIV-1 protease, preventing the processing of viral gag and gag–pol polyprotein precursors and results in the formation of immature non-infectious viral particles. In vitro, amprenavir has synergistic anti-HIV-1 activity in combination with abacavir, zidovudine, didanosine, or saquinavir, and additive anti-HIV-1 activity in combination with indinavir, nelfinavir, and ritonavir. Adverse effects associated with amprenavir administration include rash, nausea, vomiting, diarrhea, abdominal pain, and perioral paresthesias. Amprenavir is metabolized by the P450 system.

Resistance to amprenavir is conferred by amino acid substitutions primarily at positions M46I/L, I47V, I50V, I54L/V, and I84V, as well as mutations in the viral protease p1/p6 cleavage site. Cross-resistance between amprenavir and the other protease inhibitors is possible.

Lopinavir/Ritonavir (Kaletra)

Lopinavir/ritonavir combination interferes with processing of viral polyprotein precursors, resulting in noninfectious progeny virions (Figure 18). The addition of ritonavir enhances the concentrations of lopinavir that can be achieved following oral administration. It is given in combination with NRTI and/or NNRTI. Side effects of lopinavir/ritonavir include diarrhea, nausea, abdominal pain, and headache.

As lopinavir/ritonavir is a relatively new addition to the protease inhibitors; a complete understanding of resistance profiles will await its widespread utilization.

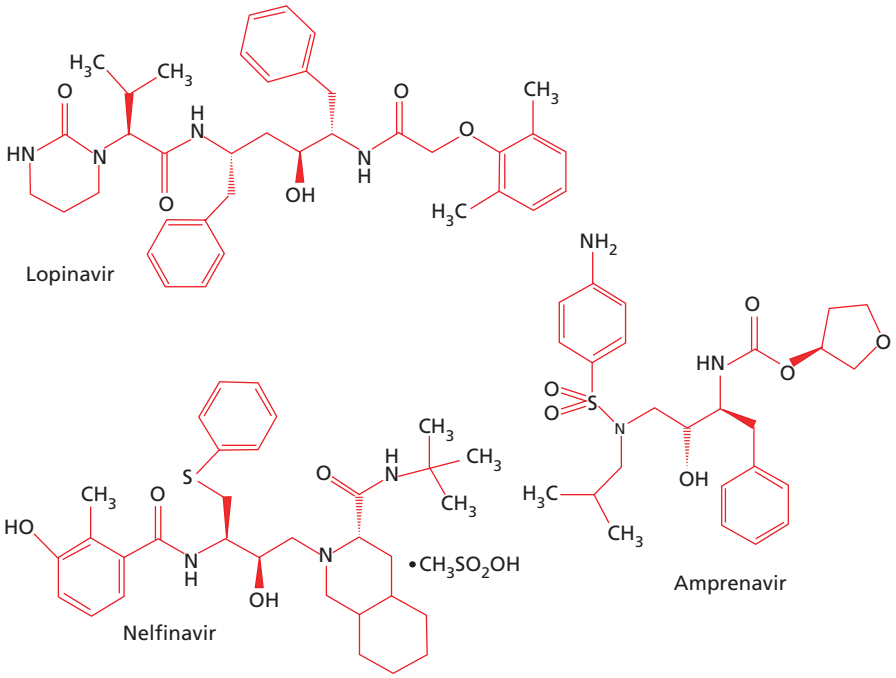

Figure 18 *Further examples of PI which are highly active against HIV*

Atazanavir (Reyataz)

Atazanavir (Figure 17) is a protease inhibitor. It prevents cells infected by HIV from producing new virus, reducing the amount of virus in the patient. It must be used in combination with at least two other anti-HIV drugs (Prober and Kimberlin 2005).

NUCLEOTIDE ANALOGUES

Tenofovir (tenofovir disoproxil fumarate) (Viread)

Tenofovir or disproxil fumarate salt (Figure 7) is an acyclic nucleoside phosphonate diester analogue of adenosine monophosphate. In vitro, the 50 percent inhibitor concentration for HIV is 0.04–8.5 μmol. After diester hydrolysis, tenofovir is phosphorylated to tenofovir-DP that then inhibits HIV reverse transcriptase by competing with the natural substrate deoxyadenosine 5-TP and, after incorporation into DNA, by DNA chain termination. Tenofovir DP is a weak inhibitor of mammalian DNApols α, β, and mitochondrial DNApol γ. Additive or synergic anti-HIV activity with nucleoside analogue, nonnucleoside analogue and protease inhibitors has been demonstrated in vitro. Side effects include lactic acidosis, hepatomegaly with steatosis, and diarrhea, (De Clercq 2002). Resistance is uncommon and occurs at codon 65.

Entecavir

Entecavir (Figure 19) is a cyclopentile guanosine nucleoside analogue with selective activity against hepatitis B viral DNApol. It is orally bioavailable, and due to a long terminal elimination half life of approximately 110 h is clearly suitable for once daily therapy.

HIV FUSION INHIBITORS

Enfuvirtide (Fuzeon)

The recent licensing of a fusion inhibitor introduces a new class of antiviral compounds for the treatment of HIV. T-20n (Figure 15) (Lalezari et al. 2003) is an inhibitor of fusion of HIV-1 with $CD4^+$ cells that consists of a 36 amino acid synthetic peptide with the N terminus acetylated and the C terminus is a carboxamide. Medication is administered subcutaneously.

Inhibitors of orthomyxo- and paramyxoviruses

EARLY PROGRESS WITH ION CHANNEL BLOCKERS

Amantadine and rimantadine

The compound amantadine (Figure 20) has long been known as a specific inhibitor of influenza virus A; influenza B and C are not affected. Clinical experience with amantadine and the chemically related rimantadine, dates from the early 1960s (Davies et al. 1964) and, although these compounds have lately been replaced, they represent major milestones in the history of the development of antiviral chemotherapy. The mechanisms of action of amantadine, and subsequently of rimantadine, which is very similar but with superior

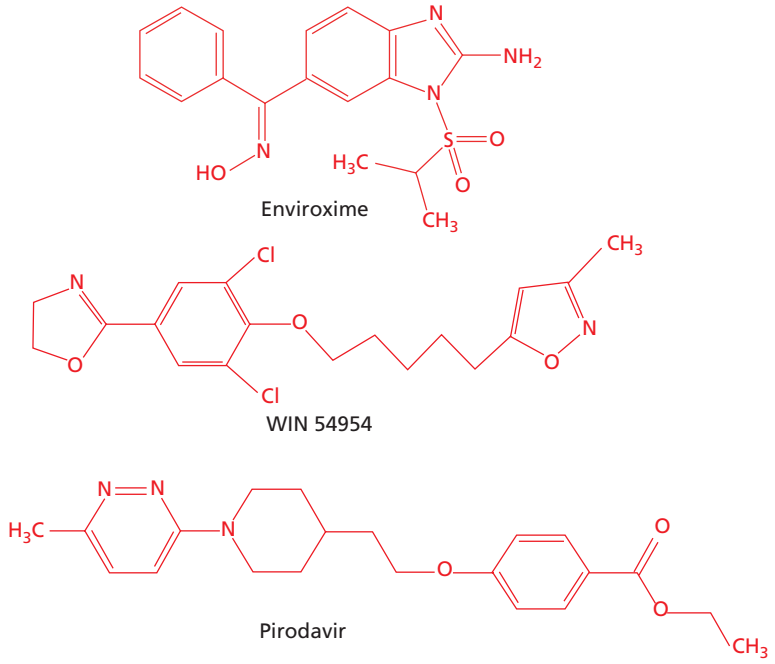

Figure 19 *Compounds with activity against the common cold – picornavirus inhibitors*

pharmacological properties (Hayden et al. 1981, 1985), were not elucidated until many years after they had been introduced into the clinic (Hay 1992).

Following attachment to host-cell plasma membrane receptors by means of the influenza envelope glycoprotein spikes, or hemagglutinin (HA), virus is taken up by cells into clathrin-coated pits. The virus, at this early stage of its replication cycle, is contained within lysosomes. Low pH within the lysosome results in conformational changes in the HA which exposes the amino-terminus region of the HA2; this region is hydrophobic and triggers a fusion between the endosomal membrane and the virus envelope, releasing the nucleocapsid into the cytoplasm of the host cell. Originally, amantadine was thought to work simply by raising lysosomal pH, thereby interfering with the conformational change leading to virus fusion with membrane. It now appears that the process of inhibition is more subtle. The M2 protein in the nucleocapsid seems to form a polymeric tube-like structure which behaves as an ion channel through which protons pass. Amantadine and rimantadine seem to act by binding to M2, possibly being inserted into the channel itself, and thus interfering with the penetration of hydrogen ions into the virion; a process essential for uncoating the single-stranded RNA genome (Wang et al. 1993). Resistant mutations map to the *M2* gene and such variants may ultimately limit the success of chemotherapy (Hayden 1994). Both amantadine and rimantadine have a basketlike hydrocarbon structure and further active compounds of this type are under study. The knowledge of how these compounds interact with the M2 proton channel should enable the rational design of further influenza inhibitors of this type.

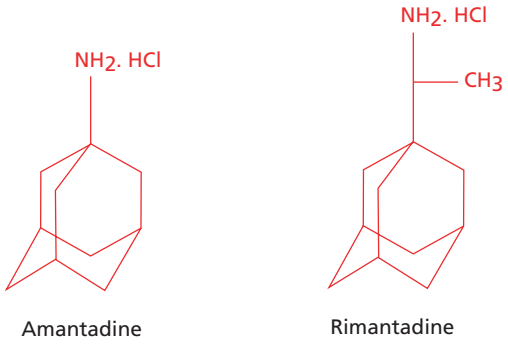

Figure 20 *Amantadine and rimantadine, early inhibitors of influenza which target the M2 protein*

The clinical efficacy of the prophylaxis and treatment of influenza virus infections with amantadine and rimantadine has been reviewed by Hayden (1997). The effectiveness of both compounds is limited by the adverse side effects, lack of activity against influenza B viruses, and rapid emergence of transmissible and pathogenic resistant viruses that remain transmissible and pathogenic emerge readily during clinical use (Hayden and Couch 1992; Monto and Arden 1992).

NEURAMINIDASE INHIBITORS

Zanamivir (Relenza) and Oseltamivir (Tamiflu)

While the study of HA dominated the early molecular characterization of influenza, it became apparent that

the influenza envelope is decorated with a second glycoprotein spike, much less numerous than HA, but with a distinctive long-stalked 'mushroom' shape. Neuraminidase (NA) was discovered to possess an enzymatic ability to cleave sialic acid from sialylated glycoproteins to yield free sialic acid. Known at first as sialidase, the term neuraminidase is now used universally. Sialic acid (Figure 21) is the receptor for the influenza virus on mammalian cells and interference with NA by mutations, anti-NA antibody or chemical compounds that bind to NA, all inhibit release of virus from infected cells. NA is also thought to have a role in the passage of virus through mucus to facilitate its colonization of respiratory mucosal cells.

An important molecule in research is Neu5Ac2en (Figure 21); this is a dehydrated neuraminidase acid derivative that mimics the geometry of the transition state during the enzymatic reaction. In the early 1990s the high resolution crystal structure of sialic acid and the transition state analogue Neu5Ac2en bound to influenza A and B NAs was solved. The NA active site contains some well-formed, large, and relatively rigid pockets that enable the rational design of molecules to interact with this virus component (reviewed by Kim et al. 1999). Several important inhibitors emerged from such studies. The guanidinyl group was substituted for a hydroxyl carbon atom of Neu5Ac2en to produce the compound 4-Guanidino-Neu5Ac2en (von Itzstein et al. 1993) or zanamivir (Relenza®; Figure 21). The polar zwitterionic properties of zanamivir give low oral bio-availability and, with rapid excretion, the compound must be administered intranasally or by inhalation. Another active compound introduced a cyclohexene ring and replaced a polar glycerol with lipophilic side chains (Tai et al. 1998; Sidwell et al. 1998; Mendel et al. 1998) to produce oseltamivir (Tamiflu®; Figure 22). This is an ethyl ester that is orally bio-available (30–100 percent) and is readily converted to the active carboxylate by esterases in the liver (Hitchcock 1996; Figure 22). Laboratory animal studies using infected mice and ferret models of influenza showed good dose-dependent antiviral effects and subsequently, both oseltamivir and zanamivir have proved successful when used prophylactically or therapeutically in clinical trials (reviewed by Oxford et al. 2002). Relatively few side-effects have been reported although a concern about zanamivir has been exacerbation of reactive airway disease (Cheer and Wagstaff 2002), however, compliance with the inhaler has been good. Oseltamivir causes some gastro-intestinal effects such as nausea. Several studies of prophylaxis among contacts in the workplace and among family members suggest a protective efficacy for zanamivir of 60–70 percent. The therapeutic use of either drug has been encouraging, and they have been shown to significantly alleviate the clinical signs of influenza (Oxford et al. 2002). Drug resistance mutations are detected following passage in cell culture. The mutations occur in both NA and HA hinting at functional interdependence between the two virus glycoproteins. However, the clinical data to date allow optimism. The incidence of resistance has been low compared to previous experience with rimantadine and where it does occur, resistance is

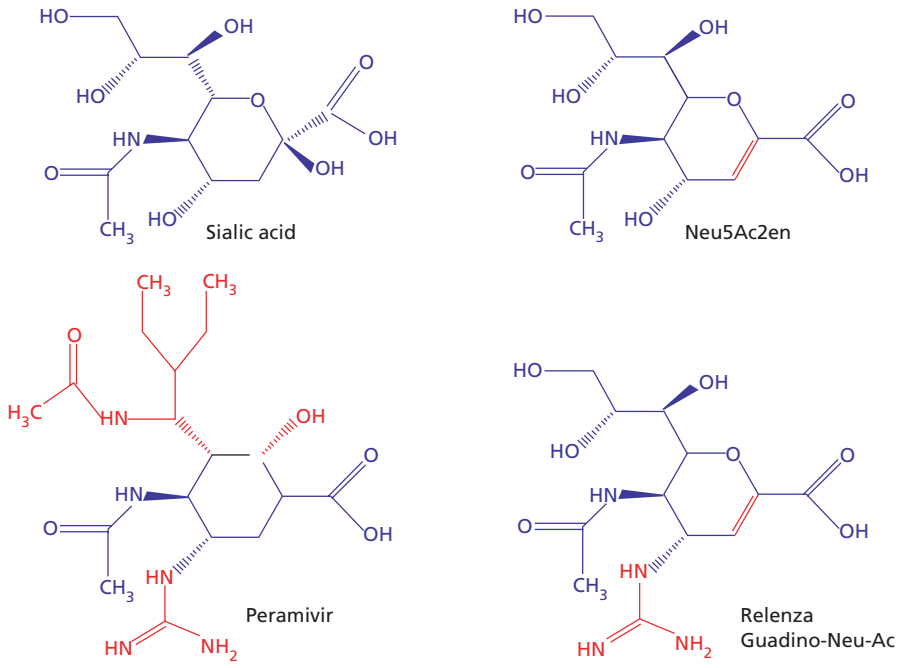

Figure 21 *The natural compound sialic acid showing its relationship to Neu5Ac2en and the first effective influenza virus neuraminidase inhibitor, relenza. Chemical modifications that vary from the natural compound are shown in red.*

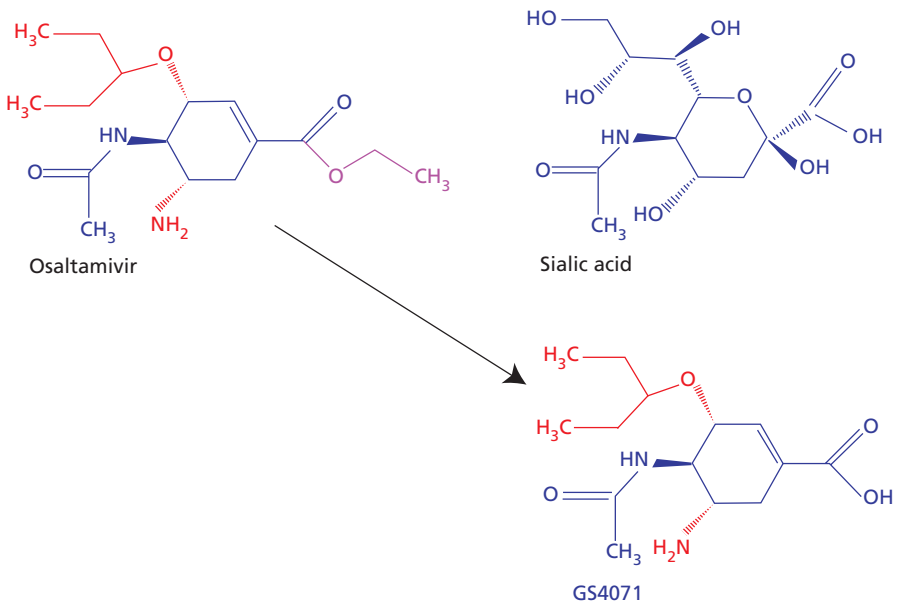

Figure 22 *Sialic acid and an orally bioavailable neuraminidase inhibitor, oseltamivir, showing its conversion to the active metabolite. The parts of the molecule shown in purple are removed by host enzyme attack to release the NA inhibitor in vivo.*

detected only transiently, arising late in infection and being cleared normally (Treanor et al. 2000). There is evidence that some of the mutants, at least, are attenuated in mice and ferret models (Herlocher et al. 2002). Thus early clinical data are very encouraging, however, the true potential of zanamivir, oseltamivir, and similar NA inhibitors now awaits the test of the next pandemic influenza outbreak.

Currently, the search for alternative NA inhibitors is active and it is likely that improved drugs will emerge. One novel compound is a dimerised zanamivir molecule that was suggested to be 100-fold more potent than zanamivir in vitro. It was shown to be retained longer in laboratory animal lungs compared with zanamivir, permitting much longer intervals between doses. Another Neu5Ac2en-derived analogue, peramivir (Figure 21) was also claimed to be more potent than zanamivir or oseltamivir in cell culture (Boivin and Goyette 2002). Phase II trials were promising, although Phase III less so, and currently development has stopped. Although these particular compounds may not be progressed, the preliminary results strongly suggest that the NA inhibitors presently in use have not achieved maximum efficacy and that more potent drugs in this class will become available in due course.

Ribavirin

Ribavirin 1-β-D-ribofuranosyl-1H-1,2,4-tiazole-3-carboxamide is an inhibitor of paramyxoviruses, particularly respiratory syncytial virus; however, clinical application has been controversial since its discovery was reported in 1972 (Sidwell et al. 1972). The compound is a guanosine analogue (Figure 15); evidence has been obtained for at least three distinct modes of action but the important molecular targets have yet to be confirmed (reviewed by Sidwell et al. 1985). It is a structural analogue of guanosine and is converted successively to ribavirin-MP, -DP, and -TP by cellular enzymes. The inhibition of virus is not, however, reversed by adding guanosine, suggesting a more complicated mode of action (Gilbert and Knight 1986). The enzyme inosine-MP dehydrogenase is effectively inhibited in vitro by ribavirin-MP, with a resulting decrease in pool size of GTP. However, this is not thought to be the single inhibitory factor. Ribavirin-resistant mutants have been very difficult, if not impossible, to isolate in the laboratory. This may be because the compound interferes with multiple virus targets; alternatively, there may be one or more important cellular effects that are not virus-specific. Clinically, aerosolized ribavirin has been reported to be efficacious for treating respiratory syncytial virus infection of infants (Sidwell et al. 1985); however, the results of more recent clinical trials cast doubt on the value of this agent (Wald et al. 1988). Ribavirin has proved to be a useful antiviral drug against several disparate virus families, e.g. hepatitis (see below). Paramyxoviruses cause a wide variety of human and animal diseases and there is a constant threat from new and dangerous viruses to emerge with pandemic potential. In molecular terms, the family has many similarities to the *Orthomyxoviridae* which includes influenza with similar potential targets for inhibition yet, to date, apart from ribavirin, to be screened there remains a paucity of effective compounds in development to combat members of the *Paramyxoviridae*.

As noted below, ribavirin is used in combination with interferon to treat HCV.

Inhibitors of hepatitis viruses

Several distinct viruses infect the liver and cause hepatitis. Furthermore, virus infections of this organ are prone to become persistent leading to chronic hepatitis and pathological sequelae including cirrhosis and liver cancer. Of the many hepatitis viruses discovered, to date, the most important are HBV and HCV. The former is a member of the *Hepadnoviridae*, a family of enveloped icosahedral viruses that contain a double-stranded, circular DNA genome and reverse transcriptase step in the replication cycle analogous to that in HIV. By contrast, HCV particles are nonenveloped and contain a small, positive single-stranded RNA genome. HCV is classified in the genus *Hepacivirus* within the family *Flaviviridae*. HCV does not replicate in conventional tissue culture systems and this has severely hampered research on potential inhibitors.

Both these viruses are major causes of human disease; there are estimated to be 300–400 million carriers of HBV worldwide (reviewed by Main et al. 1998) and some 170 million chronic HCV carriers (Walker et al. 2003), causing an estimated 10–12 000 deaths per annum in the USA alone. In both cases, chronic infection can lead to progressive liver disease, especially cirrhosis, with the increased risk of hepatocellular carcinoma. There is an effective subunit vaccine for HBV but this has no benefit for those already infected. The aim of antiviral chemotherapy is to clear the virus from the liver and thus prevent the life-threatening complications of chronic virus hepatitis and reduce the risk of transmission to others.

INTERFERONS

Since the early 1970s, interferon-α (IFN-α) has been used to treat chronic HBV and success rates of up to 40 percent have been reported for those who acquired infection as adults although treatment of carriers who acquired infection perinatally is less successful. Leucocyte and lymphoblastoid interferon (IFN), of both human and recombinant origin, have been reported as effective in decreasing viral replication in patients (Hoofnagle 1994). The mechanism of action is uncertain but may include the effects of increasing natural killer cell activity and enhancing MHC class-1 activity bearing in mind that hepatocytes naturally have little MHC -1 display. A typical regimen is 5–10 MU/m^2 three times weekly for 3–4 months. IFN-α treatment of Asian patients does not prevent the occurrence of cirrhosis-related complications and hepatocellular carcinoma (Yuen et al. 2001). For the treatment of HCV, like HBV, IFN-α monotherapy has enjoyed some success. Recently, PEG–IFN is now the preferred IFN molecule which is chemically modified form using mono-methoxy polyethylene glycol (PEG) or a branched PEG molecule. This modification has the effect of slowing IFN absorption, decreasing the rate of systemic clearance and produces an approximately 5–10-fold increase in serum half-life. For the treatment of HCV infection, PEG-IFN is used only in combination with ribavirin.

NUCLEOSIDE AND NUCLEOTIDE ANALOGUES

Apart from IFN-γ, there are currently several antiviral compounds in clinical use for the treatment of HBV. While treatment with several nucleoside analogues (e.g. fialuridine, ribavirin, and lamivudine) have been investigated (Honkoop and de Man 1995) only two are licensed: lamivudine and adefovir dipivoxil (Figures 7 and 13). The L-isomer of 3TC is more active against HBV replication and less cytotoxic than the D-isomer and is assumed to act on the HBV reverse transcriptase step and it may also inhibit the completion of double-stranded DNA. The drug is remarkably free of side effects but there is a high relapse rate, thus, after 6–9 months therapy, drug resistance develops due to mutations in the catalytic domain of the HBV polymerase gene. There is some evidence that the resistant viruses may be less replication-competent compared with the parental virus, however, resistant virus is thought to be responsible for the flare-up of hepatitis. Trials showed a rapid decrease in levels of HBV DNA in treated patients but a return to baseline at the end of therapy.

The nucleotide analogue adefovir dipivoxil (9-2-phosphonylmethoxyethyl) adenine (bis(POM)PMEA) (Figure 7) appears to be less susceptible to the development of resistance. The dose of adefovir is significantly lower than that used in studies of HIV infection where renal toxicity was observed. Whether this poses a problem on long-term administration remains to be determined.

COMBINATION THERAPY

Treatment of chronic HBV infection is associated with relapse on cessation of therapy and the emergence of drug-resistance. Following the success of combination therapy for HIV, the use of combinations of drugs to treat HBV and HCV have become common. IFN-α plus lamivudine or adefovir or the use of lamivudine and adefovir combinations are currently under investigation (Yuen and Lai 2003).

The combination of ribavirin with PEG–IFN-α-2a (rebetron) or PEG–IFN-α-2b, typically for 12–24 weeks, results in sustained virologic responses in the range of 40 to 50 percent, however, outcome is phenotype dependent.

Animal models for studying hepatitis virus chemotherapy

HBV and HCV are extremely difficult viruses to manipulate in tissue culture. Stably transfected lines of HepG2 cells can be used to study the replication of HBV; it is tetracyclin regulated. These cells can be used to screen and study inhibitors. However, much development work

for antiviral therapy has depended on the use of laboratory animal infection models. Chimpanzees provide reliable HBV and HCV models for evaluation of vaccines and therapeutic agents (Farci and Purcell 1993; Caselmann 1994; Purcell 1994) but severe restrictions are imposed on the use of nonhuman primates including ethical concerns, welfare considerations, and simply the very high cost of maintaining primates. Tree shrews (*Tupaia belangeri*) can be infected by inoculation with human serum positive with HBV and duck hepatitis has been studied in Pekin ducks. A virus related to HBV was discovered in woodchucks (WHV) that mimics human disease, including the progression of chronic liver infection to hepatocellular carcinoma. HBV is also studied in specially prepared mice: the HBV-Trimera mouse in which mice irradiated lethal total whole body irradiation reconstituted with severe combined immunodeficiency (SCID) mouse bone marrow cells. Human HCV- or HBV-infected liver tissue can be engrafted under the murine kidney capsule which then models the chronically infected tissue in vivo and is available for the study of therapeutic regimens (Ilan et al. 1999). Finally, the pestivirus bovine diarrhea virus (BVDV) is genetically related to HCV and has been used as a surrogate in cell culture system for evaluating anti-HCV compounds. This is currently an extremely active area of research among many academic institutions and pharmaceutical research laboratories. Likely progress will occur with the production of improved tissue culture systems and more convenient and reliable in vivo models to study the prevention and therapy of virus hepatitis; one of the most exciting major growth areas in antiviral therapy today.

Inhibitors of picornaviruses

PIRODAVIR AND PLECONARIL

The *Picornaviridae* are among the smallest of the RNA viruses and cause a broad spectrum of human and animal diseases. Among the *Picornaviridae* are the rhinoviruses. Scientists seeking to develop antiviral chemotherapy are often reproached with failure to 'cure the common cold.' An increasing number of compounds has been reported as potent inhibitors of rhinoviruses; they comprise an assorted collection that fall into two classes, with different antiviral targets. The first class (noncapsid binding) includes compounds such as enviroxime (Figure 19) (De Long 1984). Compounds of this type seem to act shortly after uncoating, inhibiting the formation of the virus RNA-dependent RNA polymerase complex. These compounds are no longer under investigation.

The second class of compounds (capsid binding) has a quite different target of inhibition. Picornaviruses possess a capsid comprising three types of protein subunit (VP1, VP2, and VP3) assembled into an icosahedral shell. The virions are not enveloped and therefore rely on receptor sites on their protein shell to engage and dock on to protein receptor molecules in the plasma membrane of the host cell. X-ray crystallographic studies revealed that attachment of the virus is mediated by a canyon-shaped receptor site which encircles each of the 12 pentameric vertices of the icosahedral capsid. Selective inhibitory compounds, e.g. pirodavir and WIN-54954, work by binding into a hydrophobic pocket (the 'win pocket') situated in VP1 beneath the canyon floor (Figure 23) (Rossmann 1990). Likely, this pocket forms a natural molecular hinge in the protein which may give flexibility to the molecule during disassembly and assembly of the icosahedral structure required when uncoating, and again during production of new virus particles. When the inhibitor is bound into the pocket it may have two effects. First it can interfere with virus attachment to the cell receptor. Secondly, and more important, it may interfere with uncoating (Woods et al. 1989; Andries et al. 1992).

The most promising antipicornavirus compound to progress into clinical development is known as pleconaril. It is a capsid-binding agent, structurally related to WIN 54954 (Pleconaril) (Figure 19) I n vitro, pleconaril inhibits the replication of most rhinoviruses (responsible for >50 percent of all common colds) and enteroviruses. Oral treatment has been studied in randomized double-blind, placebo-controlled trials and was found to produce significant benefits (Hayden et al.

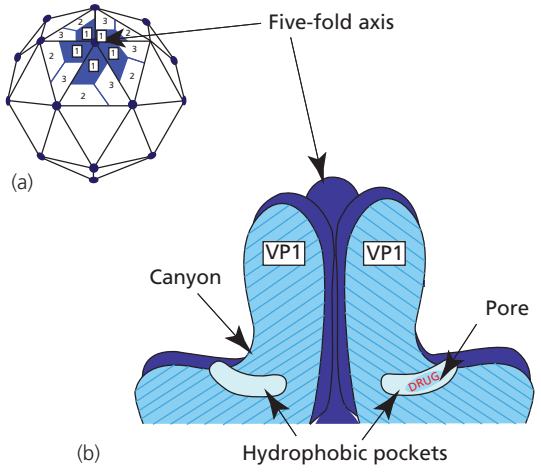

Figure 23 *The proposed mechanism of action for capsid-binding inhibitors of picornaviruses, including rhinoviruses.* **(a)** *Icosahedral capsid of a rhinovirus, depicting the arrangement of the three capsid proteins about a five-fold axis.* **(b)** *Three of the five VP1 proteins at the five-fold axis. A typical rhinovirus inhibitor is binding into the hydrophobic pocket at the base of the canyon, probably reducing the flexibility of the VP1 protein and affecting receptor binding and uncoating. An amino acid substitution in the region forming the pocket may lead to resistance because of the lost ability to bind drug. (Field and Goldthorpe (1985), with permission.)*

2003). Phase III clinical trials involving over 2 000 patients who took the drug showed early and substantial reduction in symptom severity and a 1 day reduction in disease duration. However, an unexpected problem was encountered; namely an interaction with oral contraceptives. Breakthrough bleeding was evident in 3 percent of women taking oral contraceptives during a 5 day course of pleconaril.

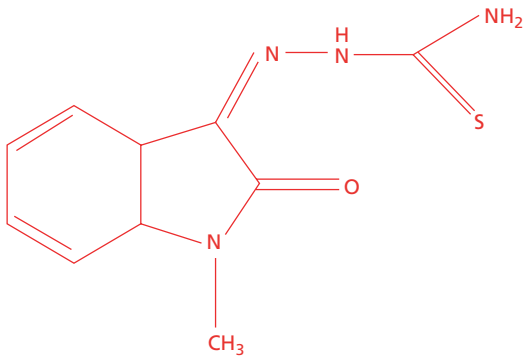
During 2002, the US Food and Drug Administration (FDA) rejected pleconaril (Picovir) as an antiviral drug being developed to treat the common cold on the grounds that this may encourage the development of resistant strains and may reduce the effectiveness of oral contraceptives (Senior 2002). Furthermore, a more recent 6 week prophylaxis study found that pleconaril induces cytochrome P-450 3A enzymes which metabolize a variety of drugs (Hayden et al. 2003).

Despite the encouraging early clinical data on the antiviral effects, the compound is unlikely to be widely used for the less severe upper respiratory virus infections at least until the pharmacological phenomena have been elucidated. It was hoped that the drug may be beneficial for the treatment of more serious picornavirus infections, however early data are less encouraging and a double-blind, placebo-controlled trial of pleconaril in infants suffering from enterovirus meningitis was inconclusive (Abzug et al. 2003).

Inhibitors of other DNA viruses

POXVIRUSES

Smallpox was officially declared to have been eradicated from the world in 1980 after a 10-year campaign of intensive surveillance and vaccination. Although smallpox has not afflicted humans for more than 20 years now, large quantities of the virus are thought to remain in storage and there is concern that this virus might be employed as a weapon of terrorism or biowarfare (Baker et al. 2003). The *Poxviridae* comprise several genera including *Orthopoxvirus* which contains variola (smallpox), vaccinia and monkeypox; *Capripoxvirus* which contains lumpy skin disease; and *Parapoxvirus* which contains orf of sheep and pseudocowpox of cattle. All these infections can infect humans and produce severe disease, especially when the subject is immunocompromised. For all these reasons there is a perceived need for effective antiviral chemotherapy. Historically, 1-methyl-isatin-β-thiosemicarbazones methisazone, Marboran (Bauer et al. 1969) (Figure 24) was among the first selective antiviral agents to be used in humans. It was used with some success during the 1960s to treat smallpox and the severe complication of vaccinia, namely *excema vaccinatum*. The mechanism of action was thought to involve interference with late virus protein synthesis (Hovi 1988). The further development of



Methisazone

Figure 24 *An very early inhibitor of poxviruses – methisazone*

thiosemicarbazones was overtaken by the eradication of smallpox. Furthermore, modern criteria for laboratory assessment of compounds suggests that the potency of marboran is, at best, modest. Members of the acyclic nucleoside phosphonate family of compounds (see Herpesvirus section above) are found to be much more promising; in particular cidofovir and adefovir derivatives (Whitley 2003; Kern 2003). Beneficial clinical responses in severe orf infections in immunocompromised patients have been claimed in single patient studies (Geerinck et al. 2001). The potential for these compounds as inhibitors of poxviruses and a comprehensive catalogue of alternative antiviral strategies for prophylaxis and therapy of poxviruses is documented by Baker et al. (2003).

PAPILLOMAVIRUSES AND ADENOVIRUSES

Human papillomavirus infections most often cause genital warts or juvenile laryngeal papillomatosis. Interferons have been extensively evaluated for treating such infections (see Viral evasion of the host immune response) The local (intralesional) therapy of genital warts refractory to cytodestructive therapy is sometimes effective. The association between genital warts and cervical carcinomas provides further impetus for the development of antiviral agents to treat diseases associated with these viruses. The broad spectrum of action of the acyclic nucleoside phosphonates includes both HPV and adenoviruses. Success has been claimed in small studies (Stragier et al. 2002) providing some optimism for the clinical utility of this family of compounds in such severe cases that are relatively rare, but clinically very difficult to manage. The potential molecular targets offered by HPV for potential antiviral attack are reviewed by Phelps et al. (1998). There has also been much interest in the compound, 1-(2-methylpropyl)-1H-imidazo[4,5-C]quinolin-4-amine), given the generic name imiquimod (Figure 10) (Miller et al. 1995). Similar to resiquimod, the antiviral activity seems to result from interferon-α induction and, if so, would place this compound among the immunomodulators.

PROBLEMS IN ANTIVIRAL CHEMOTHERAPY

Virus evolution and resistance

A DEFINITION OF VIRUS DRUG RESISTANCE

As for all forms of microorganism, including eukaryotic cells, viruses can readily become resistant to inhibitors. This may be defined as: 'An acquired genetic change such that the virus is relieved from inhibition at drug concentrations that are normally inhibitory in the therapeutic range'. For viruses, this is always the result of one or more mutations in the virus genome.

Thus, drug resistance in viruses implies the emergence of strains for which the ED_{50} significantly exceeds the inhibitory concentration normally achieved in vivo (Field 1988b). When possible, a drug-resistant variant is compared directly with its drug-sensitive parent (Figure 25), but in clinical practice the latter may not be available. Criteria have been established to define acquired drug resistance which are particular to each family of virus and are related to the appropriate laboratory tests. Assays which detect mutations known to be associated with resistance are called 'genotypic tests' whereas 'phenotypic tests' are applied to infectious virus (Table 3). There are advantages and disadvantages associated with each type of test (Blaise et al. 2002). Virus families that are naturally insensitive to a compound should not properly be included within the definition of drug resistance.

REASONS FOR STUDYING DRUG RESISTANCE IN VIRUSES

Clearly, drug resistance is an important medical problem which may subvert otherwise successful therapy. However, the phenomenon also has some uses. The detection of resistant mutants is a very important criterion for demonstrating that a particular drug is selective for the target virus. Once drug-resistant mutants have been obtained, the location and nature of drug resistance mutations enables the identification of the target gene(s) in the virus and functional domains in target proteins to be defined at a molecular level. In turn, this enables patterns of cross resistance to be predicted and is often important in the development of further compounds with improved antiviral characteristics. Thus, the selection and study of drug-resistant variants plays a vital part in the development process of all new compounds

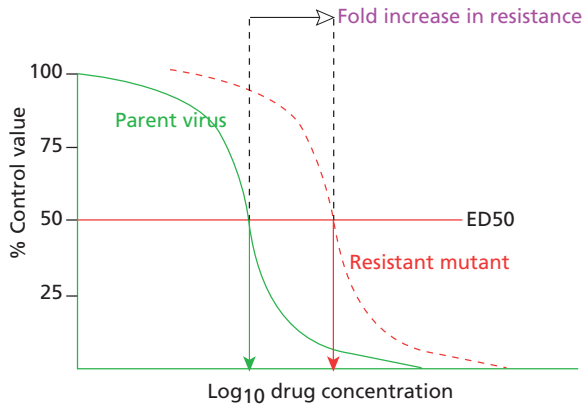


Figure 25 *Measurement of increase in resistance, e.g. when the ED_{50} of the mutant is 10 μg/ml and the parental strain is 0.1. This would represent an increased resistance of 100-fold.*

VIRUS EVOLUTION

Point mutations, or small groups of mutations, can readily lead to substantial increases in resistance to various specific antiviral drugs (Coen 1986; Field and Owen 1988; Mellors et al. 1995). Viruses are susceptible to natural mutations which may occur as a result of

- damage due to chemical mutagens, ionizing radiation cosmic rays etc
- enzymatic modification after replication
- errors by the polymerase during replication.

Of the three possibilities, the last is the most important. Some antiviral drugs are potential chemical mutagens, notwithstanding, most mutants appear to arise naturally and have a selective advantage in the presence of the inhibitor. Several types of mutation are possible: transition (A↔G, C↔T); transversion (A↔C↔G, A↔T↔G), insertion; and deletion. Insertions and deletions are particularly common when there are runs of identical nucleotides such as several consecutive guanosine residues, sometimes referred to as a 'G-string'. Insertions or deletions into such a sequence may introduce a frame-shift and disruption of the normal polypeptide.

VIRUS POLYMERASES ARE ERROR-PRONE

DNA viruses have a relatively low intrinsic error rate (1×10^{-7} to 1×10^{-8} errors per nucleotide). In double-stranded DNA viruses, a 3′–5′ exonuclease proofreading function can edit out errors giving an overall rate of $<1 \times 10^{-9}$. However, given the large number of viruses in an infected host, this is still sufficiently high for DNA viruses to evolve very rapidly relative to higher life forms.

RNA viruses have very high intrinsic mutation rates and there are no proofreading or repair mechanisms available. This high rate of mutation ($\geqslant 1 \times 10^{-4}$), coupled with a large population size, can quickly lead to enormous genetic diversity within a single infected host. For example, HIV has a single-stranded RNA genome of approximately 9 000 nucleotides. The replication rate in an infected individual has been estimated to be approximately 10^9 daily, thus, $10^{-4} \times 9\,000 \times 10^9 = 9 \times 10^8$ mutants occur each day. This means that, in theory, every point mutation occurs 10^5 times per day in an HIV-infected individual and every double mutant ten

Table 3 *Methods for detecting resistance in clinical specimens*

Advantages and disadvantages	
Phenotypic[a]	**Genotypic**[b]
Slow	More rapid
Cumbersome	Less cumbersome
Expensive	Less expensive
Clinically relevant	May not correlate with phenotype
May underestimate reResistance in vivo	May exaggerate resistance in vivo
May not detect mixtures	Insensitive to minor species

a) Usually tissue-culture based
b) Usually PCR-based

times per day! As a result, HIV actually exists as a 'quasi species' or 'swarm' around a particular consensus sequence.

PRIMARY, SECONDARY, AND COMPENSATING DRUG RESISTANCE MUTATIONS

Mutations that give rise to amino acid substitutions in, or close to, the site that interacts with the inhibitor and that are clearly associated with a biochemical change in the interaction leading to resistance, are termed 'primary mutations.' Such mutations characterize variants that arise early upon exposure to the inhibitor. Further mutations may accumulate – and these are termed 'secondary mutations' and these may contribute to the overall level of resistance. However, yet further mutations may appear which are apparently unrelated to the sites on proteins that interact with the drug. Such mutations may have no direct effect on biochemical drug sensitivity but may increase enzyme efficiency so as to compensate for the deleterious effects of the primary and secondary mutations. Another example has been observed in HIV where a mutation may change the protease cleavage site in the target protein that compensates for a change in the substrate specificity of the HIV protease itself due to a primary resistance mutations. Many compensating mutations are suspected but, in most cases, their precise role has yet to be elucidated (Swanstrom and Erona 2000).

BIOCHEMICAL VS CLINICAL DRUG RESISTANCE

From the earliest attempts at therapy of ocular herpesvirus, it was realized that treatment failure did not necessarily correlate with biochemical resistance in virus isolates. Conversely, patients carrying HIV with multiple drug resistance mutations may still respond to therapy; virus replication remains suppressed and immune function near normal despite the presence of highly resistant variants. There are likely to be several different explanations for these observations. First, the assay methods to measure resistance may not accurately reflect the conditions in the host, e.g. cell type (including the species/tissue of origin), the growth rate of cells (resting or multiplying), the complexity of media components (that may interfere with specific drugs), the multiplicity of infection, heterogeneous virus populations, and the existence of latently infected cells. Other possible host factors include noncompliance or changes in the patient that effect metabolism of the drug. Furthermore, the fact that many mutations may result in attenuation is probably a factor in resistance development by all types of virus (see below).

MATHEMATICAL MODELS TO PREDICT FUTURE RESISTANCE TRENDS

Based upon virus mutation rates (see above) alone, it would follow that virus infections would evolve to resist any specific inhibitor within a few days, rendering any drug useless. However, experience shows that this is rarely the case because the possession of drug resistance mutations usually has a biological price. For example, many mutations in the reverse transcriptase nucleotide binding site or protease active site in HIV or neuramidase of influenza are thought to reduce the catalytic activity of these enzymes and negatively affect replication and/or transmission efficiency. Similarly, HSV TK^{-ve} mutants are highly resistant to aciclovir; while such mutants replicate efficiently in tissue culture, normal TK activity is required for virus replication in neurons and to enable HSV to reactivate from latency. In some cases the attenuation may be reduced by compensating mutations although such effects are likely to be difficult to define.

VIRUS FITNESS

Some drug-resistant mutant viruses are clearly attenuated or 'less fit.' The biochemical changes resulting from mutations in the virus genome may, of course, be extremely subtle and the biological effects very difficult to measure. Much effort has been directed to the establishment of relevant laboratory tests to estimate attenuation (e.g. Weber et al. 2003). Certain constellations of changes may give rise to more successful drug-resistant viruses that will then dominate the population. These effects have been quantified by mathematical modelers. With increased understanding of virus pathogenesis and the mechanism of action of virus inhibitors, the

theoretical models have become increasingly sophisticated. Some predictions are optimistic, e.g. the likely future development of aciclovir resistance in genital herpes (Gershengorn et al. 2003), and influenza virus resistance to neuraminidase inhibitors (Ferguson et al. 2003) are both expected to remain low. However, for HIV, the predictions are more pessimistic and the expectation from the models is that, despite combination therapy, HIV drug resistance will eventually overtake the therapeutic effort. (Blower and Volberding 2002). However, this is a dynamic situation and viruses will continue to evolve. Resistance thus remains a threat for all types of antiviral therapy. The key general features of virus drug resistance are summarized in Table 4 and the methods for isolating and study of resistance in Tables 5 and 6.

DRUG RESISTANCE IN HERPES SIMPLEX AND VARICELLA-ZOSTER VIRUS

In the immunologically normal host

Historically, HSV was among the first viruses where the phenomenon of drug resistance was studied. A single passage of virus in the presence of a subinhibitory concentration of the compound (e.g. aciclovir, penciclovir or brivudin) results in significant decrease in sensitivity to the respective compound (Larder and Darby 1984). Clinical isolates, including those obtained from normal patients who have never received chemotherapy, contain a small proportion (perhaps 0.1 percent) of pre-existing drug-resistant mutants (Paris and Harrington 1982) that can continue to multiply when selective pressure is applied.

Table 4 *Acquired drug resistance*

Summary of general features
Results from one or more mutations in genes coding for target proteins
Develops spontaneously due to high mutation rates in viruses
Found in all viruses, for almost all classes[a] of specific inhibitor
Resistance is the hall-mark of selectivity for antiviral compound
Useful for elucidation of mechanism of drug action
Many resistance mutations alter virus pathogenicity (fitness)
Variants may be present among heterogeneous populations
Clinical importance varies among virus families
Incidence predicted from mathematical models
Especially important in immunocompromised host

a) Exceptions are immunomodulators and compounds with a cellular target for virus inhibition. It is arguable whether such compounds are true 'antiviral' compounds.

Table 5 *Methods for obtaining laboratory drug-resistant strains*

Methods
Passage of virus in presence of subinhibitory concentrations
Selection by using alternative drug with same target e.g. TK
Genetic recombination with resistant virus
Obtain molecular clone with induced mutation; recombine with wild-type
Obtain virus strains from clinical isolates following therapy

Table 6 *Sequence for the study of drug resistance to a new compound*

Sequence
Virus selected for resistance
Resistance demonstrated in tissue culture and, if possible, in animal model
Mutations mapped to specific gene
DNA sequence reveals: deletion, insertion, point mutation (homopolymers in TK)
Protein is analyzed and single amino acid substitutions/ truncations predicted
Enzyme shown to have lower affinity for substrate or be insensitive in vitro
Site-directed mutagenesis generate new mutants; then shown to be resistant
Patterns of cross-resistance to alternative drugs explored
Clinical isolates from treated patients shown with identical mutations

Selection for resistance in the laboratory

Aciclovir and similar nucleoside analogues were found to select for resistance mutations in two loci: DNApol and TK (Larder and Darby 1984; Coen 1986) (Table 7). Several laboratory mutants of each type shown in this table have been fully characterized (Larder and Darby 1984; Coen 1986). The mutant proteins (TK or DNApol) undergo changes in their enzymatic properties and DNA sequencing has identified the specific base substitutions of other changes that give rise to the drug-resistant phenotype; thus, the origin of resistance is fully explained (Collins and Darby 1991). The most common mutations are probably single G insertions into the G-string motif (Sasadeusz et al. 1997; Harris et al. 2003). Furthermore, several drug-resistant strains obtained from clinical isolates (almost all from immunocompromised patients following drug failure) proved to have genotypes identical to the previously characterized laboratory-selected strains (Larder and Darby 1984).

Herpesvirus DNApol is essential for virus replication and resistance mutations are generally single base substitutions that alter the affinity of the enzyme for nucleoside analogue triphosphates. Pyrophosphate analogues (e.g. foscarnet) also select for resistance mutations in DNApol. In contrast to DNApol, HSV TK is not essen-

Table 7 *Nature of herpes virus drug-resistant mutants so far isolated*

Genetic locus	Genetic change	Resistance	Frequency in clinical isolates
TK (TK^-)	Base: substitution, insertion or deletion	Little or no TK enzyme to phosphorylate thymidine or thymidine analogue	Relatively common (in mixtures) but usually attenuated
Mutations in promoter site			
TK (TK^r)	Base substitution	Altered TK substrate specificity; reduced phosphorylation of inhibitor but whole or partial phosphorylation of thymidine analogue	Quite rare
$DNApol^r$ ($DNApol^r$)	Base substitution	Low affinity for nucleoside analogue triphosphate	Very rare

tial for replication and TK^{-ve} viruses grow with normal kinetics in actively dividing cell cultures. In resting cells, however, TK^{-ve} viruses are less efficient and have restricted ability to replicate in neurons. Mutants with drug-resistance mutations in the TK gene may produce full-length polypeptides with base substitutions leading to altered enzyme substrate specificity (TK-altered) or the enzyme activity may be absent (TK-defective or TK^{-ve}). In laboratory animal infection models both DNApol and TK mutants of both types have been shown to be attenuated and, TK^{-ve} mutants show particularly marked reductions in neuropathogenicity.

In clinical practice, the incidence of resistant viruses is very low (<1 percent) in virus isolates obtained from immunocompetent patients. Large surveys measuring the sensitivity of virus isolates to aciclovir have been carried out regularly from 1979 to the present day and these show no significant changes in the mean sensitivity of isolates (ED_{50} approximately 1 μM). There is no evidence of increased incidence of resistance after more than 20 years use including oral prescription and widespread availability of topical formulations over the counter. Furthermore, daily administration to individual patients for more than 10 years for suppression of their recurrent disease has not been associated with resistance development. Recent surveys for penciclovir sensitivity among clinical isolates also show no evidence for increase in resistance (Bacon et al. 2002; Shin et al. 2003)

The explanation for the lack of resistance to HSV antiviral drugs in clinical practice appears to be that the majority of resistance mutations are of reduced pathogenicity. In cell culture, the kinetics and yields of such mutants are similar to those of their parental strains, but they are usually more or less attenuated when tested in animal models (Field et al. 1980, reviewed by Field 1989). It may be that the early establishment of neuronal latency with sensitive virus is another important factor (Field 2001).

Occasionally, TK^{-ve} viruses have been isolated that appear to be highly pathogenic in animal models. One such virus was recently elucidated. Sequencing showed that the TK^{-ve} phenotype resulted from a double G insertion into a G-string giving rise to a truncated polypeptide. However, this virus underwent a high frequency mutation event inserting a further G into the G-string thus restoring the open reading frame. Passage of this virus through the nervous system of mice resulted in rapid selection of the TK^{+ve} variant (Grey et al. 2003). Such viruses are likely to remain rare in nature, but this work reminds us of the potential for new and unexpected possibilities in the future.

Varicella-zoster virus resistance appears to follow the same pattern as HSV although there are no convenient rodent laboratory infection models to explore the pathogenicity of resistant strains as has been the case for HSV (Kimberlin et al. 1995). Currently, drug resistance is not regarded as a problem for either of these viruses except in immunocompetent patients.

Resistance to herpes simplex in the immunocompromised patient

Drug resistance to ACV has been encountered among immunocompromised patients, of whom several large surveys suggest that about 5 percent shed resistant virus (Wade et al. 1982; Englund et al. 1990). All three mechanisms of drug resistance have been observed (Table 3) and, in some cases, clinical isolates comprise mixtures of sensitive and resistant viruses, perhaps with more than one type of resistant virus present (Martin et al. 1985; Christophers and Sutton 1987; Sacks et al. 1989). Viruses that are resistant through lack of TK are, naturally, cross-resistant to other drugs that depend on virus TK for activation, whereas viruses of the TK^r phenotype show varying patterns of cross-resistance. Foscarnet selects for resistance only at the DNApol locus and is a possible alternative for therapeutic use when resistance develops to the nucleoside analogues. However, multiple drug resistance has occurred in some patients (Crumpacker et al. 1982). In summary, although drug resistance in the immunocompetent patient does not seem to be a problem at present, it may prove to be a very serious matter in the individual patient with defective immunity.

DRUG RESISTANCE IN HCMV

HCMV infection is one of the major virological problems in the immunocompromised patient and, unfortunately, drug resistance has emerged as a significant additional problem in these cases (Drew et al. 1991). Viruses that have acquired resistance to GCV have been encountered, and analysis of these strains led to the discovery of a hitherto unsuspected site of action of the drug (Drew et al. 1991; Drew et al. 1993). The drug-resistance mutations were traced to gene *UL97*, which, as mentioned under 'Ganciclovir', encodes a protein kinase function (Littler et al. 1992; Sullivan et al. 1992). Although this finding confirms a serious problem in these patients that renders the therapy ineffective, at a biochemical level it was an exciting discovery because it revealed a novel potential target for the design of inhibitors against this and other viruses (Birch and Mills 1994; Biron 1994). Relevantly, documentation of GCV resistance in transplant recipients may occur as frequently as 20 percent of the time.

Drug resistance in HIV

In contrast to the earlier experience with herpesviruses, antiviral drug resistance has emerged as one of the major problems in the management of HIV. Indeed, the study of resistance has had a central role in HIV drug development; it is the subject of numerous research communications and thus the subject has necessarily been covered in the consideration of HIV as a target for chemotherapy (see section on Inhibitors of human immunodeficiency virus above). HIV drug resistance is considered to be the most important factor limiting the continued effectiveness of all three classes of anti-HIV drug currently in use (RT inhibitors, nonnucleoside RT inhibitors, and protease inhibitors (Bean et al. 1987; Ljungman et al. 1990; Safrin et al. 1994) in patients undergoing monotherapy. This problem led to the introduction of the successful strategy of drug combinations in HAART.

At first it was difficult to show the development of resistance to the early drugs directed against HIV such as AZT. Unfortunately, this turned out to be due to a technical problem and, once the methods for detection were improved, virus drug resistance was revealed as a universal feature of all chemotherapeutic strategies so far employed against this infection.

Drug resistance in HIV results from point mutations leading to alterations in the affinity of reverse transcriptase for the inhibitor (the most important mutations are documented for individual HIV drugs in the section on Inhibitors of human immunodeficiency virus above) although this has, in many cases, been very difficult to prove by testing the enzyme functions for reduced sensitivity to inhibition in vitro. Development of resistance was first shown for zidovudine (Larder et al. 1989; Larder and Kemp 1989), and subsequently for all other nucleoside inhibitors. Resistance to the NNRTI apparently occurs even more readily and the resistant strains are cross-resistant (Richman et al. 1991; Condra et al. 1992). Resistance to the various proteinase inhibitors has also been clearly demonstrated (Otto et al. 1993; Kaplan et al. 1994; Mellors et al. 1995). Several hundred resistance mutations have now been documented and the sequential patterns of mutations are well understood (D'Aquila et al. 2003; Swanstrom and Erona 2000).

Particular mutations (and in some cases sequences of mutations) lead to progressively more resistant virus populations in the patient. Knowledge of resistance patterns to individual drugs enables rational strategies for combinations of drugs. The monitoring for resistance in individual patients has led to the possibility of tailoring therapeutic regimens to the patient. However, the success of triple or quadruple drug regimens has produced long-term suppression of virus growth in the patient and sustained normality of T-cell populations. Furthermore, it has come to light that among the heterogeneous population of virions in the patient, highly drug-resistant variants are present. The fact that the patient appears to be able to tolerate their presence may be explained by the fact that the resistant variants are of lower pathogenicity, i.e. less fit (discussed above).

A North American study (Little et al. 2000) showed that between 1–11 percent HIV infections were already resistant to one or more compounds when acquired and the proportion of new HIV infections involving resistance is increasing. Even taking into account the reduced fitness of some drug-resistant variants, mathematical models remain pessimistic, predicting that the long term future for the continued success of current antiviral agents is fairly bleak

DRUG RESISTANCE IN ORTHOMYXOVIRUSES

Influenza A virus has long been known to develop resistance to amantadine (Cochran et al. 1965; Oxford et al. 1970). Resistance was mapped first to the hemagglutinin and subsequently to the *M2* gene (Lamb et al. 1985; Hay et al. 1986) which codes for a component of the nucleocapsid. Of the two sites, changes in the M2 protein are the more important (Hay et al. 1985). Analyses of such drug-resistant mutants were of paramount importance in defining the mechanism of action of amantadine and similar compounds (Field and Owen 1988) (see section on Inhibitors of orthomyxo- and paramyxoviruses).

The rapid development of resistance following transmission to susceptible birds was reported following the experimental infection and therapy of chickens with highly virulent avian influenza virus causing fowl plague (Webster et al. 1986), and more recently a similar rapid development of drug resistance has been observed in humans infected with influenza A (Belshe et al. 1989;

Hayden et al. 1989, 1991; Hayden 1994). Although drug resistance is readily selected for in cell culture, there has been much debate on the significance of published surveys to assess the impact of resistance in humans to amantadine (Stilianakis et al. 1998).

The neuraminidase inhibitors zanamivir and oseltamivir select for resistance mutations in the neuraminidase gene and polymorphisms in the hemagglutinin may be important in determining the sensitivity of isolates (Gubareva et al. 2001a, 2001b). The new inhibitors were introduced into clinical practice in various parts of the world between 1999 and 2002. In order to monitor the potential development of resistance, the 'Neuraminidase Inhibitor Susceptibility Network' was established to coordinate testing of clinical isolates (McKimm-Breschkin et al. 2003). This has established a base line susceptibility of over 1 000 clinical isolates. It will enable accurate monitoring of resistance emerging in the future, particularly in the inevitable widespread use of anti-influenza virus therapy during an influenza pandemic. To date, resistance to the neuraminidase inhibitors appears to be limited in clinical practice and taken with the predictions from mathematical models (Ferguson et al. 2003), this allows cautious optimisms regarding the future impact of resistance in the treatment and prevention of influenza.

DRUG RESISTANCE IN HEPATITIS VIRUSES

Although there are relatively few data on clinical resistance compared to that for HIV, the development of resistance during HBV therapy appears to parallel that observed among retroviruses. Lamivudine treatment is associated with the rapid development of drug-resistance variants with specific polymerase mutations. Similarly, adefovir dipivoxil therapy is associated with the selection of mutations in the HBV polymerase, however, at a very low rate of occurrence (Angus et al. 2003). Compared with the monotherapy of HIV, resistance development is slower to emerge during HBV treatment, possible reflecting the slow rate of infected hepatocyte turnover which is significantly slower than infected lymphocyte turnover during HIV (Mutimer 1998). Similar to HIV, the most important approach is thought to be the introduction of combination therapy using two or more different drugs simultaneously. Treatment failures are also observed in HCV therapy by means of combinations of an antiviral drug with pegylated interferon. These failures are suspected to involve drug resistance although the mechanisms are, to date, unknown.

DRUG RESISTANCE IN PICORNAVIRUSES

The action of capsid-binding molecules that interact with rhinoviruses is readily reversed by the growth of mutants with point mutations in the genes coding for the capsid proteins concerned (Ninomiya et al. 1985). The patterns of cross-resistance have been widely studied (Yasin et al. 1990a) and in some cases, cross-resistance to the effects of neutralizing antibodies occurs (Dutko and Diana 1990; Rossmann 1990). Such antibodies also depend on capsid-binding at a nearby site in order to achieve neutralization. Although the study of such resistance is very useful in elucidating precise virus-inhibitor mechanisms, its implication for the future use of anti-picornavirus compounds of this type is far from clear. Resistance has the potential to arise very rapidly in vitro, and the unresolved question is whether such resistant variants will have impaired pathogenicity or reduced ability to spread. One trial suggested that this may indeed be the case (Dearden et al. 1989; Yasin et al. 1990b); however, there is as yet far too little information to predict the possible impact of drug resistance in the clinic of such compounds becoming widely used (Al-Nakib 1993). Pleconaril readily selects for drug resistant variants in tissue culture. There has been too little experience with the compound to determine whether or not this will be important in clinical practice. However, concern about resistance development has been cited among the reasons for the 2002 US Food and Drug Administration ruling that pleconaril should be rejected as an antiviral drug being developed to treat the common cold.

VIRUS DRUG RESISTANCE – CODA

Although drug resistance may be seen as a setback after many years of otherwise successful development of new drugs, it does have useful aspects: the isolation of resistant variants defines the compound as having a virus-specific mode of action; it enables the molecular targets for drug action to be identified with certainty; and, particularly when such targets are unsuspected, it may reveal hitherto unknown targets for the design of further inhibitors. Finally, when the precise mechanisms of drug resistance are elucidated, this information may provide a rationale for alternative therapeutic strategies to minimize or circumvent the impact of drug resistance in the patient.

The problem of toxicity of antiviral compounds

As stated at the outset of this chapter, the principal obstacle to the development of antiviral compounds has been to obtain selective toxicity. Having established both in in vitro and animal models that a compound has a high selective index, problems may be encountered when the compounds are administered to humans. In some cases the toxic effects may be caused by minor metabolites of the original compound.

Nucleoside analogues often cause a variety of acute effects, including malaise, weight loss, tremors, mutism,

peripheral neuropathy, acute liver and kidney damage as well as the more common complaints of nausea and vomiting. In some cases these effects have been related to the inhibition of cellular enzymes, particularly mitochondrial enzymes, by the antiviral compounds. (The problems encountered when treating patients with particular HIV drugs are considered in the section entitled Inhibitors of human immunodeficiency virus, above). Amantadine administration is associated with reversible neurological change (rimantadine is used successfully in the control of Parkinson's disease) and these effects are thought to relate to the release and uptake of dopamine in the central nervous system (Mizoguchi et al. 1994). To these problems must be added the long-term concern regarding possible teratogenicity and genetic damage caused by agents that interact with DNA (Griffiths 1995). The latter can theoretically occur when nucleoside analogues are incorporated into host-cell DNA or, indirectly, as a result of inhibition of DNA repair systems (Darby 1995).

'Familiarity breeds contempt' and there have been two incidences of toxicity in patients that resulted in deaths, reminding us of the need for constant attention to the potential that antiviral agents have for producing serious side-effects.

TWO EXAMPLES OF SEVERE TOXICITY PROBLEMS IN HUMANS

Fialuridine toxicity

Fialuridine (1-2′-deoxy-2′-fluoro-1-β-D-arabinofuranosyl-5-iodouracil; FIAU) is an orally bioavailable compound active against HBV (Fried et al. 1992). Pilot studies with a four-week course were encouraging and showed that significant reduction in virus replication could be achieved. However, further trials with a longer treatment period were stopped after 12 weeks when patients developed myopathy, lactic acidosis, peripheral neuropathy, pancreatitis and liver failure; there were several deaths (Meeting Report 1995). The mechanism for this unexpected delayed toxicity seems to be a consequence of FIAU incorporation into mitochondrial DNA.

Sorivudine, BVaraU: toxic interactions with 5-fluoruracil

Sorivudine, or BVaraU, is a potent inhibitor of VZV (see section on Inhibitors of herpesviruses) and the drug is currently undergoing clinical trials. It was licensed in Japan in 1993 but the license was withdrawn when several deaths occurred in patients also receiving 5-fluorouracil. The toxicity resulted from the formation of the metabolite bromovinyluracil (Ashida et al. 1993) which inhibits dihydrothymine dehydrogenase, normally responsible for degrading 5-fluorouracil. This drug interaction led to the accumulation of 5-uracil in cancer patients receiving both drugs, and thus to fatal bone marrow suppression.

The problem of virus latency

HERPESVIRUS LATENCY

Several viruses are capable of establishing latency in infected cells. This is a particular feature of all the herpesviruses, and both HSV and VZV can remain latent in neurons for the lifetime of the infected individual (Wildy et al. 1982). Periodic reactivations may cause clinical recurrences. In some cases they are subclinical but, whether or not disease is apparent, the infection may be transmitted during the episode to a susceptible contact. Because, during the latent phase, the virus does not express the genes coding for virus proteins, including TK and DNApol, it is unaffected by any of the conventional nucleoside analogues or drugs that rely on viral protein targets. Experimental infection in animal models suggests that latency is established early, and foci of latently infected neurons are detected a few hours after the first round of virus replication at the mucosal site of infection (Thackray and Field 2000). In man, the process of establishing latency may take a little longer, but the implication is that chemotherapy is unlikely to be started early enough to prevent the establishment of latency during a primary infection. Even if chemotherapy is successful in limiting the clinical signs of disease, the virus will persist, to reactivate later (Darby and Field 1984). However, both famiclovir and aciclovir do suppress recurrent infections and patients have taken suppressive therapy for this purpose over periods up to 10 years (Douglas et al. 1984; Straus et al. 1984; Goldberg et al. 1993; Mertz et al. 1997). Furthermore, prophylaxis can prevent episodes of herpes resulting from reactivation in immunosuppressed patients. The problem of eradicating herpesvirus DNA harbored in latently infected cells is one for which there remains no obvious solution however, the early establishment of latency and the subsequent role of the nervous system in the reactivation and recurrence of infection may underlie the very low incidence (discussed above in section entitled The problem of toxicity of antiviral compounds), of HSV drug resistance (Field 2001).

RETROVIRUS LATENCY

HIV can establish a different kind of latency in which the viral DNA, always formed as an intermediate during replication, may become stably integrated into the chromosome of the host cell. In some cases the cells survive infection and continue to harbor the viral genes, which are not expressed, or are expressed at a very low level, with the potential to become active later. Furthermore, the stimulation of resting lymphocytes is associated with the activation of latent HIV (Hermankova et al. 2003). HAART has been effective in reducing the plasma

levels of HIV-1 RNA below the limits of detection of most clinical assays. However, the infection has not been eradicated by HAART and this is likely due to latent HIV-1 replication-competent provirus in resting $CD4^+$ T-lymphocytes (Pomerantz 2003).

COMBINATION CHEMOTHERAPY FOR VIRAL INFECTIONS

As with the treatment of some bacterial diseases, especially mycobacterial infections, combinations of drugs have proven exceedingly valuable. The recognition that monotherapy of HIV infections has not resulted in a cure has led to numerous clinical trials evaluating various combinations of antiretroviral therapy (e.g. nucleoside analogues combined with nonnucleoside analogues and/or protease inhibitors) (Schinazi 1991, 1995). This has led to the concept of HAART. This strategy has proved extremely successful with suppression of virus to below the level of detection and a marked and sustained benefit (De Clercq 1998). However, the toxic effects of the chronic use of the current compounds remains a limiting factor in the medium to long term. Similarly, for life-threatening herpesvirus infections (e.g. encephalitis or neonatal herpes), combination therapies will be tested, including the combined use of drugs and immunoglobulins or cytokines, including interferons.

CONCLUSIONS AND FUTURE PROSPECTS

The rapid application of molecular biology to the study of viruses most assuredly will lead to the development of novel antiviral drugs. Already, the identification of protease in a variety of viruses other than HIV has led to a great increase in research directed toward the synthesis of peptidomimetics that inhibit these enzymes. Hepatitis C, HSV, CMV etc. are prime targets. For HSV alone, many genes provide targets for debilitation of viral replication; they include both those essential for viral replication and others that are not. The application of antisense RNA, triplex-forming oligonucleotides, ribozymes and direct DNA targeting, although intellectually appealing, poses drug delivery problems that have yet to be overcome in clinical practice.

INTRODUCTION

The emergence of new diseases

New or previously unrecognized viral diseases are constantly being identified. In most cases, there is no way to predict when or where the next important new viral pathogen will emerge. Neither is there any way to predict the ultimate importance of a virus as it first emerges: it may be the cause of a geographically limited curiosity, of intermittent outbreaks of disease or of a new epidemic. New viral diseases seem to be emerging globally with increasing frequency, as suggested by published reports of cases, outbreaks, and epidemics and by the rate of identification of new pathogenic viruses (Mahy 2000). The list of newly emergent viruses of humans and animals is impressive (Figure 1; Tables 1 and 2).

DETERMINANTS CONTRIBUTING TO THE EMERGENCE OF NEW DISEASES

Many different factors can contribute to the emergence of a new viral disease. These include: (1) virological determinants such as mutation, recombination, reassortment, natural selection, fitness adaptation, and evolutionary progression; (2) individual host determinants such as specific risk behaviors, innate resistance, acquired immunity, and physiological factors such as age, nutritional status, and pregnancy; (3) host population determinants such as community, behavioral, societal, transport, commercial, and iatrogenic factors; (4) environmental determinants such as ecological and zoonotic influences; (5) viruses intentionally used for harm – the threat of bioterrorism. These determinants need to be understood if we are to develop control measures to prevent the occurrence and spread of specific diseases within human and/or animal populations. In this chapter we consider the underlying causes for emergence and re-emergence and illustrate them with selected examples.

Initial recognition of new, emerging diseases

Since 1986, following upon the development of the polymerase chain reaction (PCR) and other very sensitive, very specific, high-throughput detection and diagnostic

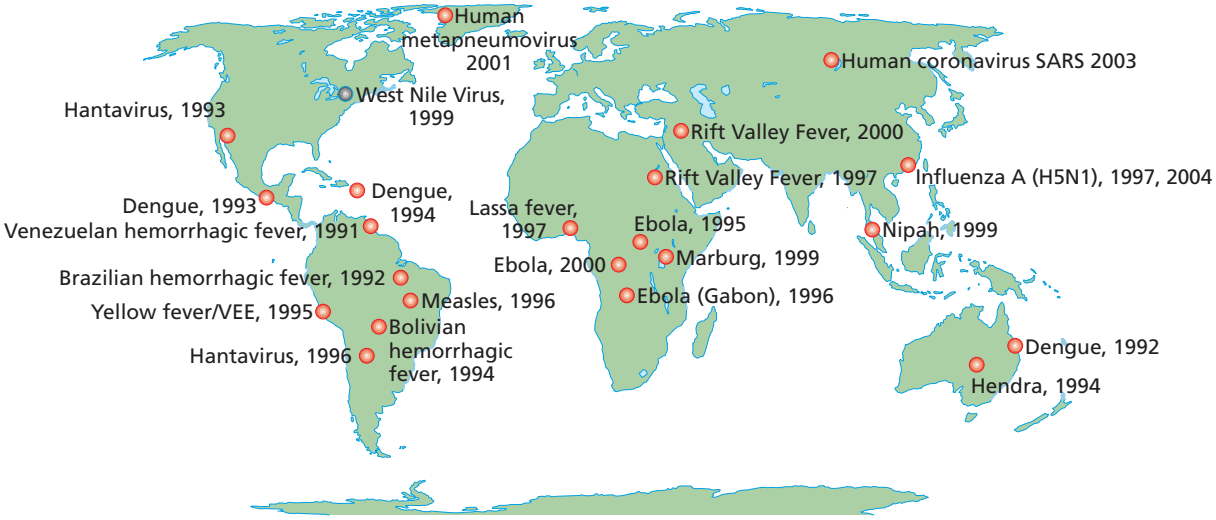

Figure 1 *Recent emergence and reemergence of human viral diseases, examples.*

methods, we have seen a dramatic increase in the direct detection of viruses, whether in diseased tissues, in cultured cells inoculated with clinical materials or in appropriate environmental samples. As a consequence, an impressive number of new, important viruses have been recognized (Table 3). In fact, some new viruses have been detected, described, and named solely on the basis of genomic sequences amplified by reverse transcription and polymerase chain reaction from postmortem tissues. For example, Bayou virus (a hantavirus distantly related to Sin Nombre virus, and an etiologic agent of hantavirus pulmonary syndrome in North America) is a case in point (Khan et al. 1995) – its significance as a human pathogen was determined entirely by indirect molecular methods.

As another example, the diversity of human papillomaviruses has been recognized solely by genomic nucleotide sequencing. The 100 or more human papillomaviruses have never been cultivated in cell culture or animals, and serotyping has not proven useful, so their pathogenic significance was not appreciated for many years. Since the advent of genomic sequence analysis, our appreciation of the importance of papillomaviruses has changed dramatically.

Human papillomaviruses can now be differentiated by sequence analysis, and exist in more than 100 recognized types in the human population (De Villiers et al. 2004) There is a clear causal relationship between certain papillomavirus types and genital cancers, especially cervical cancer (see Papillomaviruses). Papillomavirus genome DNA is a small circular molecule that is easily cloned from biopsy specimens of infected tissues. Originally these viruses were classified by DNA hybridization, and considered to be different types if they shared less than 50 percent homology. It was soon realized that certain types were frequently associated with cervical and other forms of genital cancer (for example types 16, 18, and 31), and other types were found in malignant respiratory papillomas (for example, types 6 and 11) so it was important to determine the human papillomavirus type as an aid in diagnosis. With the advent of simpler methods for DNA sequencing, some of the original hybridization data proved to be inconsistent, and a human papillomavirus type is now defined as new when the genome DNA is more than 10 percent dissimilar in the combined nucleotide sequences of 3 genes, E6, E7, and L1. This requires determination of 2.4 kbp of sequence (one-third of the genome) for each new isolate. More than 100 human papillomaviruses have now been recognized as types by this method, and divided into supergroups. For example, 54 papillomavirus types of genital origin form one supergroup (A) by sequence analysis, and another includes 24 types associated with epidermodysplasia verruciformis and other cutaneous lesions (Chan et al. 1995). Those human papillomavirus types that are presently known to be associated with a high risk of genital cancer are types 16, 18, 31–35, 51–52, 56, 58, 61, 66, 68, 70, and 73.

Another major advance in public health which stemmed directly from the application of molecular methods was the identification of hepatitis C virus. In 1989, as a result of a collaboration between CDC and Chiron Corporation to search for the cause of non-A non-B hepatitis, a new hepatitis virus, hepatitis C virus, was cloned from the blood of a chimpanzee that had been experimentally infected with blood factor VIII that was known to transmit non-A non-B hepatitis (Choo et al. 1989; Matsuura and Miyamura 1993). RNA extracted from the chimpanzee blood was reverse-transcribed to make cDNAs using random primers. The DNA was cloned in the bacteriophage gt 11 expression vector, and the resultant bacterial colonies were screened using sera from patients with non-A non-B hepatitis. After screening thousands of clones in this

Table 1 *Some of the most important new, emerging and re-emerging human viral pathogens*

Virus	Association of the virus(es) with human disease
Alkhurma virus[a]	Newly recognized member virus of the family *Flaviviridae*; the etiologic agent of severe hemorrhagic fever with a 25 percent mortality rate; tick-borne; first recognized in 1995 in Saudi Arabia where it has caused substantial morbidity and mortality
Australian bat lyssavirus	Newly recognized member virus of the genus *Lyssavirus*, family *Rhabdoviridae*; the etiologic agent of fatal rabies-like disease in humans and domestic animals; reservoir host fruit bats; found throughout eastern Australia
B-virus	Member virus of the family *Herpesviridae*; the common herpesvirus of macaques, especially rhesus macaques; the etiologic agent of severe, often lethal, encephalitis in humans; increasing as a threat because of increasing use of these animals in medical research
Crimean–Congo hemorrhagic fever virus[a]	Member virus of the genus *Nairovirus*, family *Bunyaviridae*; etiologic agent of severe hemorrhagic fever in humans with 10 percent mortality; tick-borne; reservoir in wildlife, sheep, and goats; widespread across Africa, the Middle East and Asia
Dengue viruses[a]	Member viruses of the family *Flaviviridae*; the etiologic agent of febrile disease with rash; mosquito-borne; the cause of millions of cases of febrile disease in the tropics and subtropics, and of dengue hemorrhagic fever (dengue shock syndrome), a life-threatening disease, especially in children
Ebola virus and Marburg virus[a]	Member viruses of the family *Filoviridae*; the etiologic agents of the most lethal hemorrhagic fevers known; zoonotic, but natural reservoir(s) unknown; there have been several recent substantial epidemics of Ebola hemorrhagic fever in central Africa
GB virus-C/hepatitis G virus	Newly recognized member viruses of the family *Flaviviridae*; disease association unproven, but there is a lifelong infection in humans and non-human primates world-wide
Guanarito virus[a]	Member virus of the family *Arenaviridae*; etiologic agent of Venezuelan hemorrhagic fever; rodent-borne
Hantaan virus and other Old World hantaviruses[a]	Member viruses of the genus *Hantavirus*, family *Bunyaviridae*; etiologic agents of hemorrhagic fever with renal syndrome; rodent-borne; an important cause of severe disease and death in Asia and Europe
Hendra virus	Newly recognized member virus of the genus *Henipavirus*, family *Paramyxoviridae*; etiologic agent of acute, often fatal, respiratory distress syndrome in humans and horses; zoonotic, reservoir host fruit bats (flying foxes); found in eastern Australia
Hepatitis C virus	Member virus of the family *Flaviviridae*; etiologic agent of hepatitis; associated with severe, chronic liver disease leading to hepatocellular carcinoma
Hepatitis delta virus	Member virus of the genus *Deltavirus*; etiologic agent is an unusual 'helper' virus; its presence makes hepatitis B more lethal
Hepatitis E virus	Member virus of the family *Picornaviridae*; etiologic agent of epidemic hepatitis, especially in Asia; recently recognized as widespread along the US–Mexico border; infection is associated with a high mortality rate in pregnant women
Human herpesvirus 8 (Kaposi sarcoma-associated herpesvirus)	Member virus of the family *Herpesviridae*; etiologically associated with Kaposi sarcoma; serologic studies show that HHV8 infection is tightly linked to KS risk; infection also associated with several uncommon lymphoproliferative syndromes in AIDS patients, including multicentric Castleman's disease and primary effusion lymphoma
Human herpesviruses 6 A and B and 7	Member viruses of the family *Herpesviridae*; etiologic agents of febrile illnesses in infants; HHV6B is the etiologic agent of roseola infantum (exanthem subitum); lifelong persistent/latent infections which may reactivate to cause disease in immunosuppressed people, typically AIDS patients and transplant recipients, sometimes culminating in rejection of transplanted organs and death
Human immunodeficiency viruses (HIV-1 and HIV-2)	Member viruses of the family *Retroviridae*; the etiologic agents of AIDS; the most important emerging infectious disease globally; still expanding in many parts of the world
Human metapneumovirus	Newly recognized member virus of the family *Paramyxoviridae*; the etiologic agent of respiratory disease in young children; first recognized in the Netherlands in 2001, now known to be distributed worldwide
Human papillomaviruses	Member viruses of the family *Papillomaviridae*; over 100 viruses, some etiologically associated with cervical, esophageal and rectal carcinomas

(*Continued over*)

Table 1 *Some of the most important new, emerging and re-emerging human viral pathogens (Continued)*

Virus	Association of the virus(es) with human disease
Human parvovirus B19	Member virus of the family *Parvoviridae*; etiologic agent of erythema infectiosum in children and a possible cause of fetal damage when pregnant women become infected
Human T-lymphotropic viruses (HTLV-I and HTLV-II)	Member viruses of the family *Retroviridae*; the etiologic agents of adult leukemia and neurological disease, especially in the tropics
Influenza viruses	Member viruses of the family *Orthomyxoviridae*; etiologic agents of influenza, causing thousands of deaths every winter in the elderly; the cause of the single most deadly epidemic ever recorded – the worldwide epidemic of 1918, in which 20–40 million people died; since 1997, highly pathogenic strains of avian influenza virus (H5N1, H7N1, and H9N2) have caused severe influenza in humans, with many fatalities, mainly in Asia, in persons in close contact with poultry
Japanese encephalitis virus	Member virus of the family *Flavivirus*; the etiologic agent of severe, often lethal, encephalitis; mosquito-borne; now spreading across southern Asia; potential for great epidemic and geographic expansion
Junin virus[a]	Member virus of the family *Arenaviridae*; etiologic agent of Argentine hemorrhagic fever; rodent-borne
Lassa virus[a]	Member virus of the family *Arenaviridae*; etiologic agent of Lassa fever; rodent-borne; a very important disease in West Africa; imported into a Chicago hospital in 1990
Machupo virus[a]	Member virus of the family *Arenaviridae*; etiologic agent of Bolivian hemorrhagic fever; rodent-borne
Measles virus	Member virus of the family *Paramyxoviridae*; the etiologic agent of the systemic disease measles; re-emerging in adolescents and young adults in many countries due to waning immunity; re-emerging in children in some countries due to poor vaccine coverage and infection in infancy before vaccination
Monkeypox virus	Member virus of the family *Poxviridae*; etiologic agent of vesiculo-pustular disease resembling a mild form of smallpox; repeated outbreaks in west Africa; reservoir in African squirrels; in 2003 mammals imported from Ghana into the USA transmitted the virus to prairie dogs from which an outbreak of monkeypox occurred in humans who had contact with infected prairie dogs
Nipah virus	Newly recognized member virus of the genus *Henipavirus*, family *Paramyxoviridae*; etiologic agent of severe, often fatal, encephalitis; zoonotic, reservoir in fruit bats; epidemic in Malaysian peninsula in 1999 with more than 100 human fatalities; since 2003 has caused outbreaks with high fatality rates in India and Bangladesh
Noroviruses	Member viruses of the family *Caliciviridae*; etiologic agents of explosive outbreaks of diarrhea and enteric disease throughout the world; increasingly associated with contaminated drinking water in institutional settings (schools, child care facilities, nursing homes) or other group settings (banquet halls, cruise ships, campgrounds)
Polioviruses	Member viruses of the family *Picornaviridae*; etiologic agents of poliomyelitis; still an important problem in developing countries of Africa and Asia; targeted by WHO for worldwide eradication by the year 2006
Rabies virus	Member virus of the genus *Lyssavirus*, family *Rhabdoviridae*; the etiologic agent of fatal encephalitis in humans and many animals; zoonotic, transmitted by the bite of rabid animals; raccoon epidemic still spreading across eastern USA; still an important human disease with ~30 000 human deaths per year globally
Rift Valley fever virus[a]	Member virus of the genus *Phlebovirus*, family *Bunyaviridae*; etiologic agent of febrile disease with hepatitis and hemorrhagic fever; mosquito-borne; the cause of one of the most explosive epidemics ever seen in Africa; recently spread from Africa to the middle East
Ross River virus	Member virus of the family *Togaviridae*; etiologic agent of febrile disease and epidemic polyarthritis; mosquito-borne; has moved from Australia across the Pacific region several times
Rotaviruses (Group A, B, and C rotaviruses)	Many member viruses of the genus *Rotavirus*, family *Reoviridae*; etiologic agents of diarrhea / enteric disease; the second leading cause of death among infants in the world; emergent when sanitary conditions deteriorate
Sabía virus[a]	Member virus of the family *Arenaviridae*; etiologic agent of Brazilian hemorrhagic fever; rodent-borne; high mortality rate, including two laboratory-acquired cases

(*Continued over*)

Table 1 *Some of the most important new, emerging and re-emerging human viral pathogens (Continued)*

Virus	Association of the virus(es) with human disease
SARS coronavirus	Newly recognized member virus of the family *Coronaviridae*; etiologic agent of severe acute respiratory distress syndrome; worldwide epidemic originating in China in 2002
Sin Nombre virus and other New World hantaviruses	Member viruses of the genus *Hantavirus*, family *Bunyaviridae*; Sin Nombre virus is the etiologic agents of hantavirus pulmonary syndrome; rodent-borne
Variant Creutzfeldt-Jakob disease prion	BSE prion; etiologic agent of invariably fatal spongiform encephalopathy; zoonotic, originating as the BSE prion; more than 150 cases in the United Kingdom in recent years
Venezuelan encephalitis virus	Member virus of the family *Togaviridae*; etiologic agent of febrile disease and encephalitis; mosquito-borne; the cause of recent major epidemics in Central and South America
West Nile virus	Member virus of the family *Flaviviridae*; etiologic agent of febrile disease and encephalitis; mosquito-borne, introduced into New York in 1999, now spread throughout the USA, north to Canada and south to Mexico and beyond
Yellow fever virus[a]	Member virus of the family *Flaviviridae*; etiologic agent of hepatitis and hemorrhagic fever; mosquito-borne; one of the most deadly diseases in history

a) The viruses that cause hemorrhagic fever in humans.

way, one was found that reacted with antibodies in the sera of infected patients but not controls. DNA from the positive clone was then used to screen other clones by DNA hybridization, and eventually the full length sequence of hepatitis C virus was determined. This enabled the development of specific diagnostic tests, including enzyme immunoassays that could be used to screen the blood supply, largely eliminating transfusion-associated transmission of hepatitis. We now recognize multiple genotypic variants of the original hepatitis C virus (see Hepatitis C virus).

Since the discovery of hepatitis C virus, additional viruses with similar characteristics (member viruses of the family *Flaviviridae*), have been found using molecular techniques (Muerhoff et al. 1995; Linnen et al. 1996). These viruses, known as GB virus A, GB virus B, and GB virus C/hepatitis G virus, appear to be widespread in human and nonhuman primate populations (Robertson 2001) but so far no human disease has been definitively ascribed to their presence (Mushahwar 2000). The search for possible new viruses causing hepatitis has revealed yet another new class of viruses, currently termed anelloviruses and typified by TT virus (Nishizawa et al. 1997). These viruses are ubiquitous in human and nonhuman primate populations, and consist of a single-stranded DNA genome of negative sense, about 3 800 nucleotides in length (Mushahwar et al. 1999; Hino 2002). So far, no specific disease association has been found for these viruses, but infection may alter the severity of other infectious diseases, such as gastritis caused by *Helicobacter pylori* (Maggi et al. 2003) (see TT virus and other Anelloviruses).

It should be emphasized that although molecular techniques may be crucial to the initial discovery of a new, emerging virus, classical techniques still have their place. For example, virus isolation in cell culture or even in experimental animals followed by characterization by histopathology, electron microscopy, immunofluorescence, and other specialized microscopy technologies still find their place in the discovery and initial characterization of new viruses. A case in point is the epidemic of severe acute respiratory syndrome, known as SARS (see Coronaviruses, toroviruses, and arteriviruses), which first appeared in China in November 2002 and then spread via Hong Kong to many countries in 2003. The importance of this epidemic and the interactive methods used to identify its cause provides lessons worthy of more detail.

An outbreak of severe pneumonia was first recognized in Guangdong Province, China, in November 2002, initially with 300 cases of unknown etiology and five deaths. This was reported to the World Health Organization (WHO) in February 2003, and initially it was thought that these pneumonia cases might be due to a novel influenza virus.

Within the next two weeks, a WHO official working in Hanoi, Vietnam reported an unusual case of severe acute respiratory disease to WHO, and this disease was soon recognized in a large number of sick health care workers in Hong Kong and Vietnam. WHO issued a global alert about these cases, and on March 14th cases of a similar disease syndrome were reported from Canada.

Over the next few weeks it became clear that all these cases of severe respiratory disease could be linked to a single hotel in Hong Kong where the index case, a 65-year old doctor from Guangdong province in China, had stayed one might before his admittance to a hospital. Eventually the disease spread from this hotel to eight countries worldwide. These countries included Vietnam, Singapore, Canada, Hong Kong, USA, Ireland, Germany, and Thailand. Cases were also exported to France from Vietnam. Virus isolated from patients was grown in Vero (African Green monkey kidney) cells, and when examined by electron microscopy was found

Table 2 *Some of the most important new, emerging and re-emerging viral pathogens of animals*

Virus	Association of the virus(es) with animal disease
African horse sickness viruses	Member viruses of the genus *Orbivirus*, family *Reoviridae*; etiologic agents of acute respiratory distress syndrome, myocarditis and massive edema in horses with a 95 percent mortality rate; zoonotic with some human cases of febrile disease; mosquito-borne; an historic problem in southern Africa; a major threat to horses world-wide
African swine fever virus	Member virus of the family *Asfarviridae*; etiologic agent of systemic febrile disease with very high mortality rate in swine; tick-borne and also spread by contact; endemic in Africa and recently has been present in Europe and South America; a major threat to commercial swine industries globally
Avian influenza viruses	Member viruses of the family *Orthomyxoviridae*; etiologic agents of avian influenza; very high mortality rate associated with some virus strains; spread by wild birds; a major threat to commercial poultry industries globally
Bluetongue viruses	Member viruses of the genus *Orbivirus*, family *Reoviridae*; etiologic agents of systemic febrile disease; culicoides-borne; the isolation of several strains in Australia became an important non-tariff trade barrier issue in the 1980s
Bovine spongiform encephalopathy prion	BSE prion; etiologic agent of invariably fatal spongiform encephalopathy; first recognized in 1986; the cause of a major epidemic in cattle in the UK, resulting in major economic loss and trade embargo; zoonotic, causing fatal variant Creutzfeld-Jakob disease (vCJD) in humans
Canine parvovirus	Member viruses of the family *Parvoviridae*; etiologic agent of systemic disease, with diarrhea and enteric disease, cardiomyopathy; a new virus in the late 1970s, originating by mutation from feline panleucopenia virus; the virus rapidly swept round the world in the 1980s causing a pandemic of severe disease in dogs; now has become endemic globally
Chronic wasting disease of deer and elk prion	CWD prion; etiologic agent of invariably fatal spongiform encephalopathy; discovered in captive animals in the USA and now spreading in captive and wild deer and elk in the USA and Canada; the question of whether this disease might be zoonotic is raising concern and prompting appropriate research
Dolphin, porpoise, and phocine (seal) morbilliviruses	Member viruses of the family *Paramyxoviridae*; the etiologic agents of epidemic respiratory disease in several species of marine mammals; first identified in 1988 in European seals; emerging pathogens endangering several marine species
Feline immunodeficiency virus and Simian immunodeficiency viruses	Member viruses of the family *Retroviridae*; etiologic agent of AIDS-like syndrome; important new viruses, the one affecting cats in nature and all serving as important models in AIDS research
Foot-and-mouth disease viruses	Member viruses of the family *Picornaviridae*; systemic vesicular disease; still considered the most dangerous disease of livestock in the world because of the great capacity for rapid transmission and great economic loss; still entrenched in Africa, the Middle East, and Asia; caused a devastating epidemic in the United Kingdom in 2001
Hendra virus	Newly recognized member virus of the genus *Henipavirus*, family *Paramyxoviridae*; etiologic agent of acute, often fatal, respiratory distress syndrome in horses and humans; reservoir host fruit bats (flying foxes); found in eastern Australia
Malignant catarrhal fever virus (Alcelaphine herpesvirus 1)	Member virus of family *Herpesviridae*; etiologic agent of systemic disease with fever and acute inflammation of nasal and oral membranes and involvement of pharynx and lungs; usually fatal; etiologic agent is silently carried by certain African wildlife species such as gnu, wildebeest, and hartebeest; it can occur in zoos, and its presence is an important non-tariff trade barrier issue throughout the world
Monkeypox virus	Member virus of the family *Poxviridae*; etiologic agent of vesiculo-pustular disease resembling a mild form of smallpox in wild and captive monkeys in contact with squirrels and other small rodents in Central and West Africa; reservoir in African squirrels; in 2003 mammals imported from Ghana into the USA transmitted the virus to prairie dogs from which an outbreak of monkeypox occurred in humans who had contact with infected prairie dogs

(*Continued over*)

Table 2 *Some of the most important new, emerging and re-emerging viral pathogens of animals (Continued)*

Virus	Association of the virus(es) with animal disease
Myxoma virus	Member virus of the family *Poxviridae*; etiologic agent of systemic exanthematous disease in rabbits; had been used to control rabbits in Australia, but with diminishing success; a damaging virus in commercial rabbit industries in some countries
Nipah virus	Newly recognized member virus of the genus *Henipavirus*, family *Paramyxoviridae*; etiologic agent of encephalitis and respiratory disease in swine; reservoir in fruit bats; massive epidemic in swine in southern Asia in 1999; zoonotic, with often fatal encephalitis in humans in contact with infected swine
Porcine reproductive and respiratory syndrome virus (PRRS virus)	Member virus of family *Arteriviridae*; etiologic agent of respiratory disease and reproductive tract disease; an important disease in commercial swine industries of several countries, with major economic impact
Rabbit hemorrhagic disease virus	Member virus of family *Caliciviridae*; etiologic agent of universally fatal hemorrhagic disease in rabbits; being used to control rabbits in Australia
Rinderpest virus	Member virus of the family *Paramyxoviridae*; etiologic agent of systemic disease with very high mortality rate in cattle and many other species of cloven footed animals; still considered very dangerous, with potential for causing great economic loss; still entrenched in limited areas in Africa and Asia; target of ongoing global eradication campaign
West Nile virus	Member virus of the family *Flaviviridae*; etiologic agent of febrile disease and encephalitis in birds and mammals, especially horses; mosquito-borne; in 1999 a particularly virulent strain from Israel moved to the USA, where it has caused thousands of deaths in crows and other passerine birds as well as horses; zoonotic, has become very important human pathogen

to resemble a coronavirus. Cultures of the virus showed immunofluorescence when reacted with serum from recovered patients (Ksiazek et al. 2003; Drosten et al. 2003). Subsequently, knowing that it was a coronavirus by electron microscopy, consensus primers were used in PCR amplification, and the complete genetic sequence of the virus was determined by several groups (Rota et al. 2003; Marra et al. 2003; Ruan et al. 2003; Thiel et al. 2003). Despite the availability of this sequence information, numerous studies have so far not determined the precise origin of the SARS coronavirus, although it is speculated that it arose from an animal reservoir, perhaps in palm civets (Guan et al. 2003).

THE VIRUS: VARIATION AND THE EMERGENCE OF NEW VIRAL PHENOTYPES

The variety and diversity of viruses

As knowledge of the molecular structure and replication of viruses has increased, we have learned that the viruses that we know to be responsible for human and animal diseases represent only a small fraction of a large, diverse global virus population. Currently, some 3 600 virus species are recognized taxonomically, but international reference centers and culture collections keep track of more than 30 000 viral strains (Murphy et al. 1995). This number continues to increase because each time a potential host species or a new disease is studied in detail, new viruses are found. In addition, clues to the existence of new viruses may sometimes be found in other species (ecological niches). For example, the picobirnaviruses, with a genome of two segments of double-stranded RNA, 2.6 and 1.5 kb in length, were first found in rat feces (Pereira et al. 1988), and only later in humans, where they may be a cause of diarrhea (Grohmann et al. 1993; Gallimore et al. 1995).

Polygenic basis for viral variation

There are several genetic mechanisms that drive virus evolution: discussed below are mutation, recombination, and reassortment of genes. However, many of the most important variances among viruses are polygenic, and of ancient derivation, the result of the natural selection of the most fit variants (Nathanson et al. 1993). A classic example of such variation was the definition many years ago of smallpox virus variants, variola major (Indian subcontinent and Europe, mortality up to 30 percent), and variola minor (South America, mortality about 1 percent) (Fenner et al. 1988). Another example was naturally occurring attenuated poliovirus variants, some of which inspired the development of Sabin live-attenuated polio vaccines (Sabin 1981). Only recently has it been possible to begin to explain such phenotypic differences from a molecular genetic perspective

Mutation

The replication of viruses involves copying the genome nucleic acid millions of times; mistakes in the copying process introduce mutations (see The origin

Table 3 *Emerging human viral diseases: recognition by molecular techniques*

Virus	Disease	Method
Human papillomaviruses (more than 100 types)	Warts, anogenital carcinomas, laryngeal papillomas, and carcinomas	Cloning and restriction fragment analysis or sequencing of viral genomic DNA from infected tissues
Hepatitis C virus	Hepatitis, often chronic, leading to hepatocellular carcinoma	Cloning, sequencing, expression, and immunoselection with specific sera
Hepatitis E virus	Acute epidemic hepatitis	Cloning, sequencing, expression, and immunoselection with specific sera
Human herpesvirus 8	Kaposi sarcoma	Representational DNA difference analysis (RDA) of normal vs. sarcoma tissue
Hepatitis G virus/GB virus-C	Unknown	Cloning, sequencing, expression, and immunoselection with specific sera
Human metapneumovirus	Respiratory disease in children	Random primer polymerase chain reaction
GBV-A, GBV-B	Unknown	Representational difference analysis
GBV-C – Hepatitis G virus	Unknown	Cloning, sequencing, expression, and immunoselection with specific sera
Sin Nombre virus	Hantavirus pulmonary syndrome	Reverse transcription and consensus sequence polymerase chain reaction amplification from infected human and rodent tissues
Bayou virus	Hantavirus pulmonary syndrome	Reverse transcription and polymerase chain reaction amplification from infected human tissues and sequence analysis
TT virus	Not known	Representational DNA difference analysis of human sera

and evolution of viruses). When such mutations lead to new phenotypic characters that enable the virus to replicate in a new host or cell type, to replicate to a higher titer or at a faster rate, or to better escape host defenses, the potential exists for emergence of a new viral disease. Genetically, mutational changes affecting phenotype may be minimal, involving one or a few nucleotides, or they may be large and complex, involving the addition of new genes into viral genomes by recombination or reassortment (see below). In any case, it is the expression of genotypic change as a new phenotype that is important in nature, and usually it is phenotypic change affecting transmission that is at the heart of the emergence of a new disease. Mutations that affect antigenic determinants on the viral surface proteins may be selected for, especially when viruses replicate in the presence of antibody. This has been clearly documented in the case of influenza. New antigenic variants of influenza viruses occur so pervasively that reformulation of vaccine is required on an annual basis.

The emergence of influenza virus variants by the accumulation of point mutations is termed genetic drift (see Orthomyxoviruses: influenza). Such mutations may dramatically alter viral pathogenicity, but more importantly they may result in new viral surface epitopes that the population does not recognize, when it is termed antigenic drift. An example of genetic drift occurred in 1983, when an outbreak of avian influenza A virus (H5N3) in Pennsylvania spread through the poultry industry of the region, leading to the destruction of 17 million fowl and a loss of about US$60 million. When the virus was sequenced, it was found to have acquired a single point mutation that altered the cleavability of its hemagglutinin, thereby greatly increasing its pathogenicity.

A dramatic example of the emergence of a new virus by mutation is afforded by canine parvovirus (Parrish 1990, 1994). Serological evidence suggests that this virus made its first appearance as a new pathogen of dogs in 1976. The virus was isolated in 1978 as the cause of severe enteritis, sometimes fatal, that occurred in dogs in North America, Europe, and Australia. Outbreaks of sudden death in puppies due to myocarditis were also linked to the new virus. Soon after its isolation, it became clear from antigenic analysis and restriction endonuclease mapping that the canine virus was closely related to feline panleukopenia virus, a pathogen that had been recognized since the 1920s. Sequence analysis of isolates of the canine virus revealed that it differed from feline panleucopenia virus in only six nucleotides, and probably originated as a result of two amino-acid changes in the viral capsid, which for the first time allowed the feline virus to replicate in dog cells. The rapidity with which canine parvovirus disease spread round the world has not been explained, but the extreme physical stability of the virus probably made fomite carriage by humans very efficient.

The special case of high frequency mutation and quasispecies formation in RNA viruses

Given their great potential for generating new genotypes, the RNA viruses seem to represent an enormous

and continuous risk with regard to the emergence of new epidemic diseases, but in fact the frequency of emergence of such new diseases is lower than might be expected (see The origin and evolution of viruses). New genotypes are tested severely by natural selection and few represent a better fit than current wild types. Better fit and better adaptation to an econiche require that a new genotype or a new virus has certain improved traits, such as improved transmissibility, and perhaps improved capacity for surviving 'lean times' such as those presented by a highly immune population or even a harsh physical environment. There is no doubt that the mode of transmission is the critically important element in this regard; viruses transmitted by the respiratory route fit their econiches very well indeed, and represent the threats to our civilization of major epidemic or pandemic disease (Mims 1991). However, as we are learning from the insidious spread of human immunodeficiency virus (HIV) in Africa and Asia, other transmission patterns can be equally deadly.

Recombination

Genetic recombination involves an interaction between two or more viral genomes during mixed infection of a cell, giving rise to progeny having a genome with characteristics derived from two or more parental genotypes. Recombination is observed with both DNA and RNA viruses, but surprisingly few examples have been documented of emergence of new viruses through this mechanism. For example, although experimental evidence exists for recombination in vivo among herpesviruses, and many individuals are dually infected by more than one herpesvirus, no herpesvirus disease manifestation in humans has ever been attributed to recombinational events (Javier et al. 1986).

There is one major exception to the dearth of evidence that recombination is important in the emergence of viral diseases: Western equine encephalitis virus (WEE) is a recombinant, its two glycoprotein genes being derived from a Sindbis-like virus progenitor and the remainder of its genome derived from Eastern equine encephalitis virus (Hahn et al. 1988). It is estimated that two cross-over events were required to produce WEEV from its progenitors, and that this probably occurred during persistent infection in a mosquito host more than 1 000 years ago (Strauss and Strauss 1994). Recombination is also well documented between serotypes of polioviruses, for example after administration of trivalent Sabin vaccine to infants, recombinant variant viruses are shed in the stool of some individuals (Liu et al. 2003). This confirms the potential for generation of recombinant viruses with altered pathogenicity or altered host range, yet it is surprising that so few examples have been found.

Reassortment

Closely related viruses that have segmented genomes often undergo genetic recombination during dual infections. This special case of recombination in which whole genome segments are recombined is termed reassortment. Different influenza A viruses can reassort their genome segments, forming viable progeny; when this results in replacement of the hemagglutinin or neuraminidase genes it is termed 'antigenic shift'. No reassortment occurs between influenza A and influenza B viruses; the basis for this restriction is not known. Each of the major human influenza pandemics of this century (1918, 1957, and 1968) was caused by reassortment of genome segments between an existing human virus and an avian virus (Webster and Kawaoka 1994). Several new strains of human influenza arose by reassortment between the prevailing human influenza virus and genes from the avian influenza virus gene pool that exists in wild ducks. For example, in 1957 the virus causing a worldwide pandemic of influenza (the Asian influenza pandemic) acquired three genes (PB1, HA, and NA) by reassortment with the influenza gene pool in ducks, and kept five other genes from the circulating human strain (Kawaoka et al. 1989). Swine may provide an important intermediate host in the stabilization of reassortants between avian and human influenza viruses. In 1997, reassortment between avian influenza virus genomes resulted in an avian influenza virus with a highly cleavable hemagglutinin. The hemagglutinin gene was apparently acquired from influenza A/Goose/Guandong/1/96 virus (Xu et al. 1999). This change allowed the variant virus to infect 18 humans, six of whom died. Fortunately this emergent virus did not readily transmit from human to human, but the virus has remained in poultry in Eastern Asia, causing many outbreaks of disease in birds and a significant number of influenza cases and deaths in humans. Clearly the danger is that the viruses now established in poultry will continue to mutate and could acquire the necessary phenotype for efficient human to human transmission through mutation, or through reassortment with a prevailing human influenza virus. Such an event would undoubtedly result in an influenza pandemic, as the H5 hemagglutinin molecule has not previously circulated widely in the human population (Li et al. 2004; Stephenson et al. 2004).

Reassortment between animal and human viruses also seems to be important in generating new pathogenic strains of rotaviruses (Gentsch et al. 1993; Iturriza-Gómara et al. 2001). Such novel viruses have been isolated as predominant outbreak strains in the USA (Ramachandran et al. 1998) and in the UK (Iturriza-Gomara et al. 2002).

Epidemic potential of newly evolved viruses

The epidemic potential of newly emergent viruses varies, depending upon the mode of transmission, the immunological and genetic susceptibility of the host population, the size of the population at risk, and other epidemiological and pathogenetic factors. Epidemic potential is greatest for an agent that is readily transmitted from host to host, particularly via the respiratory route. Conversely, zoonotic agents and arthropod-borne agents are usually limited in their geographic range, although the latter are certainly not limited in their capacity for causing very large epidemics.

Certain kinds of phenotypic change are most notable as the bases for the epidemic potential of particular viruses. An extension in host range can permit a virus to spread into a new species with devastating consequences. An increase in virulence (based on any of several mechanisms) can convert a nonpathogenic or trivially pathogenic virus into one with devastating pathogenic qualities. A change in antigenic signature can permit a virus to infect a population already immune to parental strains of the same virus.

THE INDIVIDUAL HOST: SUSCEPTIBILITY/RESISTANCE FACTORS FAVORING THE EMERGENCE OF VIRAL DISEASES

In many ways, the influence of the host on the emergence of viral diseases is more important than influences attributed to the virus per se. The host brings a much more complex genome to the battle between virus and host that involves the qualities of the virus that are crucial for its transmission and survival, and the resistance of the host. These host factors are usually categorized under (1) innate resistance, mostly dependent on poorly understood nonspecific resistance factors, (2) acquired resistance (e.g. macrophages and the cellular and humoral immune responses), and (3) physiological factors affecting resistance (e.g. age, nutritional status, hormonal effects especially in pregnancy, fever). When host resistance is optimal, infection may be subclinical or abortive, but when host response is inadequate qualitatively or quantitatively, disease is the usual outcome. Furthermore, when an overly exuberant immune response occurs there can be immunopathological disease.

The host immune response

Studies with inbred mice have identified a large repertoire of genes that confer survival potential on the host. Most of these genes are specific for a single family of viruses, although a few map to the major histocompatibility locus and encode proteins that influence host immune responses to multiple agents. Polygenic resistance characteristics are less well understood, but seemingly are even more important. For example, linebreeding and inbreeding experiments led to the development of the classic strains of mice that are exquisitely sensitive to certain viruses: these mice have been used for many years to isolate arboviruses, rabies virus, and picornaviruses. The genes selected for in these mice may be unknown, but the implication is that many genes may affect host resistance to viral infections.

The age of the host

The age of the host may also affect viral pathogenesis. This is true of poliomyelitis, a disease which emerged concurrently with improved sanitation and hygiene. It is likely that poliomyelitis occurred as a sporadic disease since ancient times. During the eighteenth and first half of the nineteenth centuries a few clusters of cases were reported, but from about 1905 onwards epidemics were reported annually in the USA. The same pattern of emergence of poliomyelitis as an epidemic disease has been repeated many times since, first in developed and then in developing countries. What accounts for this emergence of epidemic poliomyelitis? There is no evidence that it was due to the appearance of virus strains of increased virulence. Epidemiological data suggest that there is a correlation between age at the time of infection and risk of paralytic disease. Before vaccines were used to control the disease, it was apparent that in virgin soil epidemics in isolated communities without prior experience of the virus, most severe cases and deaths occurred in adults. It was proposed by Nathanson and Martin (1979) that the appearance of epidemic poliomyelitis was due, paradoxically, to improvements in public sanitation and personal hygiene, which led to a reduction in virus transmission. A delay in the age of initial infection, beyond the age when infants are protected by passively acquired maternal antibody, is postulated to have increased the risk of clinical disease. However, at the present time the phenomenon of increased disease severity of poliovirus infection in adults is still not completely understood.

Persistent infection and chronic shedding

The dynamics of emergence of a new viral disease can vary greatly, depending on the incubation period, whether the infection is rapidly self-limiting or persistent and whether the resulting disease (and shedding pattern) is acute or chronic. When associated with a short incubation period and acute disease, emergence can be a dramatic event. However, when the emerging agent is associated with a long incubation period, the resulting epidemic may rise over a period of years

before it reaches a peak. Furthermore, a long interval between infection and disease occurrence may obscure the identification of the causal agent and its mode of transmission and may thereby delay intervention actions. Finally, if the disease is chronic, the impact on the healthcare system may spread over decades rather than weeks, with major economic consequences beyond those ordinarily associated with an acute epidemic.

HIV AND ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS)

The premier example of the importance of a long incubation period disease in the emergence of a new disease is AIDS. In fact, the length of the incubation period, which averages 8–10 years, repeatedly led to underestimates of the true extent of spread and penetration of the epidemic (Figure 2). Associated with this was uncertainty regarding the proportion of infections that would lead to death. The long incubation period led to the initial assumption that only a small proportion of infections, perhaps no more than 10 percent, would be fatal; projections of total AIDS incidence were correspondingly low. Also important was a failure to appreciate the epidemiological impact of lifelong persistence of infection and virus shedding. It proved difficult to devise a model of the number of potentially infectious individuals in the population at any given time, and their impact on transmission dynamics. Finally, it was not appreciated that the chronic nature of AIDS would produce a vast new burden upon the healthcare system.

Coincident change in viral virulence and host resistance

The best documented example of coincident change in host and virus leading to the emergence of a variant disease involves the rabbit and myxoma virus. The disease, myxomatosis of rabbits, is caused by the poxvirus, myxoma virus; it occurs naturally as a mild infection of rabbits in South America and California (*Sylvilagus* spp.) where it produces a skin tumor from which virus is transmitted mechanically by biting insects. However, in the European rabbit (*Oryctolagus cuniculus*), myxoma virus causes a lethal infection, a finding that led to its use for biological control of wild rabbits in Australia. The European rabbit was introduced into Australia in 1859 for sporting purposes and rapidly spread to become the major animal pest of agricultural and pastoral industries. Myxoma virus was successfully introduced into this rabbit population in 1950; when originally introduced the virus produced case-fatality rates of over 99 percent. This highly virulent virus was readily transmitted by mosquitoes. Farmers operated 'inoculation campaigns' to introduce the virus into wild rabbit populations.

It might have been predicted that the disease, and with it the virus, would disappear at the end of each summer, owing to the greatly diminished numbers of susceptible rabbits and mosquitoes during the winter. This must have occurred often in localized areas, but it did not happen over the continent as a whole. The capacity of virus to survive the winter conferred a great selective advantage on viral mutants of reduced lethality: during this period,

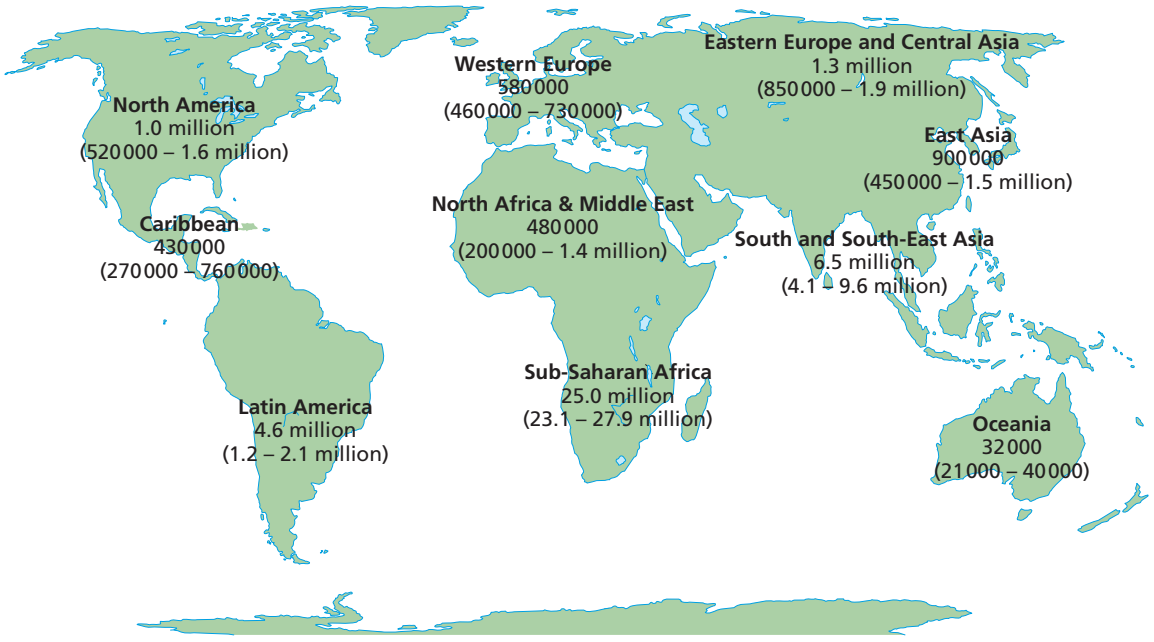

Figure 2 *Adults and children estimated to be living with HIV as of the end of 2003. Source WHO UNAIDS Programme.*

Table 4 *Emerging viral diseases: examples of probable crossings of the species barrier*

Year	Virus	Disease	Species Involved	Cause
1931	HIV-1	AIDS	Chimpanzees to humans	? Mutation
1940	HIV-2	AIDS	Sooty Mangabies to humans	? Mutation
1978	Canine parvovirus	Pandemic enteritis, myocarditis	Cat to dog	Mutation of feline panleucopenia virus
1988	Phocid distemper virus 1	Fatal respiratory disease (distemper)	Harp seals to harbor seals	Migration of harp seals due to climatic conditions
1989	Phocid distemper virus 2	Fatal respiratory disease (distemper)	Dogs to Siberian seals	Contact between different marine species or contact with terrestial animals (dogs)
1994	Hendra virus	Acute respiratory distress syndrome (ARDS), and encephalitis	Fruit bats to horses and humans	Unknown
1999	Nipah virus	Severe respiratory disease and encephalitis	Fruit bats to pigs and humans	Unknown

when mosquito numbers were low, rabbits infected by such mutants survived in an infectious condition for weeks instead of a few days and thereby contributed disproportionately to the progeny pool. Within 3 years such 'attenuated' mutants became the dominant strains throughout Australia. Thus, the original highly lethal virus was progressively replaced by a heterogeneous collection of strains of lower virulence, but most of them were still virulent enough to kill 70–90 percent of genetically unselected rabbits.

Rabbits that recover from myxomatosis are immune to reinfection. However, because most wild rabbits have a life-span of less than a year, herd immunity is not an important factor in the epidemiology of myxomatosis. Selection for more genetically resistant animals operated from the outset of the 'inoculation campaigns'. In areas where repeated outbreaks occurred, the genetic resistance of surviving rabbits increased progressively. The early appearance of viral strains of lower virulence, which allowed 10 percent of genetically unselected rabbits to recover, was an important factor in allowing the number of genetically resistant rabbits to increase. In areas where annual outbreaks occurred, the case-fatality rate fell from 90 percent to 25 percent within 7 years. Subsequently, in areas where there were frequent outbreaks, somewhat more virulent strains of virus became dominant, because they produced the kind of disease that was best transmitted in populations of genetically resistant rabbits. Thus, the ultimate balance struck between myxoma virus and Australian rabbits involved adaptations of virus and host populations, reaching a dynamic equilibrium that finds rabbits still greatly reduced compared with their pre-myxomatosis numbers, but too numerous for the wishes of farmers and conservationists.

'Species-jumping' – crossing the species barrier

The ability of animal viruses to cross the species barrier as a result of mutations has been documented in several cases (Mahy and Brown, 2000; Table 4) but in many cases involving humans, further transmission does not occur, and humans are a 'dead-end ' host (e.g. hantavirus pulmonary syndrome) (Mims 1991). Among important human viral pathogens, HIV-1 and HIV-2 provide the best examples of crossing the species barrier (Korber et al. 2000).

HIV-1 AND HIV-2

Perhaps the most significant example of species-jumping occurred when HIV entered the human population from a simian reservoir. Although the disease went unrecognized in the human population until 1977, careful molecular dating analysis suggests that HIV-1 entered the human population around 1931 (Korber et al. 2000) and HIV-2 around 1940 (Lemey et al. 2003).

Both HIV-1 and HIV-2 viruses have a narrow host range, seemingly limited to humans. The viruses can experimentally infect certain nonhuman primates, in which replication usually occurs without apparent disease. However, simian lentiviruses (simian immunodeficiency viruses (SIV)) can be recovered from a range of African monkey species, and phylogenetic analysis has confirmed the simian origins of both HIV-1 and HIV-2 (Myers et al. 1992; Korber et al. 2000). HIV-1 seems to have arisen as a cause of immunodeficiency in humans by species-jumping from the chimpanzee, and HIV-2 came from sooty-mangabeys in West Africa (Hahn et al. 2000); there is clear overlap between the areas in Africa where HIV-2 was first detected and the range of known SIV-infected monkey species (Smallman-Raynor and Cliff 1991). Humans in close contact with nonhuman primates are susceptible to infection with SIVs (Gao et al. 1992; Khabbaz et al. 1994), but these infections are usually asymptomatic and the precise mutational changes that led to the emergence of HIV as an epidemic disease spreading in the human population are unknown.

HENDRA VIRUS AND NIPAH VIRUS

The emergence of Hendra virus provides yet another lesson-filled example of the importance of species-jumping. In 1994 a horse trainer and a stablehand in Hendra, Queensland, Australia, became ill with interstitial pneumonia (acute respiratory distress syndrome (ARDS)) while nursing a sick horse that had recently been brought onto the property. The disease spread to other horses in the stables, and 14 of 21 infected horses died from a pulmonary disease with hemorrhagic manifestations that was caused by a previously unknown virus. Although the stablehand survived the infection, the trainer died. A virus was isolated from both equine lung tissue and human kidney tissue taken at autopsy, and from structural and antigenic studies was named an 'equine morbillivirus' (Murray et al. 1995), though subsequently it was renamed 'Hendra virus'. One year later a horse farmer 600 miles away, in Mackay, Queensland died of encephalitis from the same virus. He had assisted at the necropsy of two of his horses that had died (one with acute respiratory disease, and the other with neurological symptoms). Although he became ill initially with mild meningitis, one year elapsed before the farmer became severely ill and died, when at autopsy Hendra virus was found in his brain (O'Sullivan et al. 1997).

In an investigation as to the origin of Hendra virus, an extensive serological survey involving over 5 000 animals was carried out. Of all species tested, only fruit-eating bats (flying foxes) of the genus *Pteropus* were found seropositive (Young et al. 1996). Subsequently, Hendra virus was directly isolated from pteropid bats, and a sampling over a wide geographic range found that almost 50 percent of pteropid bats had serological evidence of infection (Field et al. 2001).

Hendra virus clearly belongs to the *Paramyxoviridae,* but has a longer genome (19 kb in length) than any previously studied members of the family, and genome sequence analysis clearly showed many unique features (Gould 1996; Wang et al. 2000). In 1999, a related virus was discovered in Malaysia following a major outbreak of respiratory disease in pigs and severe neurological disease in humans in close contact with diseased pigs. More than 100 humans died, and in a successful effort to control the disease 1.1 million pigs were slaughtered. A virus was isolated from brain tissue from a fatal human case – the patient had lived in Nipah River Village, and so the virus was named Nipah virus (Chua et al. 2000). Hendra virus and Nipah virus cross-react antigenically, and once the two viruses were compared by sequence analysis it was obvious that they belong to the same genus, which has been named '*Henipavirus*'. Although all human cases from the original Nipah virus outbreak had close contact with pigs, a 'mystery disease' recognized in India in 2003, and seen subsequently in Bangladesh in 2004 (Hsu et al. 2004), seems to involve direct infection of humans by Nipah virus without an intermediate domestic animal host. These new outbreaks seem to be due to direct transmission between Nipah virus-infected pteropid bats or their excreta and humans, most of whom have been young boys who climb trees in which infected bats can be found.

Spread in the human population

Many viruses can cross the species barrier and infect humans, but transmission to humans represents a 'dead end' for the virus and no further transmission occurs (Mims 1991). On the other hand, some are regularly or irregularly transmitted from human-to-human, but without establishing an independent long-term exclusively human reservoir. All of these variations define the terms 'zoonosis' and 'zoonoses'. Many of these zoonotic viruses are arthropod-borne, including alphaviruses such as Eastern equine encephalitis virus and Western equine encephalitis virus, flaviviruses such as West Nile virus and Japanese encephalitis virus and St. Louis encephalitis virus, and bunyaviruses such as La Crosse virus and Rift Valley fever virus. Other viruses are transmitted directly to humans from zoonotic animal reservoirs, most commonly from rodent reservoirs. Examples include bunyaviruses such as Hantaan virus (the etiologic agent of hemorrhagic fever with renal syndrome), Seoul virus, Puumala virus (the etiologic agent of nephropathia epidemica), and Sin Nombre virus (the etiologic agent of hantavirus pulmonary syndrome), and arenaviruses such as Machupo virus (the etiologic agent of Bolivian hemorrhagic fever), Junin virus (the etiologic agent of Argentine hemorrhagic fever) and Lassa virus (the etiologic agent of Lassa fever). Historically, each of these viruses has been responsible for the emergence of a 'new' human disease.

THE HOST POPULATION: INDIVIDUAL AND SOCIETAL BEHAVIORAL FACTORS FAVORING THE EMERGENCE OF VIRAL DISEASES

Several influences pertaining to human behavior (individual and societal behavior) have favored the emergence of new virus diseases; all of these influences seem to have accelerated over the last century. The global human population has continued to grow inexorably, bringing increasingly larger numbers of people into close contact. There have been successive revolutions in the speed of transportation, making it possible to circumnavigate the globe in less than the incubation period of most viral infections (Murphy and Nathanson 1994). For this reason, viral diseases occurring anywhere in the world can no longer be presumed to stay confined to their country or continent of origin. The death of a patient from Lassa fever in a hospital in Chicago in 1989

provided sobering testimony to the distance and speed that exotic viruses can move around the world (Holmes et al. 1990). The patient, an American citizen who had visited Nigeria to attend his mother's funeral, became ill 2 days after his return to Chicago. A total of 102 people had contact with him in the hospital. Fortunately, none of these contacts became infected. However, the incident illustrates the potential vulnerability of populations remote from the normal locale of geographically limited diseases. More recently, at least four cases of Lassa fever virus infection in European persons who had visited West Africa have been recorded, raising concern regarding the clinical management of such cases in diverse European settings (Crowcroft 2002).

The influence of individual behavioral factors

There are diverse influences pertaining to the behavior of individuals that can lead to the emergence of new diseases or new patterns of disease transmission. Many diseases that depend upon such factors are emergent or re-emergent. Behavioral influences include: (1) risk factors leading to sexually transmitted diseases (e.g. multiple sex partners, homosexual risk behaviors); (2) behavioral risk factors associated with day care and school; (3) behavioral risk factors favoring the transmission of childhood diseases in the community; (4) risk factors pertaining to food preparation and storage in the home; (5) risk factors associated with keeping pet animals in the home; and (6) viruses intentionally used for harm by bioterrorists.

SEXUALLY TRANSMITTED DISEASES

After declining over many years in developed countries, sexually transmitted diseases are now increasing at epidemic rates in urban populations in Europe, the USA, and many developing countries. Changes in sexual attitudes and behavior, combined with injectable drug use, have led to rapid amplification of certain viral diseases that are spread sexually. This is especially disturbing because many of the sexually transmitted diseases enhance the risk of transmission of each other (via new bacteria and viruses entering through established lesions). Thus, the risk of transmission is increased beyond expected rates and 'curable' diseases, such as gonorrhea and syphilis, support the spread of 'incurable' diseases, such as genital herpes and HIV infection/AIDS. The major societal failing in this regard stems from declining support for public health programmes, but in some instances emergence reflects advances in our ability to detect new viruses. One example is the emergence of human papillomavirus infection, genital papillomatosis, and cervical cancer. Multiple risk factors contribute to cervical cancer; these include behavioral (sexual behavior), dietary, hormonal, and viral risk factors (zur Hausen 2002). There are several theories but no real proof as to how these risk factors, in concert, lead to cervical neoplasia. Now that one risk factor for cervical cancer is known to be infection with certain types of human papillomaviruses, DNA probes for these viruses are being added to cytological screening programmes.

DAY CARE AND VIRAL INFECTIONS

Shifts in the structure of the family in all developed countries have resulted in a dramatic increase in the proportion of children in day care; currently in the USA, 35 million children under 14 years with working mothers spend 22–40 hours per week in day care. This trend is likely to continue, and in the year 2001 it was estimated that more than nine million families included working mothers with children under 5 years of age. Viral diseases represent the most important problems in day care, respiratory and diarrheal illnesses being most common. Children attending day care facilities may also become silent reservoir hosts for some agents of disease, such as hepatitis A virus and several enteroviruses. Depending on the disease, children attending day care have a 2- to 18-fold increased risk of becoming ill compared with children at home. The most common viral diarrheal pathogens acquired in day-care centers are rotaviruses. Rotaviruses, first discovered in 1973, infect every child in its first 3–4 years of life; this leads, in the USA, to an estimated 3 million cases of diarrhea, 500 000 doctor visits, 70 000 hospitalizations for 300 000 inpatient days and 75–125 deaths, and the costs for hospital care total US$200–400 million per year. Worldwide, some 600 000 children die each year of rotavirus diarrhea (Bern et al. 1992).

KEEPING PET ANIMALS

There have been many episodes of the introduction of new pathogens, such as exotic *Salmonella* types, via reptiles and amphibians kept as pets, but until recently viruses received little attention in this regard. The introduction in 2003 of monkeypox virus into the USA from Africa changed all this (CDC 2003b). A pet supplier in Texas, USA imported a shipment of rodents from Accra, Ghana which included giant Gambian rats, tree squirrels, rope squirrels, dormice, and several other African rodent species. One or more of these species were infected with monkeypox virus, which is endemic in Africa. These animals were housed by the importer together with prairie dogs, an American ground squirrel (*Cynomys* sp.) that is very popular as a family pet. The prairie dogs readily became infected with monkeypox virus, and when sold as pets human cases of monkeypox began to emerge in the mid-western United States (Guarner et al. 2004b). As a result, more than eighty human cases of monkeypox occurred in the USA, and there was a real danger that monkeypox virus could

become endemic in wild rodent populations. Following this episode, regulation of imports and interstate movement of exotic mammals have been upgraded, but it seems likely that we will see more of this kind of threat from imported pathogens in the future.

VIRUSES INTENTIONALLY USED FOR HARM

Since the terrorist attacks of September 11th 2001 in the USA, and the subsequent anthrax attacks through the US mail system, the possible use of viruses as weapons of bioterrorism must be considered (Smolinski et al. 2003). Although smallpox was eradicated in 1980, the possibility that the virus could be deliberately reintroduced into the world population remains the subject of considerable concern (Henderson 1999; Mahy 2003) and several countries are taking steps to prepare for such an event. Many other viral pathogens are also considered to be possible agents of biological warfare, including viruses causing severe hemorrhagic fever such as filoviruses (e.g. Ebola virus and Marburg virus), arenaviruses (e.g. Lassa fever, Machupo virus), and viruses causing severe encephalitis (e.g. Venezuelan equine encephalitis virus, Eastern equine encephalitis virus, Western equine encephalitis virus). The possible use of a virus to cause harm to the agricultural economy must also be considered, and in this context foot-and-mouth disease virus must be a prime candidate.

These threats also include the potential which now exists for deliberate genetic engineering of an existing virus so as to alter properties like pathogenicity or susceptibility to control by vaccination. The future emergence of a harmful virus disease by deliberate human action remains uncertain, but only by recognizing the possibilities can we prepare for, and minimize, the impact of such an event.

The influence of societal, commercial, and iatrogenic factors

There are diverse societal, commercial, and medical care factors that lead to the emergence of new diseases or new disease patterns. Again, many diseases that depend on such factors are emergent or re-emergent. Such risk factors include: (1) those associated with the commercial food industries, from sources on the farm to processing, transportation, wholesaling, and retailing; (2) those associated with water supply, (3) those associated with pharmaceuticals and biologicals; (4) those causing iatrogenic diseases.

DISEASES ASSOCIATED WITH ADVANCED MEDICAL CARE

Diseases such as those associated with immunosuppressive drug therapy, organ transplantation (including xenotransplantation), blood banking, and kidney dialysis are all increasing substantially in all developed countries. Since the early 1980s there has been an unprecedented rise in opportunistic infections associated with these medical care practices. In particular, the increase in organ transplantation and cancer chemotherapy, with their associated immunosuppressive drug therapies, has combined with the emerging AIDS epidemic to create a large, highly susceptible population at risk for a variety of viral diseases (see Reoviruses, orbiviruses and coltiviruses). In many cases viruses cause diseases of greatly increased severity in such individuals. These include diseases caused by DNA viruses, such as cytomegalovirus, Epstein-Barr virus, varicella-zoster virus, human herpesvirus 6, human papillomaviruses, human parvovirus B19, human polyomaviruses JC and BK, adenoviruses, hepatitis B virus, and molluscum contagiosum virus, and RNA viruses such as measles virus, hepatitis C virus, influenza, respiratory syncytial virus and parainfluenza virus.

Human herpesvirus 8, which is strongly associated with and may be the cause of Kaposi's sarcoma, is an example of an emerging virus that might not have been recognized except for its association with HIV and its immunosuppressive effects (Chang et al. 1994). As the number of naturally and therapeutically immunosuppressed people continues to expand throughout the world, it is likely that more and more new viral diseases, or new manifestations of old viral diseases, will continue to be seen.

MODERN AGRICULTURAL AND FOOD INDUSTRY PRACTICES AND VIRAL INFECTIONS

Changes in every aspect of the food industry, from on-the-farm technologies to processing technologies, favor the emergence of new viral disease problems. Animal husbandry has changed in ways that increase stress and promote viral transmission and endemic infection cycles in livestock and poultry. Large numbers of animals are being confined in limited space and at very high density, cared for by a few, inadequately trained workers. Elaborate housing systems are used, with good evaluation of cost:benefit, but with inadequate evaluation of health effects of systems for ventilation, feeding, waste disposal, and cleaning. In addition, some diseases are favored by the global expansion of agricultural markets, involving the global transport of animals, animal products, and animal semen and embryos. Yet, other diseases can emerge as a consequence of changes in processing systems and distribution systems for finished foods.

In 1997 there was an outbreak of hepatitis A which was first noticed in Michigan schoolchildren and later in Maine. Investigation of these two outbreaks linked them to the consumption of frozen strawberries commercially prepared by the same processor. By genetic sequence analysis, the virus causing illness in 126 patients from Michigan and Maine was identical. Later investigation found virus of the same sequence in patients with hepatitis A in Arizona, Louisiana, and Wisconsin, all of whom had eaten strawberries supplied by the same food processor

(Hutin et al. 1999). In 2003, an outbreak of hepatitis A in Pennsylvania was linked to the consumption of green onions in a Mexican restaurant where they were served in salsa. As a result of this food-borne outbreak immune globulin was provided to approximately 9 000 persons. Traceback investigations showed that the green onions consumed in Pennsylvania came from one or more farms in Mexico. By genetic sequence analysis, this outbreak was linked to similar hepatitis A outbreaks in Tennessee, Georgia, and North Carolina that also were associated with eating green onions (CDC 2003c).

Hepatitis A virus outbreaks provide good examples of the ease with which a pathogen can be widely dispersed in the population due to current food processing and distribution systems (Tauxe 1997).

Nipah virus, which emerged in Malaysia in an intense pig farming area, and then spread with movement of infected animals to several other parts of Malaysia and even to Singapore, may have stemmed in part from certain newly-introduced farming practices. The disease caused severe respiratory distress and some encephalitis in the pigs, but when a large number of workers on the pig farms developed encephalitis, and more than 100 died, it was decided to slaughter more than a million pigs, and this stopped the disease spread to humans. Fortunately, as noted above, humans were a dead-end host for Nipah virus infection, and no secondary spread was noted in the human community. The virus was identified because of its close relationship to Hendra virus. Using antiserum against Hendra virus, cell cultures growing the Nipah virus fluoresced, and this soon led to complete characterization and sequencing of the Nipah virus (Chua et al. 2000).

LIVESTOCK DISEASES

We usually think of the importance of livestock diseases in terms of financial losses, because the capacity of the commercial livestock food and fiber industries of developed countries are such that surpluses are a greater problem than are shortages. However, in developing countries this is not the case: livestock diseases, especially new, emerging or re-emerging diseases, cause immediate human suffering by substantially compromising scarce human food resources, especially the supply of high-quality protein.

Epidemiological considerations

Perpetuation of a virus in nature depends on the maintenance of serial infections, i.e. a chain of transmission; the occurrence of disease is neither required nor necessarily advantageous. Although clinical cases may be somewhat more productive sources of virus than inapparent or mild infections, the latter are generally more numerous and do not restrict the movement of infectious individuals, and thus provide a major mechanism of viral dissemination and emergence.

Epidemics are classically divided according to their means of spread into two major categories, propagated and common source (Nathanson 1996).

PROPAGATED EPIDEMICS AND CRITICAL COMMUNITY SIZE

In propagated epidemics, spread from host to host continues to expand as long as each infection gives rise to more than one new infection. The rate of transmission depends on a number of variables, such as the density of the population, the proportion of the population that is susceptible, the degree and duration of contagiousness, and the frequency of contacts leading to transmission. The classic large epidemics of viral diseases have all been propagated epidemics.

In most instances, for viruses that produce acute self-limiting infections to survive, the susceptible host population must be both large and relatively dense. Such viruses may disappear from a population because they exhaust the supply of susceptible hosts as they acquire immunity to reinfection. Persistent viruses, on the other hand, may survive in very small populations, sometimes by spanning generations. Depending on the duration of immunity and the pattern of virus shedding, the critical community size varies considerably with different viruses.

MEASLES

Much was learned about the dynamics of the viral transmission chain by Panum, who studied the devastating measles epidemic of 1846 in the Faroe Islands; this was at a time when even the concept of a virus was unknown (Panum 1939). Nevertheless, Panum described the incubation period of measles and the lifelong immunity that follows infection. With an incubation period of about 12 days, maximum viral excretion for the next 6 days and solid immunity to reinfection, between 20 and 30 susceptibles would need to be infected in series to maintain measles transmission for a year. Since nothing like such precise one-to-one transmission occurs, many more than 30 susceptibles are needed to maintain endemicity. Analyses of the incidence of measles in different size communities have shown that a population of about half a million people is needed to ensure a large enough annual input of new susceptibles, provided by the annual birth cohort, to maintain measles indefinitely as an endemic disease. Because infection depends on close contact, the duration of epidemics of measles is correlated inversely with population density. If a population is dispersed over a large area, the rate of spread is reduced and the epidemic will last longer, so the number of susceptible persons needed to maintain endemicity is reduced. On the other hand, in such a situation, a break in the transmission cycle is much more likely. If a large proportion of the population is initially susceptible, the intensity of the epidemic builds up very quickly, often reaching almost 100 percent. Virgin-soil epidemics in

isolated communities have had devastating consequences owing to lack of medical care and the disruption of work capacity. In large urban communities, before the era of vaccination, measles epidemics occurred every 2–3 years, each time exhausting available susceptibles; this epidemic cycle occurred on a continental scale. Before the introduction of vaccine, the cyclic occurrence of measles epidemics was influenced by several variables besides the build-up of susceptibles; these included the dynamics of reintroduction of the virus and seasonal influences.

COMMON SOURCE EPIDEMICS

Common source epidemics occur when a virus is disseminated from a single focus; they usually result from contamination of air, food, water, drugs, biomedical devices or the like. If a virus is introduced from a common source into a large population, disease can emerge on an epidemic scale. An excellent example is provided by the unwitting introduction of hepatitis B virus during immunization against yellow fever.

In the early stages of World War II, it was decided to immunize large numbers of American troops with 17D yellow fever vaccine. In order to stabilize the infectivity of the live attenuated 17D virus, protein was added to the final vaccine formulation. To prevent serum sickness, human serum was selected as the protein source. Almost 1 000 donors were used; unfortunately, at least one donor was a carrier of hepatitis B virus. Consequently, in the spring of 1942 over 400 000 troops received contaminated vaccine, causing about 20 000 cases of hepatitis (Sawyer et al. 1944). Although the onset of disease was spread over a considerable time, when plotted according to the interval from administration of the vaccine the timeline formed a classic log-normal curve, thereby providing statistical proof of the association of the epidemic with the administration of the vaccine. This epidemic clearly established hepatitis B as a distinct entity, separable from hepatitis A (e.g. different mean incubation periods: 3 months for hepatitis B, one month for hepatitis A).

THE ENVIRONMENT: ECOLOGICAL AND ZOONOTIC FACTORS FAVORING THE EMERGENCE OF VIRAL DISEASES

Ecological factors pertaining to unique environments and geographic isolation often underpin the emergence of new viruses and thereby new viral diseases. Such factors favor the adaptation of viruses to new econiches. When ecosystems are altered, viral infections of humans and animals follow. Population movements and the intrusion of humans and domestic animals into new arthropod habitats have resulted in many new emergent disease episodes. The classic example of this was the emergence of yellow fever when susceptible humans entered the Central American jungle to build the Panama Canal; there are many contemporary examples suggesting that similar events will continue to happen, in most cases in unanticipated circumstances. Deforestation has been the key to the exposure of farmers and domestic animals to new arthropods and the viruses they carry. The occurrence of Mayaro virus disease in Brazilian wood-cutters as they cleared the Amazonian forest in recent years is a case in point. Increased long-distance transportation facilitates the carriage of exotic arthropod vectors around the world. The carriage of the Asian mosquito, *Aedes albopictus*, a vector for dengue viruses and California encephalitis virus, into the USA in the water contained in imported used tyres, represents an unsolved problem of this kind. Increased long-distance transportation of livestock facilitates the carriage of viral agents and arthropods (especially ticks) around the world. The introduction of the tick-borne agent, African swine fever virus, from Africa into Portugal (1957), Spain (1960), and South America (1960s and 1970s) is thought to have occurred in this way; it is just a matter of time until this virus makes further international forays.

A recent dramatic example is provided by West Nile virus (WNV), a flavivirus which appeared for the first time in the Western hemisphere in 1999 (Briese et al. 1999; Lanciotti et al. 1999). Although originally isolated in Uganda in 1937, from where it spread to Egypt, Israel, India, and other parts of Africa, the virus caused occasional outbreaks of human disease in the 50 years following its discovery, but was not considered a serious public health problem. However in the mid-1990s, the virulence of WNV apparently changed (Hubalek and Halouzka 1999; Murgue et al. 2001a,b) and epidemics associated with severe neurological disease in humans and high mortality in birds began to occur in the Mediterranean basin and surrounding countries before WNV appeared in New York in 1999 (Ostlund et al. 2001). Following its isolation and characterization, the New York virus was found to be virtually identical in nucleotide sequence to an isolate of WNV made in Israel (Lanciotti et al. 1999). The mode by which the virus moved across the Atlantic ocean is unknown, but transport of an infected mosquito or bird in the hold of a jetliner are reasonable possibilities. An infected human or other mammal seems unlikely to have seeded the virus in the US, because the level of viremia would be rather low compared to that in a bird or carried in a mosquito. From its origin in New York, the virus has spread at an alarming rate throughout the continent, and reached California by August 2003, also spreading north into Canada and south into Mexico and the Caribbean. (Petersen et al. 2003). Many of the human cases have involved severe encephalomyelitis (Guarner et al. 2004a), but this represents the tip of the iceberg, and many asymptomatic infections also occur. Direct human-to-human transmission through blood has been documented with WNV; this is the first time that the US

blood supply has had to be checked for a mosquito-borne virus (Armstrong et al. 2003; CDC 2003a).

Changing routes of long-distance bird migrations, brought about by new water impoundments, represent an important yet still untested additional risk of introduction of arboviruses into new areas. This may be a key to some of the movement of Japanese encephalitis virus into new areas of Asia. Ecological factors pertaining to environmental pollution and uncontrolled urbanization are contributing to many new, emergent disease episodes. Arthropod vectors breeding in accumulations of water (tin cans, old tyres, etc.) is a problem worldwide. Environmental chemical toxicants (herbicides, pesticides, residues) can also affect vector–virus relationships directly or indirectly. For example, mosquito resistance to all licensed insecticides in parts of California is a known direct effect of unsound mosquito abatement programmes, augmented indirectly by poorly regulated pesticide usage against crop pests. Ecological factors relating to water use (i.e. increasing irrigation and the expanding reuse of water) are becoming important factors in the emergence of viral diseases. The problem with primitive water and irrigation systems that are developed without attention to arthropod control is exemplified in the emergence of Japanese encephalitis in new areas of southeast Asia and the Indian subcontinent. Global warming, affecting sea level, estuarine wetlands, swamps, and human habitation patterns, may be affecting arthropod vector relationships throughout the tropics; however, data are scarce and too many programmes to study the effect of global warming have not included the participation of viral disease experts.

Dengue

Dengue is one of the most rapidly emerging diseases in the tropical parts of the world, millions of cases occurring each year. For example, Puerto Rico had five dengue epidemics in the first 75 years of the 20th century, but more recently has had epidemics nearly every year, at an estimated cost of over US$150 million. At the same time, a record number of cases have occurred elsewhere in the Americas; Brazil, Bolivia, Colombia, Paraguay, Ecuador, Venezuela, Nicaragua, Cuba, and Mexico have experienced major dengue epidemics. These epidemics have involved multiple virus types: all four dengue virus types are now circulating in the Caribbean region. These are the circumstances that lead to dengue hemorrhagic fever (dengue shock syndrome): the lethal end of the dengue disease spectrum. Dengue hemorrhagic fever first occurred in the Americas in 1981; since then, most countries have reported cases, and in 1998 more than a million cases of dengue/dengue hemorrhagic fever were reported to WHO. By the beginning of the 21st century it was estimated that, globally, between 50 million and 100 million cases of dengue fever and several hundred thousands of cases of dengue hemorrhagic fever occur each year, the latter accompanied by case fatality rates of 1–10 percent, depending on the country (Gubler 2002).

Why is dengue emerging, especially in the Americas? The answer is simple: urban mosquito habitats are expanding (the vector mosquito, *Aedes aegypti*, is extremely well adapted to human proximity), mosquito density is increasing, and mosquito control is failing. This is occurring not just in the least developed countries but also in many developed countries. Financial resources for public health are severely limited and, too often, mosquito control, which is very expensive, falls off the bottom of the priority list. Meanwhile, mosquito control is becoming more expensive as older, cheaper chemicals lose effectiveness or are banned as damaging to the environment. As mosquito control fails, dengue follows quickly.

Yellow fever

An even more frightening situation associated with failing mosquito control is that yellow fever virus, which is transmitted by the same mosquito vector as dengue, *Aedes aegypti*, might also re-emerge. Where dengue occurs, the conditions are also appropriate for yellow fever (initiated by importation via an infected person or an infected mosquito). It is one of the mysteries of tropical medicine that yellow fever has not occurred more often where vector density and a susceptible human population coexist (Monath 2001). However, since the 1980s there has been a resurgence of yellow fever both across Africa and in South America: this is a potential risk to the USA, since *Aedes aegypti* is present in urban areas in the South (Robertson et al. 1996).

In fact, no one knows where, when or even if yellow fever virus will re-emerge in the kinds of epidemics that were the scourge of tropical and subtropical cities of the western hemisphere and Africa throughout the seventeenth, eighteenth, and nineteenth centuries; however, because this virus is so dangerous, the possibility is constantly on the mind of national and international health officials.

Hantaviruses and hemorrhagic fever with renal syndrome

Hantaviruses provide an example of a virus species that no doubt has existed for a long time in the same habitats, but was only recognized relatively recently. The first well characterized hantavirus disease was Korean hemorrhagic fever, which emerged during the Korean war of 1950–52. Thousands of United Nations troops developed a mysterious disease marked by fever, headache, hemorrhage, and acute renal failure; the mortality rate was 5–10 percent. Despite much research, the agent of this disease remained unknown for 26 years; then, in

1976, a new virus, named Hantaan virus, was isolated in Korea from fieldmice. The discovery of this virus was, however, just 'the tip of an iceberg.' In subsequent years, related viruses have been found in many parts of the world in association with different rodents and as the cause of human diseases with more than 150 different local names (Schmaljohn and Hjelle 1997). It has been found in recent years that, from an ecological perspective, there are seven or eight different subgroups of viruses and three different transmission patterns: rural, urban, and laboratory acquired. From a clinical perspective, two disease patterns are described, one marked by severe disease (hemorrhagic fever with renal syndrome, with significant mortality) and the other by mild disease (febrile disease, without mortality). The rural, severe disease is widespread in the Far East (e.g. Korean hemorrhagic fever in Korea; 'epidemic hemorrhagic fever' in China, causing more than 100 000 cases per year). A similar rural, severe disease is emerging in the Balkans (mortality rate c. 20 percent).

Hantaviruses and acute respiratory distress syndrome

In May 1993, a new hantavirus disease was recognized in the southwestern region of the USA. The disease appeared as an acute respiratory distress syndrome. Clinical signs include fever, headache, and cough, followed by acute pulmonary congestion and edema leading to hypoxia, shock, and, in many cases, death. Within a short time, cases were found in 23 states and eventually throughout the USA. By July 2004, 366 cases of hantavirus pulmonary syndrome have been confirmed in the United States, with an overall case fatality rate of 38 per cent.

The causative virus was shown to be a previously unknown hantavirus (Nichol et al. 1993), now named Sin Nombre virus, that has a reservoir in the deer mouse (*Peromyscus maniculatus)*. Horizontal transmission, via biting, is believed to be an important route of transmission between rodents. Human infection occurs following inhalation of virus particles from rodent urine, feces, and saliva, from contact of broken skin or mucous membranes with infectious virus, or by rodent bite. Viral RNA amplified from patients' specimens by PCR, when sequenced and compared to sequences obtained from specimens from different areas, indicates that several different variant viruses, all new and previously unknown, are active in different rodent species and subspecies in the USA, some causing human disease and others merely present in rodent populations without any human disease association. Hantavirus sequences have been used in expression systems to produce homologous antigens for further studies and diagnostic services. The same serological and molecular biological methods were applied to large numbers of rodents collected in the areas where patients lived; this proved that at least eight species of rodents were involved, the primary reservoir host in the southwest being *Peromyscus maniculatus*, the deer mouse (c. 30 percent of this species were found to harbor the viruses in several areas of southwestern USA) (Morzunov et al. 1998). The viruses have very likely always been present in the large area of the western region of the USA inhabited by *Peromyscus* species; they were recognized in 1993 only because of the number and clustering of human cases, which in turn were probably caused by a great increase in rodent numbers consequent on an increase in piñon seeds and other rodent food. As a result of this kind of rapid field and laboratory investigation, the public is being advised about reducing the risk of infection, mostly by reducing rodent habitats and food supplies in and near homes and taking precautions when cleaning rodent-contaminated areas. Fortunately, human-to-human transmission has not been observed with hantaviruses in North America. Humans become infected by contact with or inhalation of rodent excreta, but are then dead-end hosts.

In 1996 it was recognized that hantaviruses are also present in rodent populations in South America, and here there has been some evidence for human-human transmission of Andes virus, which occurs mainly in Argentina and Chile (Wells et al. 1997). As in North America, there are both pathogenic and nonpathogenic hantaviruses in South America, and since the first report several hundred cases of human hantavirus pulmonary syndrome have been recorded. Fortunately, the rodents which transmit hantavirus pulmonary syndrome are confined to the S*igmodontinae*, a subfamily of the *Muridae*, members of which are only found in the Western hemisphere (Figure 3). The other murid subfamilies that transmit hantaviruses are the *Murinae,* (e.g. Hantaan virus, Dobrava-Belgrade virus, and Seoul virus) and the *Arvicolinae* (e.g. Puumala virus) both associated with hemorrhagic fever with renal syndrome in Europe and Asia. Interestingly, although several hantavirus species are associated with arvicoline rodent species in North America, none has been associated with human disease (Table 5).

Rabies

Rabies can serve as an example of ecological factors relating to the adaptation and emergence of viruses in new econiches. The most dramatic illustration of this in recent years has been the appearance of epidemic raccoon rabies in eastern USA. The epizootic has been traced to the importation of raccoons from Florida to West Virginia in 1977. This epidemic demonstrates dramatically how human disturbance of the environment, in this instance involving the transportation of wild animals, can lead to emergence of a disease in a previously unaffected area. A key to our understanding of this episode was the discovery that rabies virus is not one virus; rather, it is a set of

Figure 3 *Geographical distribution of New World hantaviruses recognized as of 2004. Viruses named in Roman face have not been associated with human disease – those named in bold face are known to cause hantavirus pulmonary syndrome. (Courtesy of James Mills, CDC).*

different genotypes, each transmitted within a separate reservoir host niche. In North America, there are about six terrestrial animal genotypes, one involving the skunk in the north-central states, one the skunk in the south-central states, one the Arctic fox and red fox in Alaska and Canada, one the grey fox in Arizona, one the coyote and feral dog in southern Texas and northern Mexico, and one the raccoon in eastern states. 'Raccoons-bite-raccoons-bite-raccoons' and after some time their virus becomes a distinct genotype, highly adapted to the host cycle and inefficient if introduced into another host cycle. When this discovery was made (first using monoclonal antibody panels and more recently partial viral genomic sequencing), many mysteries of rabies ecology were clarified.

THE PREVENTION AND CONTROL OF NEW, EMERGING, AND RE-EMERGING VIRAL DISEASES

Since 1991 we have witnessed the emergence or re-emergence of a large number of new human viruses (Figure 4). When a new virus disease is suspected, a complex continuum of prevention and control activities may be called into action, but, given financial and resource constraints, decisions must be made and priorities must be set. The full continuum comprises the following activities and resources, which may be divided into investigative and interventional phases.

The investigative phase

- The disease must be characterized (usually the work of clinicians and pathologists).
- There is nearly always need for epidemiological field investigation to assess the risk to the population (usually the work of medical epidemiologists).
- The agent must always be sought. When a new virus is suspected, it must be isolated, identified, characterized.
- There is usually need for diagnostics development, to provide and authenticate primary, reference, and confirmatory tests.
- An integrated research programme is usually needed (but not always implemented), covering sciences as diverse as molecular virology, pathogenesis, pathophysiology, immunology, ecology, epidemiology, sociology and behavior, vector biology, etc.

Table 5 *Recognized hantaviruses in the world, their hosts, the recognized geographic occurrence of the virus, and the diseases caused*

Virus	Host species (subspecies)[a]	Distribution of virus	Disease
	Order *Rodentia*, Family *Muridae*, Subfamily *Murinae*		
Hantaan virus (HTNV)[b]	*Apodemus agrarius (mantchuricus)*	Eastern Russia, Northern Asia, Balkans	Severe HFRS
Seoul virus (SEOV)[b]	*Rattus norvegicus*	Nearly Worldwide	Mild/Moderate HFRS
Dobrava-Belgrade virus (DOBV)[b]	*Apodemus flavicollis*	Balkans	Severe HFRS
Thailand virus (THAIV)[b]	*Bandicota indica*	India	NR
Saarema virus (SAAV)[b]	*Apodemus agrarius (agrarius)*	Europe	Mild HFRS
Amur virus (AMRV)	*Apodemus peninsulae*	Far Eastern Russia	HFRS
	Order *Rodentia*, Family *Muridae*, Subfamily *Arvicolinae*		
Puumala virus (PUUV)[b]	*Clethrionomys glareolus*	Europe, Scandinavia, Russia, Balkans	Mild HFRS
Prospect Hill virus (PHV)[b]	*Microtus pennsylvanicus*	North America	NR
Bloodland Lake virus (BLLV)	*Microtus ochrogaster*	North America	NR
Isla Vista virus (ISLAV)	*Microtus californicus*	North America	NR
Tula virus (TULV)	*Microtus arvalis/ M. rossiaemeridionalis*	Russia, Slovakia	NR
Khabarovsk virus (KBRV)	*Microtus fortis*	Eastern Russia	NR
Topografov virus (TOPV)	*Lemmus sibericus*	Siberia	NR
	Order *Rodentia*, Family *Muridae*, Subfamily *Sigmontinae*		
Sin Nombre virus (SNV)[b]	*Peromyscus maniculatus*	North America	HPS
New York virus (NYV) [b]	*Peromyscus leucopus*	Eastern USA and Central USA	HPS
Black Creek Canal virus (BCCV)[b]	*Sigmodon hispidus*	Southeastern USA	HPS
Bayou virus (BAYV)[b]	*Oryzomys palustris*	Southeastern USA	HPS
Muleshoe virus (MULEV)	*Sigmodon hispidus (texianus)*	Southern USA	HPS
Monongahela virus (MONV)	*Peromyscus maniculatus (nubiterrae)*	Eastern USA and Canada	HPS
Limestone Canyon virus (LSCV)	*Peromyscus boylii*	Southwestern USA	NR
Blue River virus (BRV)	*Peromyscus leucopus*	Central USA	NR
El Moro Canyon virus (ELMCV)[b]	*Reithrodontomys megalotis*	Western USA and Mexico	NR
Río Segundo virus (RIOSV)	*Reithrodontomys mexicanus*	Costa Rica	NR
Caño Delgadito virus (CDGV)[b]	*Sigmodon alstoni*	Venezuela	NR
Juquitiba virus (JUQV)	Unknown	Southeastern Brazil	HPS
Araraquara virus (ARAV)	Unknown	Southeastern Brazil	HPS
Castelo dos Sonhos virus (CASV)	Unknown	Central Brazil	HPS
Anajatuba virus (AJV)	*Oligoryzomys fornesi*	Northern Brazil	NR
Río Mearim virus (RMV)	*Holochilus sciureus*	Northen Brazil	NR
Río Mamoré virus (RIOMV)	*Oligoryzomys microtus*	Bolivia, Peru	NR
Laguna Negra virus (LNV)[b]	*Calomys laucha*	Western Paraguay and Bolivia	HPS
Andes virus (ANDV)[b]	*Oligoryzomys longicaudatus*	Southern Argentina and Chile	HPS
Lechiguanas virus (LECV)[b]	*Oligoryzomys flavescens*	Central Argentina	HPS
Bermejo virus (BMJV)	*Oligoryzomys chacoensis*	Northwestern Argentina, Southern Bolivia	HPS
Orán virus (ORNV)	*Oligoryzomys longicaudatus*[c]	Northwestern Argentina, Southern Bolivia	HPS
Maciel virus (MACV)	*Bolomys obscurus*	Central Argentina	NR
Hu39694	Unknown	Central Argentina	HPS
Pergamino virus	*Akodon azarae*	Central Argentina	NR

(*Continued over*)

Table 5 *Recognized hantaviruses in the world, their hosts, the recognized geographic occurrence of the virus, and the diseases caused (Continued)*

Virus	Host species (subspecies)[a]	Distribution of virus	Disease
Choclo virus	*Oligoryzomys fulvescens (costaricensis)*	Southwestern Panama	HPS
Calabazo virus	*Zygodontomys brevicauda (cherriei)*	Southwestern Panama	NR
Maporal virus	*Oecomys bicolor*	Central Venezuela	NR
	Order *Insectivora*, Family *Soricidae*		
Thottapalayam[b]	*Suncus murinus*	India	NR

HFRS = hemorrhagic fever with renal syndrome; HPS = hantavirus pulmonary syndrome; NR = None Recognized.
a) Taxonomy follows Wilson and Reeder (1992).
b) Virus isolated in cell culture; others identified from genetic sequence.

The interventional phase

- There is always a need for comprehensive communications systems.
- There is often need for technology transfer (transfer of diagnostics technology to local agencies and transfer of information pertinent to vaccine and drug development to the commercial sector).
- There is usually need for training and clinical continuing education.
- Comprehensive public health systems may need to be adapted to the disease at hand. This may involve new public education programmes, new vital record and disease register systems, rapid case reporting, new surveillance systems, expanded laboratory diagnostics services, new staffing and staff support, new logistical systems (facilities, equipment, supplies, transport), and the like.
- There may be a need for new policy decisions, new risk management decisions. These may involve new legislation and regulations, new law enforcement action, and even new administrative and management systems.
- There may be need for new clinical medical systems (isolation of cases by quarantine, barrier nursing, physical biocontainment, and extra disinfection and sterilization). There may be need for new patient management systems and even need for improving the general health of the population at risk (better nutrition, housing, primary medical care).
- There may be need for specialist systems, such as vector control, reservoir host control, environmental control (water, animal, and arthropod habitats, etc.) and sanitary engineering (to provide safe food and water, sewage treatment, etc.).
- In the largest epidemics there are also global issues to be dealt with, such as control of international movement of people and animals, establishment of international disease control task forces, and the like. Finally, there is the global issue of adequate funding for such programmes.

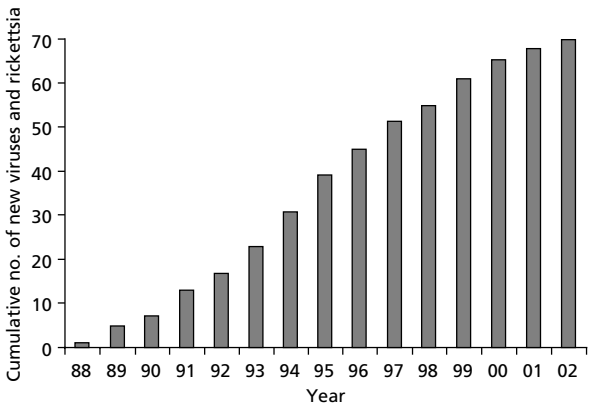

Figure 4 *Emergence of newly recognized viruses affecting humans over the period 1988–2002. Cumulative plot showing the annual increase in numbers of new viruses. (Courtesy of CDC)*

All these activities must be integrated to construct a comprehensive view of the immediate problem at hand and strategy and programmes for its control. Today, this kind of integrated investigative, problem-solving activity is usually thought to be the sole responsibility of government agencies, but, in fact, many professionals from throughout the health sector have played central roles in recent episodes. As it turns out, assessing risk and guiding intervention involve quite diverse activities; for example, in some cases complex field studies of the incidence of infection in the general population or in a selected subpopulation are necessary to determine risk factors for infection, mode of transmission, targets for intervention, etc., whereas in other cases, studies of the pathogenetic mechanisms underpinning the clinical presentation in the individual patient might hold the key. Today, in nearly every instance, important clues lie in characterizing the molecular structure and replication strategy of the virus and the cellular pathobiology of the infection.
